At about the age of 12 the patient had become involved in a drinking bout and whilst under the influence of alcohol had drunk about one cupful of a liquid which he had later realized was an acid (this was probably acetic acid as it was freely available in the part of the country where he lived because of its use in the manufacture of rubber). Soon afterwards he had begun to vomit rather severely and had been given a stomach wash. He had continued to vomit blood-stained material and had been treated with intravenous fluids as he had found difficulty in swallowing. He had made a slow recovery and had been discharged some 3 months later, at which time he had been able to take semisolid food. During the course of the following year he had returned to a normal diet of rice and curry but he had only been able to manage small quantities at a time, so that he had been forced to have meals every 2 hours in order to satisfy his hunger. Any attempt at ingesting a normal-sized meal had given rise to severe abdominal discomfort and vomiting.

The patient was found to be dehydrated and thin, weighing only 33·6 kg. The cardiovascular and respiratory systems were clinically normal, and physical examination revealed no abnormal findings in the abdomen or elsewhere.

On 4 April a barium-meal screening was carried out. The appearances were reported as those of 'a carcinoma of the body of the stomach, since a constant-filling defect was seen in this area. The stomach was greatly reduced in size and the pylorus lay well to the left of the midline' (*Fig.* 1).

---

* Present address and address for reprints: 17 Ritchie Way, Cloverdale, West Australia 6105.

Gastric secretions collected overnight for 12 hours were found to contain no free hydrochloric acid, and gastric washings which were examined for malignant cells showed a large number of squames with the cells appearing uniform and the changes being of only Grade 1 intensity.

OPERATION.—On 18 April, following adequate preparation, the abdomen was opened through a midline epigastric incision. The first part of the duodenum was found lying across the midline with the pyloric part of the stomach well to the left. The antrum and the body of the stomach were markedly reduced in size and the peritoneal surface was smooth and shiny. This area was quite hard to the touch and the only area of the stomach which appeared normal was a 3·8-cm. segment of cardia, fundus, and lesser curvature just distal to the oesophagogastric junction. The diseased area of the stomach was mobile and metastases appeared to be confined to the few small and hard lymph-nodes along the right gastro-epiploic vessels.

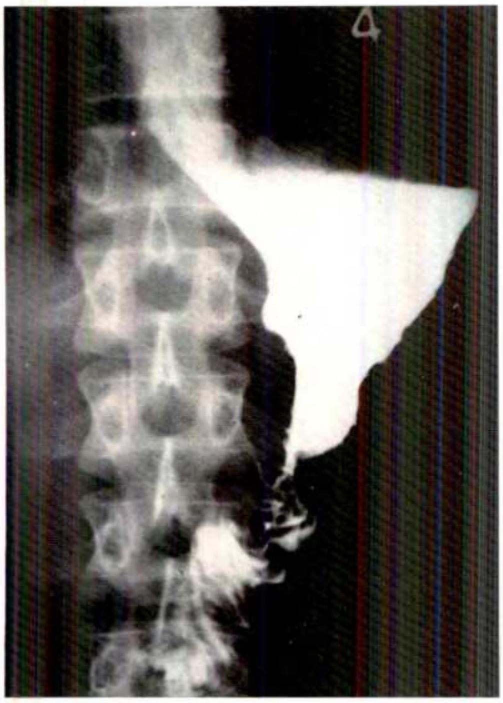

FIG. 1.—*Case* 1. Barium-meal film showing the deformity in the body of the stomach together with shortening of the stomach which has drawn the duodenum to the left.

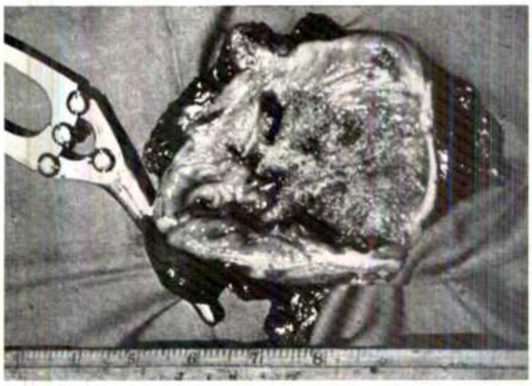

FIG. 3.—*Case* 1. The stomach has been opened along the lesser curvature to show normal mucosa towards the pylorus, a grossly ulcerated portion of the stomach in the middle, and smooth mucosa towards the oesophageal end in the upper right-hand portion.

A near-total radical gastrectomy was carried out, the tiny cuff of stomach at the cardiac end being anastomosed to the apex of a loop of proximal jejunum which was brought up behind the colon. The limbs of the jejunal loop were anastomosed side to side to each other to form a gastric pouch.

PATHOLOGY.—The resected specimen was 12·5 cm. in length and consisted of almost the entire stomach distal to the cardiac orifice (*Fig.* 2). When opened along the lesser curvature, normal-looking gastric mucosa was seen at the pyloric end of the stomach, the mid-portion of the stomach was granular and devoid of normal epithelium, and apparently normal mucosa was seen again at the cardiac end (*Fig.* 3).

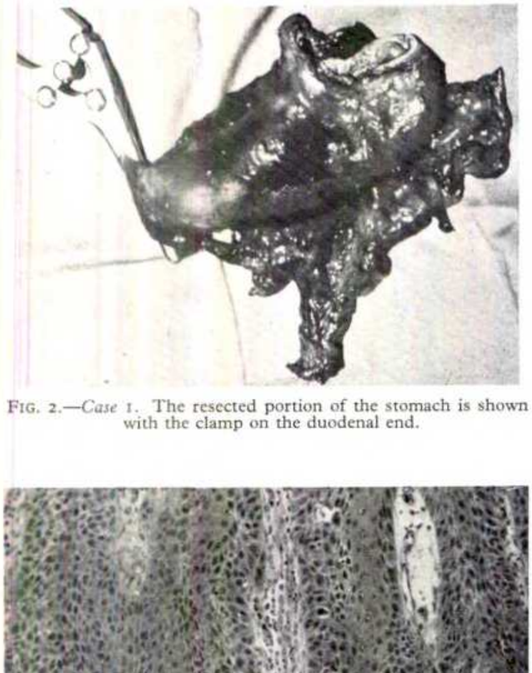

FIG. 2.—*Case* 1. The resected portion of the stomach is shown with the clamp on the duodenal end.

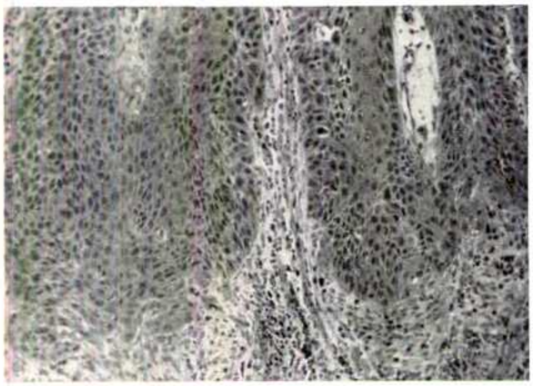

FIG. 4.—*Case* 1. Squamous carcinoma of the stomach from the ulcerated area. H. and E. (× 80.)

Histologically, the ulcerated area was a squamous carcinoma (*Fig.* 4), and sections taken from the edge of this area towards the cardia showed squamous epithelium all along it (*Fig.* 5). Sections from the distal part of the ulcerated area near the pylorus showed a transition to gastric mucosa (*Fig.* 6). Serial sections showed that the whole of the stomach proximal to this transitional area was covered with squamous epithelium with no intervening islets of gastric mucosa. The muscle coat of the stomach showed diffuse fibrosis with breaks of a complete nature with scarring in the floor of the ulcer (*Fig.* 7). No metastases were found in the lymph-nodes.

POSTOPERATION.—The patient's postoperative convalescence was complicated by a left subphrenic abscess which was drained on the seventeenth day after surgery. Following this there was rapid improvement and the patient was discharged home on 27 May, a little over 1 month after gastrectomy, having gained 4·5 kg. in weight and being able to eat a large plateful of rice without difficulty at a single meal.

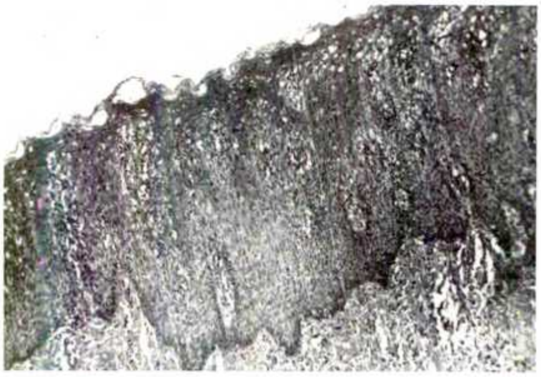

FIG. 5.—*Case* 1. Photomicrograph showing the proximal part of the stomach wall lined by hyperplastic squamous epithelium. H. and E. (× 50.)

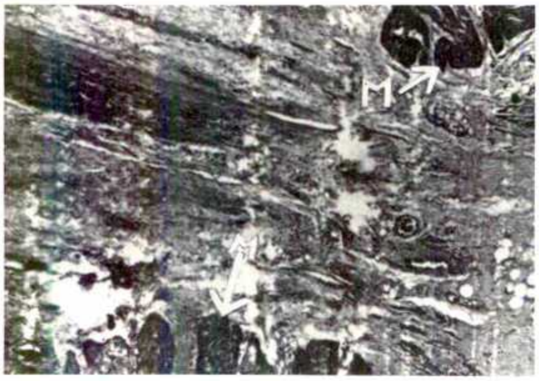

FIG. 7.—*Case* 1. Photomicrograph to show a break in the muscularis replaced by fibrous tissue. M, Muscle separated by fibrous tissue. H. and E. (× 70.)

The patient has been seen regularly at follow-up and has remained well. In April, 1971, his weight was stable at 44 kg. He has resumed work as a waiter, and has found that he can satisfy his hunger with about a cupful of rice (about half the quantity he was able to take soon after his operation), which is about the average quantity consumed at a single meal by a person not engaged in heavy manual work.

Case 2.—S. W. S., a Sinhalese housewife aged 26 years, was admitted to the Surgical Unit of the University at Kandy General Hospital on 7 Oct., 1970, complaining of progressive difficulty in swallowing of about 4 months' duration. During this period the patient had also experienced pain in the upper abdomen radiating to the back which had been worse when she had been hungry. There had been no vomiting but regurgitation of food mixed with blood had occurred occasionally. The patient was able to swallow solids only if they were accompanied by a drink. Symptoms were worse on lying down and were relieved on sitting up. Over the past 4 months loss of appetite had occurred and had become progressive, causing a significant loss of weight.

Twelve years earlier the patient had accidentally swallowed about a cupful of acid used for electroplating, after which she had vomited blood and subsequently had developed difficulty in swallowing. One month later she had undergone an operation in the General Hospital, Colombo, where a sleeve resection of the middle of the body of the stomach had been carried out for an acid stricture. She had been discharged 1 month later free of symptoms, and had remained well until the present illness. In the intervening period she had married and had had 1 child.

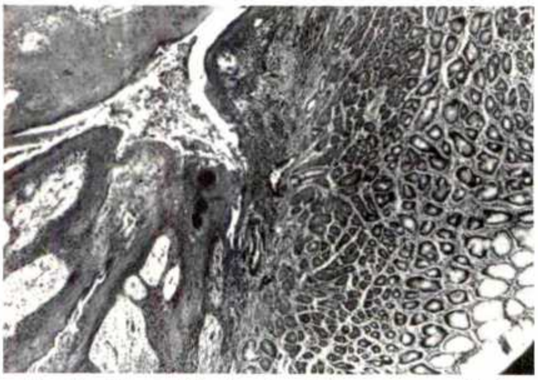

FIG. 6.—*Case* 1. The junction of the squamous epithelium with the gastric mucosa at the distal part of the ulcerated area. H. and E. (× 50.)

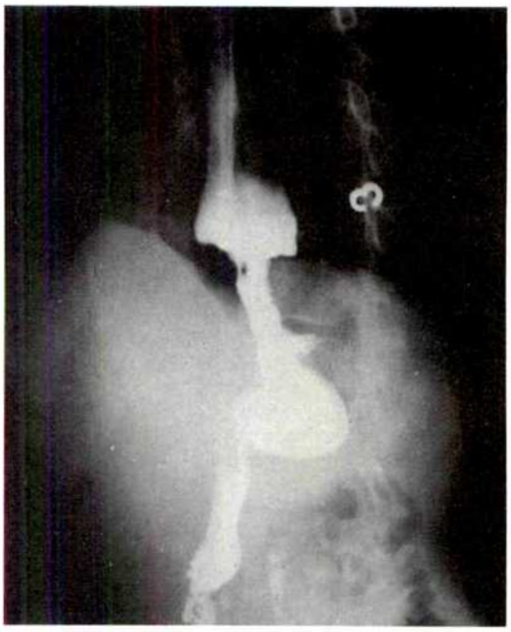

FIG. 8.—*Case* 2. Barium-meal film showing a normal oesophagus with a patulous oesophagogastric junction and a small part of the stomach in the thorax.

Examination showed an anaemic and wasted woman who was in obvious pain and weighed only 23 kg. The abdomen was scaphoid and showed an old midline epigastric scar. Except for vague tenderness in the epigastrium, physical examination showed no abnormality in the abdomen or elsewhere.

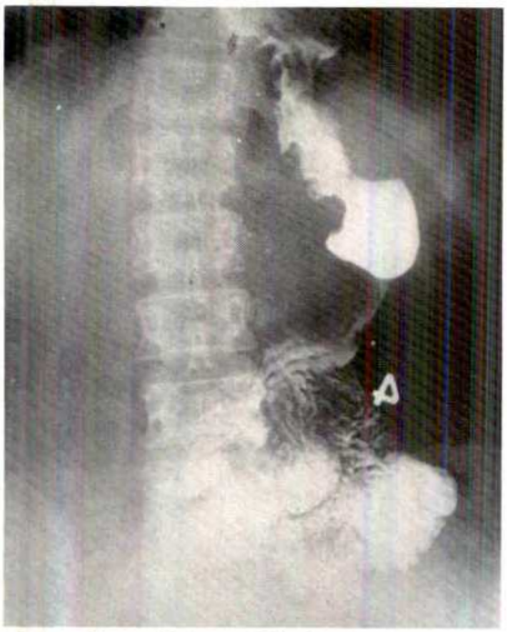

FIG. 9.—*Case* 2. Barium-meal film showing the gross irregularity in the mid-portion of the stomach with normal mucosal folds in the distal few centimetres.

Barium-meal screening carried out on 19 Oct. was reported as showing 'the proximal seven-eighths of the oesophagus to be normal. The rest of the oesophagus appeared to have been resected. A small part of the stomach was in the thorax and there was a patulous oesophagogastric junction (*Fig*. 8). There was gross irregularity of the mid-portion of the stomach with narrowing of the lumen (*Fig*. 9). There were two areas of severe stricture formation, as a result of which pockets had formed in the lesser curvature. The distal few centimetres of the stomach showed normal mucosal folds, and the gastroduodenal junction was normal though stretched to some extent. At 24 hours there was a small residue of barium in the stomach (*Fig*. 10). The appearances were strongly suggestive of malignancy of the stomach, very probably superimposed on corrosion by acid.'

On 17 Oct. the patient was oesophagoscoped and the oesophagus, though containing some fluid, was found to be clear up to 38 cm. Beyond this point the tip of the endoscope had to be deflected abruptly (? oesophagogastric junction) and thereupon the mucosa appeared whitish, protuberant, and hard. A biopsy was taken from this area with some difficulty as the jaws of the instrument tended to slip off the mass.

The biopsy was reported as showing a squamous carcinoma.

OPERATION.—After adequate preparation, exploration was carried out on 1 Nov. employing a left-sided thoraco-abdominal incision through the bed of the seventh rib. A tumour about the size of a cricket ball was found in the upper part of the stomach and was densely adherent anteriorly to the left lobe of the liver and posteriorly to the structures of the abdominal wall, making resection impracticable. A palliative Roux-en-Y end-to-side oesophagojejunostomy was constructed at the level of the hilum of the left lung.

Postoperatively, the patient's condition was unsatisfactory and she was managed in an intensive care unit; despite treatment she died on the morning of 3 Nov.

PATHOLOGY.—Only a partial post-mortem examination was allowed and the specimen removed showed the oesophagus to be normal down to the level of the diaphragm from where a growth was found extending down to within 5 cm. of the pylorus (*Fig*. 11). The growth was closely adherent to the liver, diaphragm, and posterior abdominal wall structures.

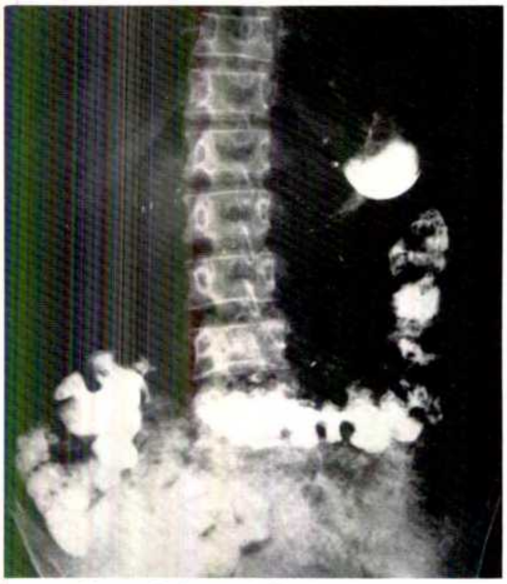

FIG. 10.—*Case* 2. Barium-meal film showing a residue in the stomach at 24 hours.

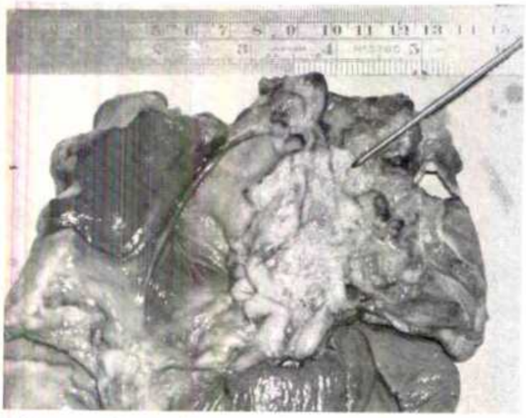

FIG. 11.—*Case* 2. The stomach opened at the post-mortem examination to show the tumour extending from the middle of the stomach to the oesophagogastric junction. The pointer is at the oesophagogastric junction.

Histology showed a squamous carcinoma infiltrating the stomach widely and deeply.

DISCUSSION

The pathological findings in *Case* 1 resemble those reported by Watson, Flint, and Stewart (1936) in a case where the upper loculus of an hour-glass stomach—caused by stricturing from hyperplastic tuberculosis—was found to be completely lined by squamous epithelium except for a narrow area along the lesser curve of the stomach. The oesophagogastric junction could not be identified from the mucosal aspect, suggesting that squamous epithelium had grown down from the oesophagus to cover the upper loculus.

In the present *Case* 1 the squamous epithelium found in the stomach was hyperplastic, was probably continuous with the epithelium of the oesophagus, and lined the whole of the stomach up to the distal margin of the ulcer. The fibrosis and discontinuity found in the muscularis subjacent to the squamous epithelium are evidence of the past damage to this area by the acid burns. In the cardiac portion of the stomach the gastric mucosa damaged by the acid had probably been completely replaced by epithelial downgrowth from the oesophageal mucosa, thus accounting for the achlorhydria found and the large number of squames seen in the gastric washings.

The malignant change that had subsequently occurred in the squamous epithelium had resulted in a pure primary squamous carcinoma.

In *Case* 2 there was also a past history of corrosive gastritis which had necessitated early surgery of an excisional nature. It is reasonable to assume that the resection of the strictured area had removed only the worst-affected area, leaving behind damaged epithelium which had been replaced by squamous epithelium. The tumour that had developed subsequently had involved the stomach extensively and the oesophagus minimally. Though the pathological picture was not as clear cut as in the first case, it is reasonable to suppose that the malignancy had supervened on squamous epithelium which had replaced gastric mucosa damaged by acid in this case as well.

Several explanations have been put forward with respect to the origin of squamous epithelium in the stomach. It has been considered to arise from (1) primitive undifferentiated basal cells in the mucosa, (2) heterotopic islets of squamous epithelium, (3) squamous metaplasia of gastric epithelium or a similar change occurring in an adenocarcinoma, and (4) a semisquamous epithelial layer covering the gastric mucosa (Duran-Jorda, 1945).

Squamous-cell metaplasia of the gastric mucosal epithelium though denied by Dreyer and Louw (1957) has been reported in 1 case by Hermann (1911), and a similar change has been produced experimentally in rats by Futterer (1904) and Saxen (1952). Boswell and Helwig (1965) have also reported squamous metaplasia—at the edge of a perforated gastric ulcer. The possibility must be accepted of subsequent development of squamous carcinoma in metaplastic gastric epithelium.

The explanation advanced by Duran-Jorda (1945) of a semisquamous epithelial layer covering the gastric mucosa was favoured by Diaz (1951) to explain the changes that he reported in his case, but Altshuler and Shaka (1966) discount this theory as they hold that electron microscopy has not shown the presence of this additional layer. On the contrary, they support the possibility of heterotopic squamous epithelium being the source of many such tumours, as islands of squamous epithelium are well known to occur, particularly near the cardia and along the lesser curve (McPeak and Warren, 1948).

In the cases reported here, in view of the past damage to the gastric mucosa, it is held that the squamous epithelial change was caused by regenerative downgrowth from the oesophagus. This conclusion is supported by the continuity of the squamous epithelium on the damaged area with that of the oesophagus.

Boswell and Helwig (1965), in analysing their 12 cases, found half of them suitable for only palliative procedures because of widespread intra-abdominal metastases. No case survived more than 1 year. These findings are in direct contrast to those of other authors who report absence of metastatic spread and forecast a reasonable prognosis. Our first case appears to fall into this category since there was no metastatic spread and the patient is in good health 1 year after surgery. He should have a better prognosis than if he had had an equivalent gastric adenocarcinoma.

The 2 cases reported here have a particular surgical significance in that malignant neoplasia followed on corrosive acid burns of the stomach. It has been the practice when dealing with acid burns of the stomach to consider them benign and to treat them by gastrojejunostomy or pyloroplasty, leaving the burnt area in situ. Paul (1951), in discussing the treatment of corrosive strictures of the stomach, stated that there appeared to be a place for partial gastrectomy rather than gastrojejunostomy as the latter may be followed by stomal or jejunal ulceration in later years and also because the possibility of malignant change cannot be discounted. Despite this he treated the patients reported by him by gastrojejunostomy only, and this appears to have been the practice followed by other surgeons too. A more radical form of surgery as suggested by us has only been performed in those cases where diffuse fibrosis has followed the corrosive burn (Strange, Finneran, Schumacher, and Bowman, 1951).

From the experience gained from these 2 cases it would appear that partial or subtotal gastrectomy rather than a conservative procedure should be adopted in patients presenting with corrosive strictures of the stomach, as they might otherwise develop a malignant lesion many years later in the deeply burnt area.

CALCIFYING EPITHELIOMA OF MALHERBE

BY S. M. JONES AND K. H. CRUMPLIN
PRINCESS MARGARET HOSPITAL, SWINDON

SUMMARY

Experience with 34 cases of calcifying epithelioma of Malherbe is analysed, and the frequency of misdiagnosis is noted. The apparent dramatic rise in incidence over the past few years may be due to an increasing awareness of the existence of this benign tumour by both clinicians and pathologists. Evidence is cited to support the view that the lesion arises from the hair-forming cells of the dermis.

CALCIFYING epithelioma of Malherbe was first described in 1880 by Malherbe and Chenantais, who stated that it was an epithelioma arising from the sebaceous glands and that it frequently became calcified. Beck in 1933 first likened the appearance and differentiation of the 'tumour' cells to hair-matrix cells. This opinion has subsequently been confirmed by Forbis and Helwig (1961), who first coined the term 'pilomatrixoma', and by McGavron (1965), who further confirmed the hair-matrix-cell origin by electron microscopy and histochemistry.

CLINICAL MATERIAL

The earlier cases in the present series were found from the pathological diagnostic index of the Pathology Department of the Princess Margaret Hospital, Swindon. In recent months increasing awareness has led to cases being more frequently diagnosed clinically and subsequently confirmed by routine microscopy. Twelve cases were recorded between 1962 and 1967, while 22 presented between January, 1968, and January, 1970 (*Table I*).

INCIDENCE

The total number of all skin tumours excised and submitted for histological examination in the period from 1962 to 1970 at the Princess Margaret Hospital, Swindon, was 2151. Thus, the incidence of epithelioma of Malherbe was 1·4 per cent.

The lesion was found in all age-groups between 3 and 96 years, but half of the patients were less than 20 years of age. In 1 patient a lump had been noticed only 2 weeks before presentation, but the majority had had symptoms for some months, and a few for 'many years'. In this series more females than males were affected, the ratio being 1·4 : 1.

Anatomical Distribution.—There was a predilection for the head and neck as the commonest site, but the upper and lower limbs were also involved.

Table I.—PRESENTATION OF CASES

Year	*No. of Cases*
1962	3
1963	2
1964	1
1965	2
1966	2
1967	2
1968	6
1969	15
January, 1970	1
Total	34

Table II.—THE PREOPERATIVE DIAGNOSIS

Preoperative Diagnosis	*No. of Cases*
No diagnosis made	12
Calcifying epithelioma of Malherbe	9
Sebaceous cyst	7
Tuberculous node	2
Histiocytoma	2
Neurofibroma	1
Inclusion dermoid	1
Total	34

The frequent occurrence near the eye noted by other authors (Richardson, Pinzon, Fetterman, Musgrave, and Gaisford, 1965) was confirmed. Size variation in our series was between 0·3 and 5 cm. in diameter.

CLINICAL PRESENTATION

The lesion appears as a firm, rounded, lobulated, occasionally tender nodule attached to skin but not to deep structures (*Fig.* 1); occasionally it may be pigmented. Calcification, if present, may be demonstrated by a plain radiograph, but this can also occur in cysts and other skin tumours. The diagnosis was correctly made in a quarter of the present series, the frequency of other diagnoses being shown in *Table II*.

PATHOLOGICAL FEATURES

The lesion is a firm or hard, encapsulated tumour, with a chalky consistency when cut across. Microscopically, the appearance is characteristic (*Fig.* 2): sheets or clusters of basophilic and 'ghost' or 'shadow' cells are randomly placed in a scanty stroma. Various other cell types are seen, some of which are degenerate, which are presumed to be transitional forms between basophil and ghost cells. Foreign-body giant cells, analogous to those seen around parenchymal uric acid deposits in gout, are seen in the supporting stroma, and areas of calcification, even ossification, may be present.

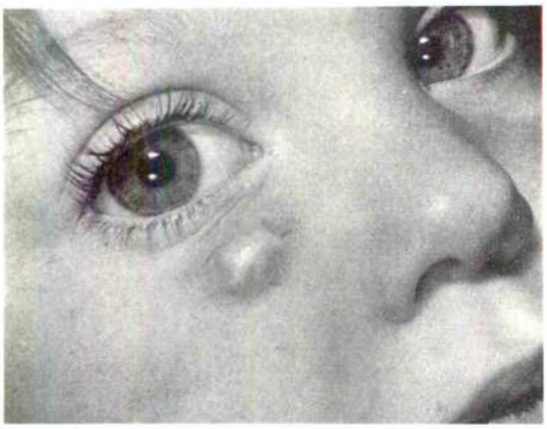

FIG. 1.—Typical lesion on the face of a 3-year-old girl. Note the prominent vessels in the overlying skin.

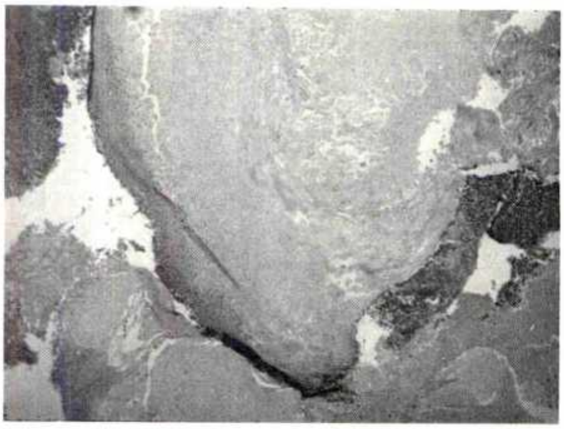

FIG. 2.—Part of a lesion showing darker-stained basal cells and ghost cells in the centre.

Differentiation from a calcified sebaceous cyst can be made by noting the presence of basophil cells, which are absent in calcified sebaceous cysts (Lever and Griesemer, 1949).

It is reasonable to term this unusual tumour a 'hamartoma of the pilogenetic structures'. McGavron (1965) has demonstrated with the electron microscope the cytological similarity between the matrix cells of this lesion and the normal hair-forming cells of the dermis. There is a transition of the matrix cells from basophilic to ghost-cell type. The nucleus : cytoplasm ratio of the basophilic cells decreases and the number of intracellular fibrils increases, forming bundles embedded in a matrix around the now redundant nucleus. The keratin that forms the cortex of normal hair shafts is also formed by aggregations of protofilaments embedded in a matrix. At the zone of keratinization the tumour-matrix cells have a high sulphydril content. This is also a feature of normal hair keratinization.

CONCLUSION

The size of previously reported personal series of epithelioma of Malherbe (Richardson and others, 1965, 55 cases; Henao and Martin, 1967, 38 cases) would seem to confirm its rarity. However, the fact that 22 of the cases in the present series (two-thirds) were seen in the past 2 years suggests that the lesion is more common than was previously supposed and that it is being recognized more frequently.

Although this lesion is most commonly seen in children and teenagers, all age-groups may be affected. There is no evidence that this tumour shows any malignant tendency, and its original name, although colourful, is inaccurate. When pigmentation is present the lesion may be mistaken for a malignant melanoma and widely excised, and if there is any doubt the lesion must be treated as a melanoma. In the absence of this diagnostic problem, simple excision is adequate and curative.

Acknowledgements.—We are indebted to Mr. P. H. Powley, Mr. E. J. C. Wynne, Mr. P. E. Huddy, and Dr. K. D. Crow for permission to include their patients in this series. We also wish to thank Dr. R. Martlew for his advice on the pathology and Mr. R. F. Gerrish of the Photographic Department.

DAMAGE FROM THE FOGARTY BALLOON CATHETER

BY G. E. MAVOR, M. G. WALKER, D. P. DAHL, AND C. A. S. PEGG
ABERDEEN ROYAL INFIRMARY

SUMMARY

The Fogarty balloon catheter is an instrument which greatly facilitates arterial thrombo-embolectomy. However, it should be used with gentleness and care, particularly in relation to the lower leg vessels. The peroneal artery is particularly susceptible to damage, and arteriovenous fistula formation may result. Even though the incidence of damage is low, when it occurs the morbidity produced may compromise an otherwise satisfactory result.

BALLOON catheters, first introduced by Fogarty, Cranley, Krause, Strasser, and Hafner in 1963, are used routinely in the treatment of cases of acute arterial embolism and thrombosis. At least 3 cases of arterial damage caused by the catheter have been noted in the last 50 cases in which the instrument has been used by the present authors, an incidence of damage of about 6 per cent. Although rare, the nature of the possible damage should be realized as then its production can probably be avoided.

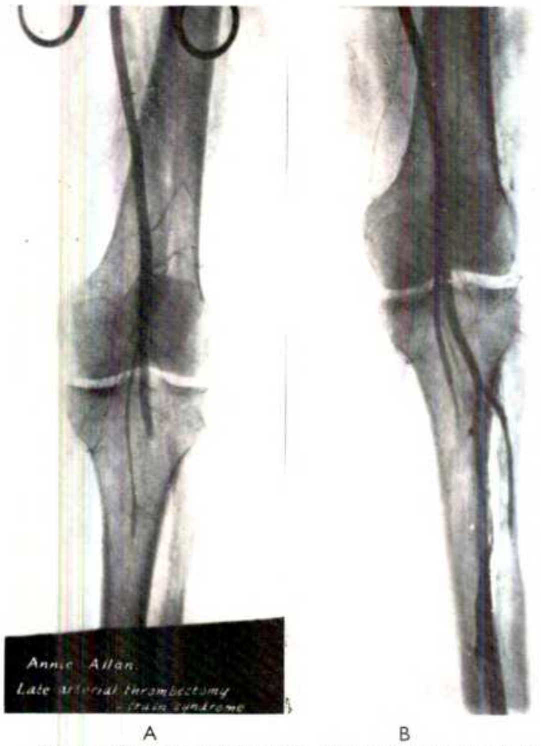

FIG. 1.—Operative arteriography shows (A) occlusion of the distal popliteal artery and (B), after clearance, contrast medium around the peroneal artery at mid-calf level and in the peroneal vein.

CASE REPORTS

Case 1.—A 62-year-old woman who had suffered serious injuries to the abdomen and pelvis in a traffic accident was seen with a 6-day-old ischaemic left foot. This was due to occlusion of the distal popliteal artery, and was presumably thrombotic in origin (*Fig.* 1 A). Clearance was satisfactorily obtained by the use of a balloon catheter. Operative arteriography confirmed this, but also showed that the peroneal artery had been damaged at mid-calf level and contrast medium was present in the peroneal vein (*Fig.* 1 B). The recovery of the leg was uneventful.

Case 2.—A 74-year-old woman who had previously been in good health apart from angina developed a right popliteal artery embolus 7 days after undergoing cholecystectomy (*Fig.* 2 A). Embolectomy was carried out and operative arteriograms showed good clearance of the popliteal artery. The anterior tibial artery was visualized, but it was stenosed at its origin (*Fig.* 2 C). The posterior tibial artery was not visualized, and the presence of contrast medium in the tissues at mid-calf level indicated damage to the peroneal artery (*Fig.* 2 B). Rapid clearance of the contrast medium from the tissues suggested that this was probably in part fistulous (*Fig.* 2 C). Distal limb ischaemia persisted, and had not the patient died 4 days later of a cerebrovascular accident, which was probably embolic in aetiology, amputation would have been necessary.

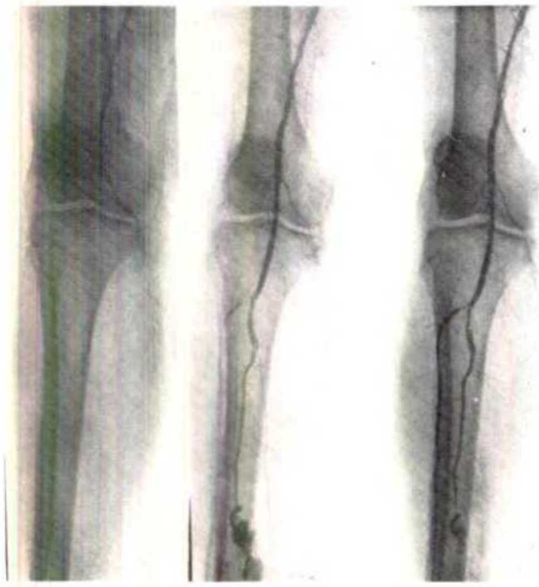

FIG. 2.—Operative arteriography shows occlusion of the popliteal artery from about joint line level (A). After clearance the posterior tibial artery is not visualized (B, C), and the anterior tibial artery is stenosed at its origin (C). The peroneal artery is perforated at mid-calf level (B), while clearance of the contrast medium is almost complete (C).

Case 3.—A 53-year-old man was admitted to hospital with a 3-week history of bilateral calf exercise pain of sudden onset, together with further complaints of coldness and discoloration of both feet. The patient was a beachcomber and the onset of pain had followed 4 miles of walking on the beaches. Three days before admission both feet had become numb and painful.

Arteriography revealed bilateral distal popliteal artery thrombosis, which was probably traumatic in aetiology (*Fig.* 3). Both popliteal arteries were exposed, opened, cleared using balloon catheters, and closed using autogenous vein-patch grafts. The right foot recovered quickly, the posterior tibial pulse being easily located. The left forefoot remained ischaemic, all the toes being anaesthetic and discoloured. No peripheral pulses were noted. Postoperative arteriography carried out 4 days after surgery showed patent arteries on the right side, but on the left side an arteriovenous fistula was present (*Fig.* 4). Serial films showed that this involved the peroneal artery and vein at about mid-calf level (*Fig.* 5). Subsequent auscultation revealed a loud bruit posteriorly at mid-calf level. Through a midline posterior calf approach the peroneal artery and vein were exposed. The fistula was located just at the origin of the nutrient artery to the fibula (*Fig.* 6). The vein was ligated and divided, and the peroneal artery was repaired. Subsequently, the forefoot recovered.

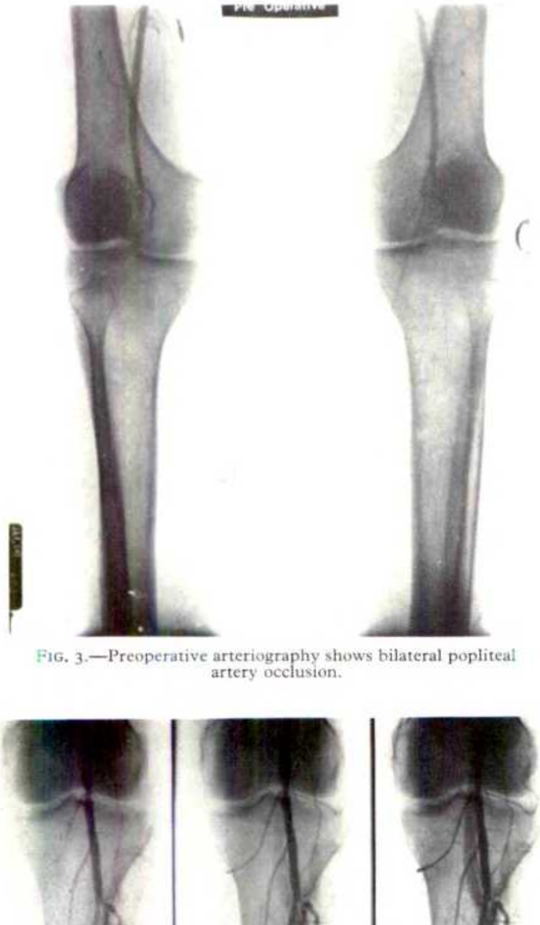

FIG. 3.—Preoperative arteriography shows bilateral popliteal artery occlusion.

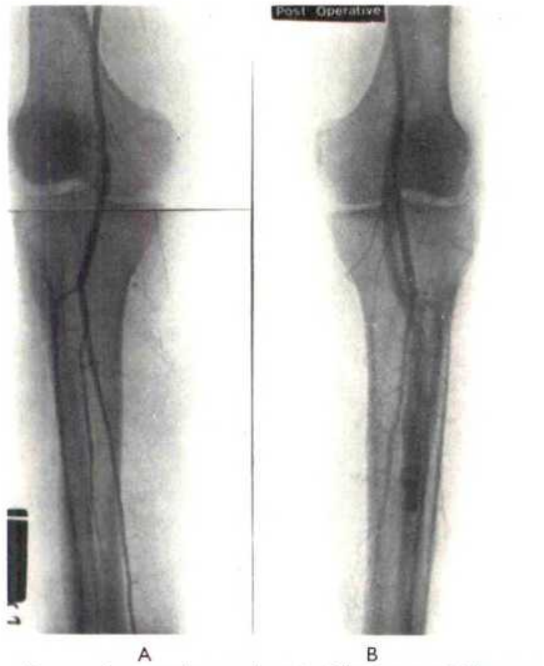

FIG. 4. —Postoperative arteriography following arterial thrombectomy and patch-graft repairs shows a satisfactory result on the right side (A). On the left side (B), there is an arteriovenous fistula situated at about mid-calf level.

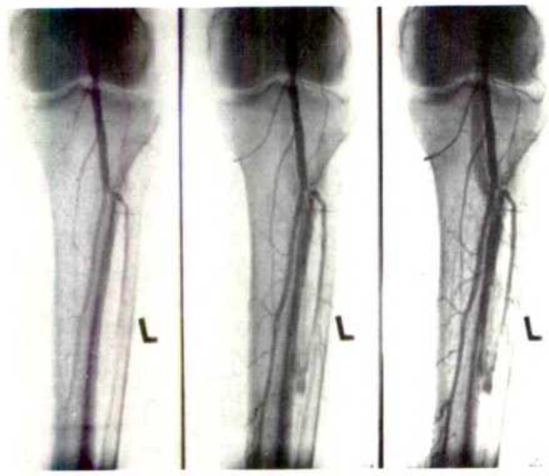

FIG. 5.—Serial arteriography shows a fistula involving the peroneal artery and vein.

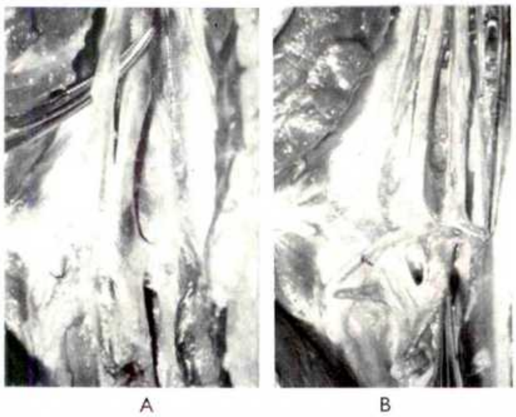

FIG. 6.—A, The peroneal artery lies over the artery forceps. The peroneal vein is considerably enlarged at the site of the fistula where it overlies and is adherent to the artery. B, Further dissection with the vein pulled medially shows the fistula opened. The nutrient artery to the fibula can be identified by the small linen stitch.

DISCUSSION

As far as can be ascertained there are only a few reports of complications arising from the use of intra-arterial balloon catheters (Krause, Cranley, Strasser, Hafner, and Fogarty, 1966; Hogg and MacDougall, 1967; Stoney, Ehrenfeld, and Wylie, 1968). Indeed it is not known what the incidence is of complications such as intimal damage or dissection with subsequent rethrombosis, or rupture of the posterior tibial or peroneal arteries. This may be because it is not routine practice to employ operative arteriography to ensure peripheral clearance during arterial embolectomy or thrombectomy. Without arteriography there is no way of judging whether in some cases damage has occurred, and clinical failures are generally, though perhaps not accurately, ascribed to failure to remove all thrombus. Where arteriography is in routine use in arterial embolectomy and thrombectomy, as in this clinic (Mavor, Walker, and Dhall, 1972), evidence has been obtained that damage as reported in the present 3 cases is possible.

It may be argued that damage is often clinically without significance, but this is uncertain. Much depends on the nature of the damage and, in the case of the lower leg, on the state of the other arteries. The type of damage which has been described includes a small false aneurysm of the profunda femoris (Stoney and others, 1968) and the avulsion of small intimal plaques (Krause and others, 1966), presumably without clinical effect. However, it would seem more certain that where the peroneal and posterior tibial arteries are ruptured or perforated there may be significant morbidity. If both are damaged the end-result of embolectomy will probably be amputation as rethrombosis is very likely (Hogg and MacDougall, 1967), while if one is damaged and both the other lower leg arteries are thrombosed or compromised by disease the same result is likely (*Case* 2).

The peroneal artery is apparently most susceptible to damage by balloon catheters, as in the 5 cases of damage to the lower leg arteries which have been reported (including the present 3), all involved the peroneal artery, although in 1 case the posterior tibial artery was also ruptured (Hogg and MacDougall, 1967). Peroneal arteriovenous fistula formation has not previously been reported, but this appears to be the nature of the damage in 2 of the present cases, and probably also in the third and in 1 of the cases reported by Hogg and MacDougall (1967). In 3 of the 4 cases serious morbidity resulted, although in 1 case (*Case* 3) repair of the fistula brought about a satisfactory result.

The position of possible peroneal damage and fistula formation is where the large nutrient artery to the fibula arises from the peroneal artery at about mid-calf level (*Fig*. 6). Undue pushing with the catheter if it sticks about mid-calf level may easily perforate the artery and simultaneously damage the neighbouring vein. It would appear prudent, therefore, to resist any tendency to attempt to push the balloon catheter if it feels obstructed and is at mid-calf level on the understanding that it may well be half-way down the peroneal artery.

ORBITAL HYDATID DISEASE IN IRAQ

BY H. TALIB

DEPARTMENT OF SURGERY, BAGHDAD UNIVERSITY, IRAQ

SUMMARY

Twenty-one patients with orbital hydatid disease are presented, constituting 19·8 per cent of the cases with unilateral exophthalmos seen from 1959 to 1971. The presenting features, investigations, and type of treatment are discussed.

THE literature contains a number of specialist studies on orbital tumours, but very little is recorded about orbital hydatid cysts, and it is of interest to examine the problem as seen by the general surgeon.

Echinococcosis can involve almost every organ or tissue in the body via the portal and the systemic circulations, but among the uncommon sites of infestation, even in the densely endemic areas, is the orbit. Lidgett (1956) reported 2 cases, making the total number of cases of orbital hydatid recorded in Australia 12. McClatchie and Manku (1967) treated 3 patients with orbital hydatid cysts in Kenya, and Jain and Rangbulla (1967) reported 1 case in India. From 1959 to 1971 the author has treated 21 patients with hydatid cyst of the orbit, of whom 13 have already been reported (Talib, 1968).

INCIDENCE

Orbital hydatid is uncommon and the frequency with which it occurs is difficult to estimate.

During the past 12 years 106 patients with unilateral exophthalmos have been admitted to the Republican Teaching Hospital, Baghdad (*Table I*). Of these, 21 patients (19·8 per cent) were proved to have hydatid cysts. This percentage makes hydatid cyst the commonest 'tumour' that involves the orbit in this series. By contrast, orbital hydatid cyst is rare in Western countries.

The age of the patients ranged between 6 and 55 years, both sexes being equally affected. There was a preponderance of infection in the left orbit over the right in the ratio of 2 : 1. This variation may be explained anatomically by the fact that the left common carotid artery arises directly from the 'summit' of the arch of the aorta.

CLINICAL FEATURES

Hydatid cyst is a slowly growing lesion and unless there are sudden changes in its morphological behaviour it may remain dormant for a long time; this is not so in the case of orbital involvement, as the orbit is conical in shape with fixed dimensions and constant capacity. Therefore, any space-occupying lesion may displace the eyeball, hinder ocular movements, and, if the cyst is located near the apex of the muscular cone, interfere with the neurovascular mechanism, thus giving rise to visual disturbances, chemosis, and oedema.

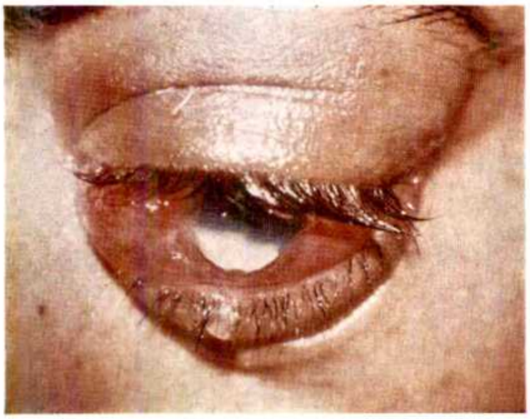

FIG. 1.—Orbital hydatid presenting with chemosis, lid oedema, and hypopyon.

Table I.—THE CAUSE OF UNILATERAL EXOPHTHALMOS IN 106 CASES ADMITTED TO THE REPUBLICAN TEACHING HOSPITAL, BAGHDAD, BETWEEN 1959 AND 1971

Cause of Exophthalmos	*No. of Cases*	*Percentage*
Conal Lesions		
Hydatid cyst	21	19·81
Vascular	4	3·77
Nerve	7	6·60
Lacrimal gland	5	4·72
Non-specific granuloma	4	3·77
Meningeal	2	1·89
Malignant	24	22·64
Encroaching Lesions		
Antral	6	5·66
Bony	3	2·83
Skin	14	13·21
Distant Metastasis		
Bronchogenic carcinoma	1	0·94
Undetermined	15	14·15
Total	106	

Unilateral proptosis was the main presenting feature in 18 patients. The average duration of the protrusion of the eye was between 5 months and 2 years. In 17 patients it was static for some time before the patient sought advice because of asymmetry or exophthalmos; only in 1 case was the proptosis variable.

One patient presented with chemosis, lid oedema, hypopyon, and rapid visual deterioration (*Fig.* 1). The remaining 2 patients presented with progressive exophthalmos and severe conjunctivitis (*Fig.* 2).

Diplopia was not a feature in spite of some degree of limitation of ocular movements.

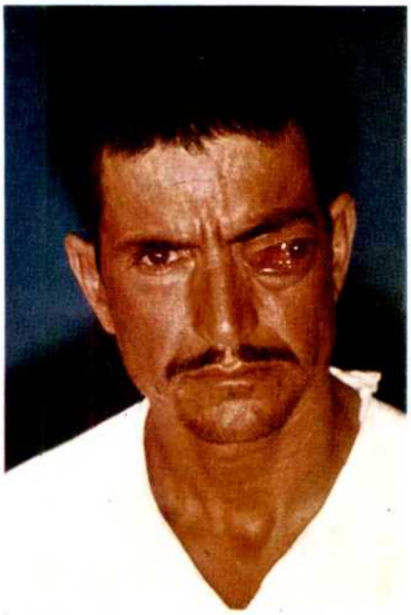

FIG. 2.—Patient with an orbital hydatid cyst showing severe conjunctivitis.

Patients with uncomplicated lesions had an almost normal visual acuity (*Fig.* 3), whereas those with complications such as infection and recurrence showed diminution or complete loss of vision (*Fig.* 4).

Local pain and headache occurred only in cases of progressive protrusion and infection.

DIAGNOSIS

It is extremely difficult to diagnose that the cause of the unilateral exophthalmos is a hydatid cyst of the orbit in the absence of other cysts elsewhere in the body. However, local physical examination may shed some light on the diagnosis if the cyst is palpable behind the medial or lateral canthus as a tense, well-defined swelling or when it is subconjunctival. An ear, nose, and throat examination should routinely be carried out in these patients to exclude antral lesions.

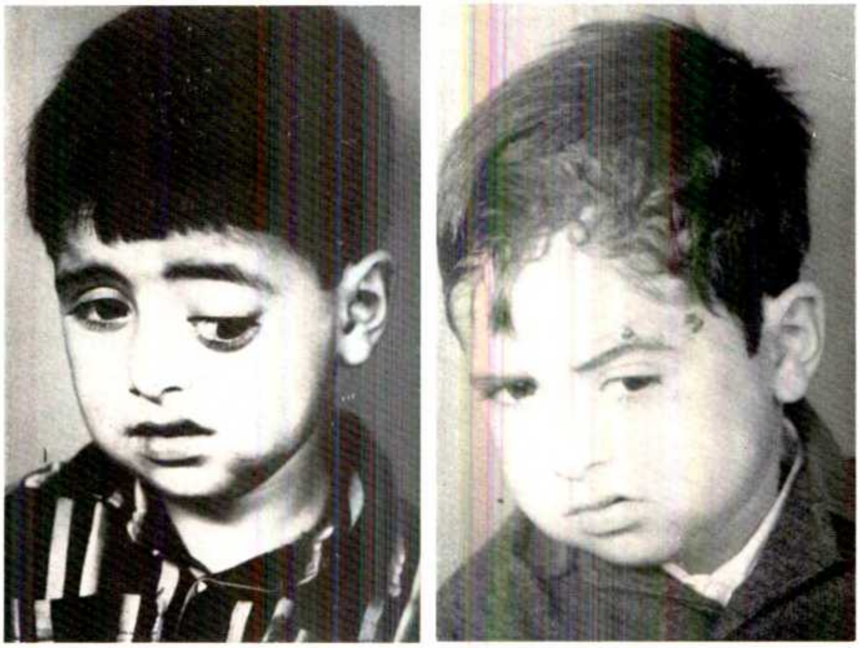
Radiographs of the orbit and optic foramina rarely show a soft-tissue shadow or a fine rim of calcification. Carotid angiography should be restricted to lesions which are suspected to be intracranial. Retro-orbital oxygen insufflation or lipiodol injection have not been used, as we think that any injudicious needling in the area may harbour the risk of rupture and dissemination. A chest radiograph is important to exclude the possibility of pulmonary hydatid disease or other thoracic lesions.

The Casoni intradermal test is unreliable, and a high eosinophil count may be due to helminthiasis which is endemic in Iraq.

In spite of elaborate laboratory and radiological investigations, none of the patients showed evidence of hydatid disease elsewhere in the body on admission. However, 1 patient returned later with a pulmonary hydatid cyst, and another came back after undergoing two laparotomies elsewhere for an hepatic hydatid cyst; a third patient developed paraplegia, presumably due to cord compression, diagnosed as a case of acute transverse myelitis although no investigations were carried out.

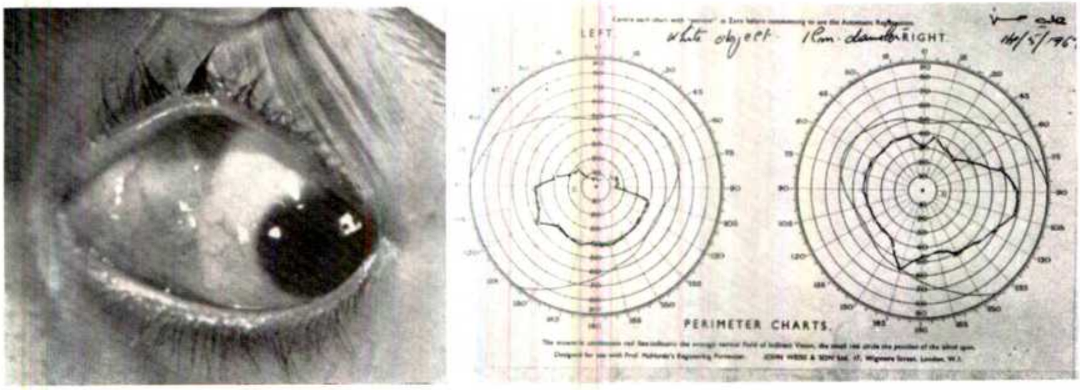
From these facts one reluctantly but inevitably admits that no diagnosis can be made with certainty before surgical exploration.

Bilateral exophthalmos can be seen as a manifesta- of metabolic, systemic, and neoplastic diseases, but it has not been noted in cases of hydatid disease either in this or in other series; this is interesting and needs more explanation.



A B

FIG. 3.—A, Child with an uncomplicated hydatid cyst of the orbit. B, Same patient 1 month after surgery



A B

FIG. 4.—A, Recurrence with a subconjunctival hydatid cyst. B, Perimetric study of the same patient showing marked restriction of the visual field on the left side.

The commonest sites of orbital hydatid are the superolateral and superomedial angles of the orbit; no hydatid cyst has been seen in the floor of the orbit, although Handousa (1947) reported 1 such case.

TREATMENT

If left for some time an orbital hydatid sooner or later will exert untoward effects on the eyeball. Provided the lesion is within the orbit it is our policy to subject every patient with unilateral exophthalmos to surgical decompression. Earlier in this series 2 patients underwent the Naffziger technique (Naffziger, 1954); the remaining patients have all been treated by a modified Dickson Wright anterolateral decompression. The latter approach gives an adequate exposure and can be extended medially should the need arise.

Partial tarsorrhaphy was used routinely either immediately after admission as an emergency measure against severe conjunctivitis or impending corneal ulceration, or during operation prior to decompression.

On 3 occasions an attempt was made to excise the ectocyst, which is a fairly thin fibrous capsule; this was not found to improve the results, and, furthermore, it is a time-consuming procedure and may endanger various delicate structures adherent to the ectocyst. Following evacuation, the cavity is wiped with 5 per cent formaldehyde solution.

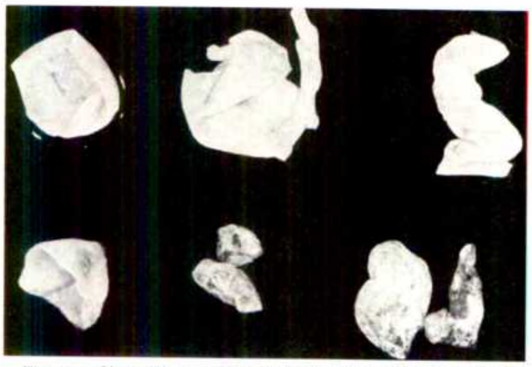


FIG. 5.—Six solitary orbital hydatid cysts. The two on the lower right represent very thin endocysts with their ectocysts; the rest are endocysts of variable thickness.

In cases of short duration the endocyst is very thin and difficult to separate from the ectocyst, while in those of long duration it is thick and can be extruded easily. In 19 cases solitary cysts were found (*Fig.* 5), and in both of the other 2 cases there were two daughter cysts.

On no occasion in this series was enucleation of the eyeball performed, even when it was severely inflamed, as the inflammation, surprisingly, subsided eventually.

Regarding postoperative complications, 6 patients developed ptosis; this corrected itself in due course, only 1 patient requiring a fascial sling. Temporary partial trismus occurred in 1 case, probably caused by fibrosis of the temporalis muscle as a result of its stripping from the temporal bone. Another patient developed a persistent discharging sinus due to erosion of the bone, necessitating curettage.

Following operation the eye remains swollen for some time owing to operative trauma and oedema, but the swelling gradually subsides.

DISCUSSION

Iraq is an endemic area for hydatid disease; unlike other such areas the incidence of orbital involvement is much higher in Iraq.

All patients present with unilateral exophthalmos varying from 6 months to 2 years in duration. The exophthalmos in most of the cases is static, but rarely it is progressive when the cyst is infected. Other clinical features include chemosis, severe conjunctivitis, deterioration of vision, and limitation of ocular movements.

In spite of all the clinical, laboratory, and radiological investigations it is extremely difficult to diagnose the condition, which can only be confirmed during surgery.

Patients with unilateral exophthalmos should be given the chance of decompression before the occurrence of serious complications which may carry the risk of damaging the eyeball.

Acknowledgements.—I wish to thank my colleagues in the Department of Ophthalmology, the Republican Teaching Hospital, Baghdad, and the Ophthalmological Staff at the Hospital for Eye Diseases for referring these patients to me.

I am also deeply grateful to Professor Harding Rains for his valuable comments and criticism.

Finally, I offer my gratitude to my senior house-surgeon, Dr. Garabet Awanes, for looking after my patients and collecting the necessary data for this work.

PROXIMAL JEJUNAL AND DISTAL ILEAL EXTRINSIC INNERVATION IN THE RABBIT AND DOG

BY D. H. R. JENKINS* AND I. B. MACLEOD
DEPARTMENT OF CLINICAL SURGERY, UNIVERSITY OF EDINBURGH

SUMMARY

The varying patterns of motor behaviour of isolated and interposed jejunal and ileal segments in the rabbit and the dog previously reported (Jenkins and Macleod, 1970) were examined by selective denervation techniques. One hundred and twenty-three paired experiments were conducted on rabbits and 55 similar experiments were performed on dogs.

Length-matched paired segments of proximal jejunum and distal ileum were isolated and filled with saline at a constant rate. Segmental resistance to filling was regarded as an index of tone. The influence of vagotomy and of sympathectomy on the tone of the segments was studied in segments supplied by one or by two vessels.

Vagotomy caused a decrease in tone in the proximal jejunal segments, while sympathectomy had little effect. In segments of distal ileum sympathectomy

---

* Present address: University Hospital of Wales, Cardiff.

resulted in segments behaving in a similar fashion, while vagotomy had an unpredictable effect on tone.

The results suggest a uniform distribution of the vagus to the whole length of the small bowel in the rabbit and the dog, serving to maintain the tone of the bowel. It is deduced that sympathetic supply to the proximal jejunum is absent in these animals and is distributed to the distal ileum only in an irregular fashion.

The relevance of these observations to the clinical use of interposed small-bowel segments is considered.

ISOLATED, interposed, antiperistaltic segments were initially used in the treatment of the dumping syndrome by Henley (1952), and others since then have utilized the technique to include the management of intestinal hurry (Rutledge, 1964; Poth, 1969). Surgical experience indicates that jejunal segments are more predictable in behaviour and safer in use than segments of distal ileum, but there has been no satisfactory explanation of this phenomenon, nor has any simple rule emerged to relate the length of the segment to its proposed therapeutic function.

Earlier work by the present authors (Jenkins and Macleod, 1970) indicated that the behaviour of an isolated and interposed segment of the small intestine in the rabbit is influenced both by the site of the segment and by the number of vessels supplying it. Interposed segments of ileum supplied by a single vessel behaved in an unpredictable manner irrespective of their polarity, and some caused obstruction out of all proportion to their short lengths. Similar findings have been reported by Youmans (1949) and Torbey (1960) in the dog and by Poth (1969) in man.

Motility and tone of the small intestine have been shown to be influenced by intestinal hormones (Fishlock, 1966; Misiewicz, Waller, and Durrell, 1966; Bennett, Misiewicz, and Waller, 1967; Murrell and Deller, 1967; Bennett, 1968), anoxia (Kosterlitz and Lees, 1964; Nylander and Wikstrom, 1968), autonomic nerve distribution (Puestow, 1932; Celender, 1959; Kerwenter, 1965; Bennett and Whitney, 1966; Burnstock, Campbell, and Rand, 1966; Smith, 1970), and the intrinsic activity of the smooth muscle (Prosser and Rafferty, 1956; Baker, 1969).

Of those mechanisms which modify intestinal tone and motility, that which is most affected by segment isolation and interposition and by changes in the vascular supply is the extrinsic innervation. It was felt that a closer study of this aspect might lead to a rational selection of segments for use in surgical procedures.

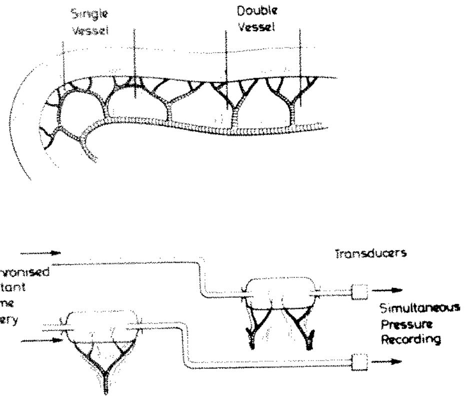
The present experiments were designed to demonstrate in the proximal jejunum and distal ileum of the rabbit and the dog the relationships between tone and extrinsic segmental innervation and blood-supply.

MATERIALS AND METHODS

In each experiment on a rabbit or a dog anaesthesia was induced with intravenous Nembutal, 24 mg. per kg., and was maintained with nitrous oxide, 1·5 litres per minute, halothane, 0·5 per cent, and oxygen, 0·75 litre per minute open circuit.

Rabbits.—

Segmental Intraluminal Pressures.—Seventy-one paired experiments were conducted on the distal ileum and 52 similar experiments were conducted on the proximal jejunum in 76 rabbits. In each experiment two adjacent intestinal segments of the same length (±0·5 cm.) supplied by one or by two vessels were selected and isolated. Segments were measured in the relaxed state, the minimum length each of a pair being 5 cm. and the maximum 10 cm. Owing to individual variations in vasculature, it was not possible for all the segments to be of the same length.



Single Vessel
Double Vessel
Synchronised Constant Volume Delivery
Transducers
Simultaneous Pressure Recording

FIG. 1.—The experimental model. Length-matched segments supplied by one and two vessels were selected and pressures recorded as filling progressed.

Portex plastic cannulas, 4·7 mm. in diameter, were inserted into each end of the isolated segments and tied in place. The margins of the longitudinal abdominal incision were supported and the open abdominal cavity was filled with 0·9 per cent saline at 37° C. to maintain a constant environment. The segments were filled with isotonic saline at 37° C. until a mean intraluminal pressure of atmospheric +5 mm. Hg was obtained, and basal recordings of segmental activity were made.

Saline was then pumped into the length-matched paired segments simultaneously at a rate of 7·5 ml. per minute by a double-barrelled constant-delivery infusion pump, and the pressures within the segments were continuously monitored via 0·9 per cent saline-filled 4·7-mm. Portex tubing connected to a Sanborn transducer No. 267BC and recorded on moving paper (*Fig.* 1). Pressure recordings were stopped and final pressures noted when the pressure in one segment had reached a value close to 20 mm. Hg. The filling time taken to reach the minimum pressure in each of the comparable groups was also noted.

The same procedure was repeated in neurologically intact, in vagotomized, and in sympathectomized length-matched paired segments from proximal jejunum and distal ileum.

Experimental Groups.—

A. Distal ileum:—

1. Normally innervated: 32 paired experiments. Length-matched adjacent segments supplied by one and by two vessels.

2. Vagotomy: 31 paired experiments. Complete vagotomy was achieved by division of the oesophagus and accompanying vagi 1 cm. above the cardio-oesophageal junction.
3. Sympathectomy: 18 paired experiments. Complete sympathectomy was achieved by division of the spinal cord above the level of the first thoracic vertebra.

B. Proximal jejunum:—
1. Normally innervated: 14 paired experiments.
2. Vagotomy: 19 paired experiments.
3. Sympathectomy: 19 paired experiments.

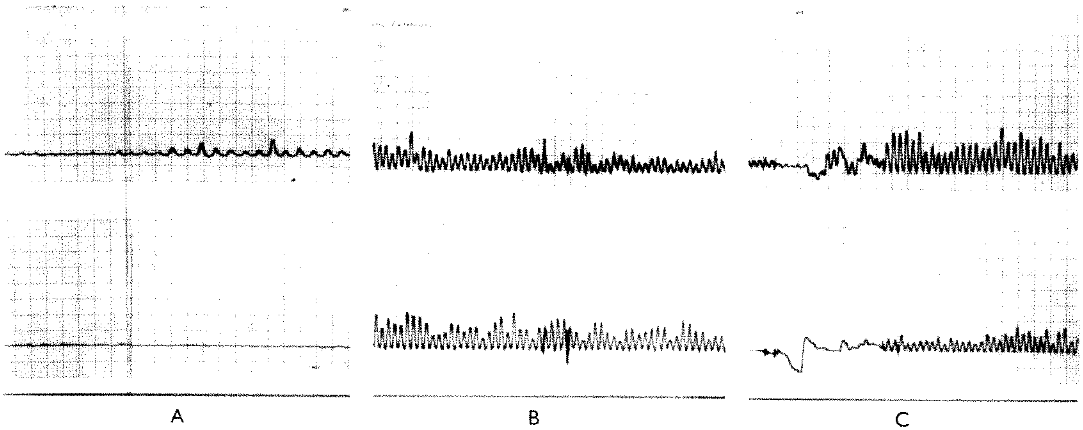


FIG. 2.—A, Pressure recordings from double-vessel (upper) and single-vessel segments (lower) of rabbit jejunum at atmospheric pressure after vagotomy showing segmental activity. B, Recordings from double-vessel (upper) and single-vessel (lower) segments of rabbit jejunum at atmospheric pressure after sympathectomy. C, Recordings of normally innervated double-vessel (upper) and single-vessel (lower) segments of rabbit proximal jejunum.

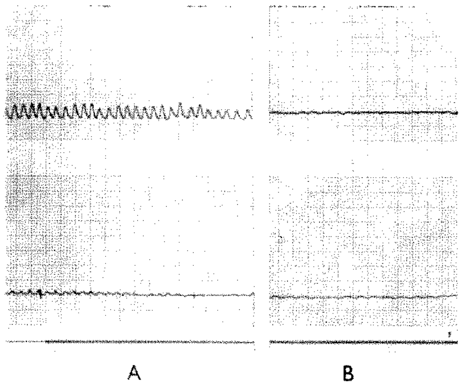

FIG. 3.—A, Recordings of double-vessel (upper) and single-vessel (lower) segment contractions in the normally innervated distal ileum of a rabbit. B, Recordings of double-vessel (upper) and single-vessel (lower) segment contractions in the distal ileum of a rabbit after vagotomy.

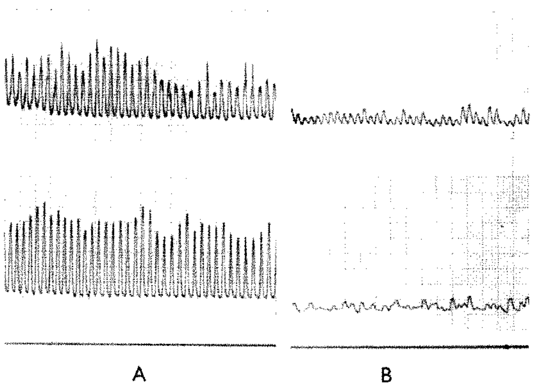

FIG. 4.—Recordings of double-vessel (upper) and single-vessel (lower) segment contractions in the distal ileum of a rabbit after sympathectomy, showing the variation in response. All segments were of the same length (8 cm.).

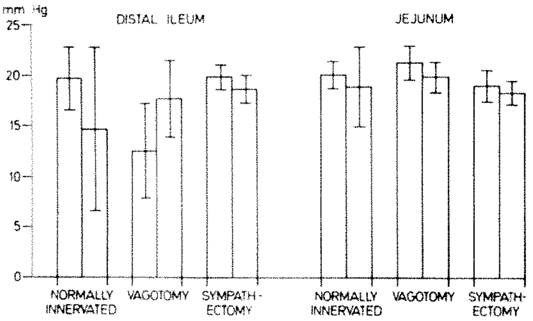

FIG. 5.—Mean values of pressure reached in the distal ileum and jejunum of the rabbit. Standard deviations are also shown Single-vessel segment values are on the left in each pair.

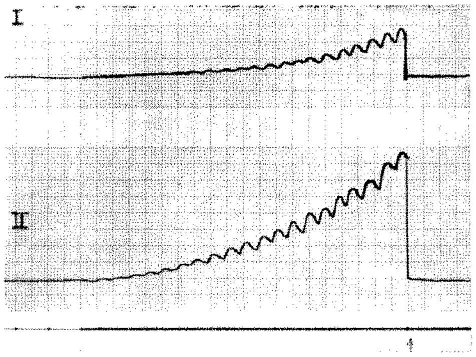

FIG. 6.—Typical pressure recordings made during simultaneous length-matched single-vessel (upper) and double-vessel (lower) segment filling in the distal ileum of the rabbit, demonstrating the difference in response which is frequently seen.

Dogs.—Fifty-five paired acute experiments were conducted on 7 dogs. The same experimental methods were adopted as in the rabbits, but in view of the greater musculature of the small intestine of the dog the rate of filling was increased to 50 ml. per minute and filling was continued until the pressure in one segment was approximately 40 mm. Hg.

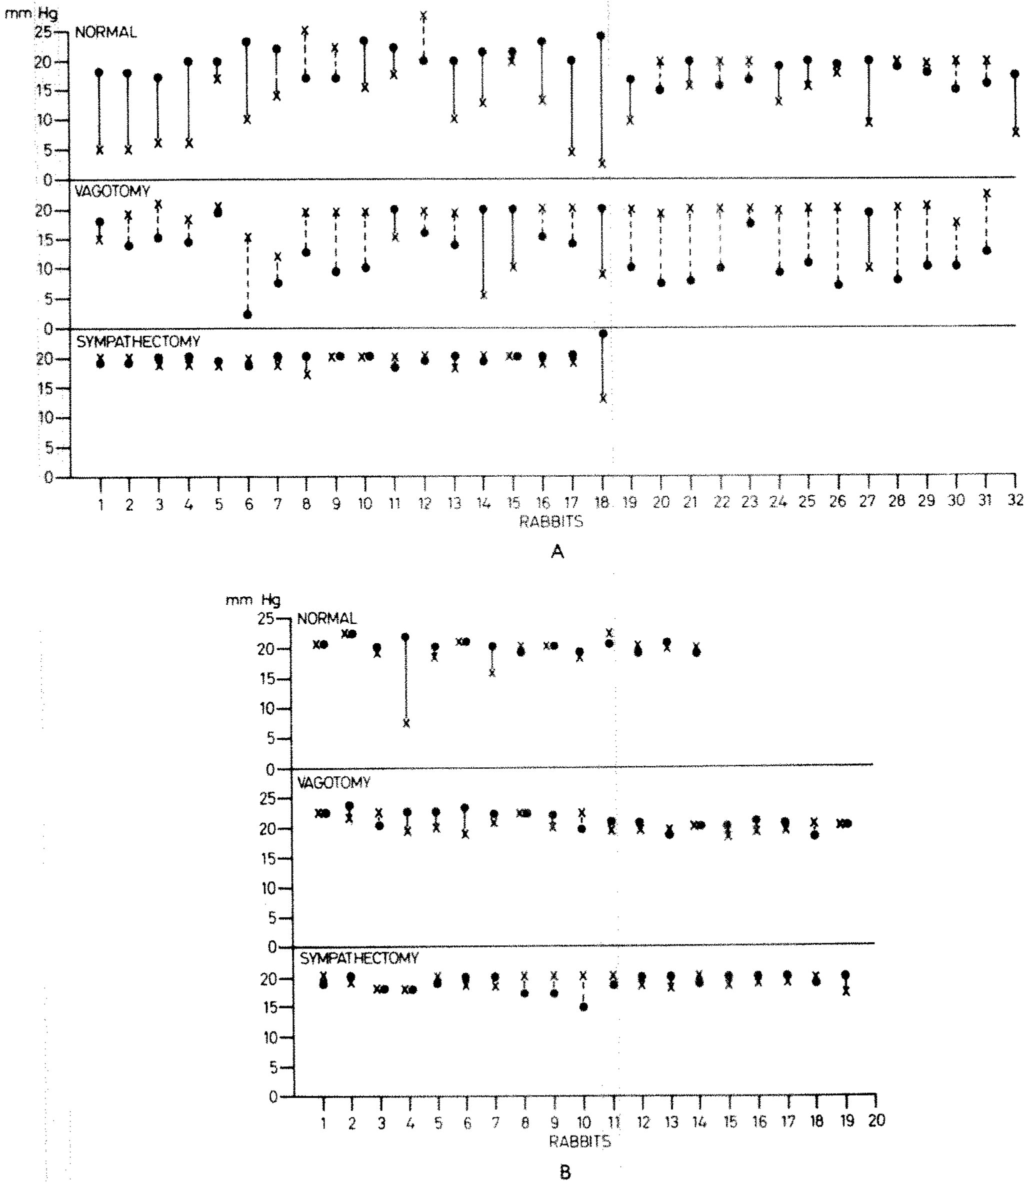

Fig. 7.—Paired pressure recordings in normally innervated and selectively denervated distal ileum (A) and jejunum (B) in the rabbit. The points recorded are those at the same point on the x-axis when one or both pressures had reached a value close to 20 mm. Hg (*see* arrow on *Fig.* 6). ×, Double-vessel segment; ●, Single-vessel segment.

Experimental Groups.—

1. Distal ileum: 30 paired experiments.
2. Jejunum: 25 paired experiments.

Selective denervation experiments were not made on dogs.

RESULTS

1. **Unstimulated Motility.**—Nineteen of the 32 single-vessel segments of normally innervated rabbit distal ileum visibly contracted in varying degrees of isolation. High tone in these segments was always demonstrated by the resistance to filling technique, but high tone was also seen in 2 segments which did not visibly contract on isolation. Single-vessel segment contraction was observed in 24 of the 30 segments of dog distal ileum. All single-vessel segments of the dog which contracted on isolation exhibited high tone of varying degrees. Only 6 of the 30 single-vessel segments of dog distal ileum did

not contract and none of these exhibited high tone. Contraction following isolation was not observed in any of the double-vessel segments of distal ileum or in any of the segments of proximal jejunum in either animal.

Recordings taken with rabbit segments filled with 0·9 per cent saline at atmospheric pressure +5 mm. Hg indicated that extrinsic innervation modifies the activity of the gut. In the proximal jejunum vagotomy decreased the amplitude of type II segmental contraction, while sympathectomy had no effect on amplitude or wave-form (*Fig.* 2). In the distal ileum vagotomy similarly decreased segmental contraction (*Fig.* 3), but sympathectomy caused considerable variation in amplitude and markedly increased it in 4 of the 18 double-vessel segments (*Fig.* 4).

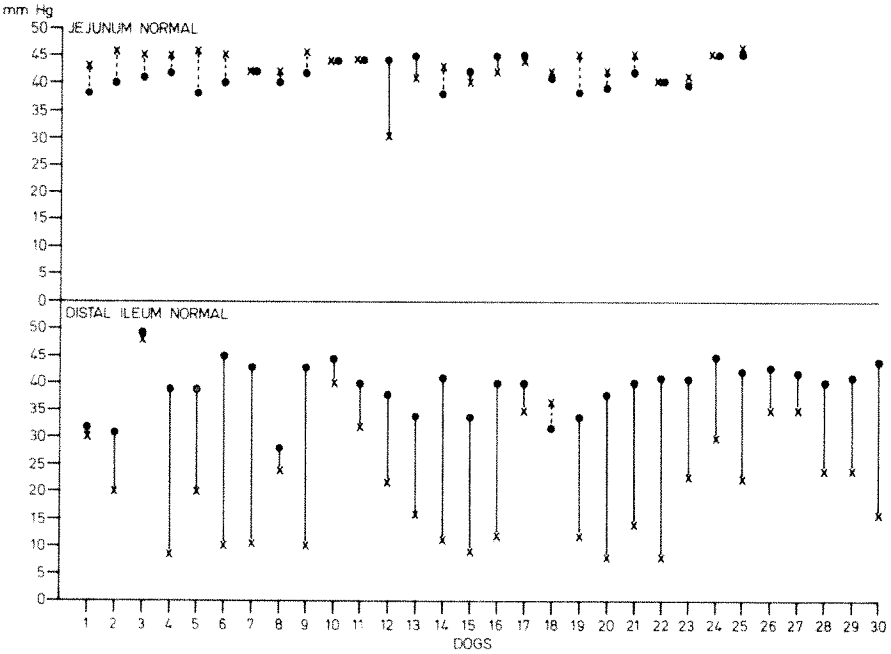

FIG. 8.—Representation of individual pressure values in single-vessel and double-vessel segments in the jejunum and distal ileum of the dog, demonstrating the comparatively high tone in most single-vessel segments of distal ileum. The points recorded are those at the same point on the x-axis when one or both pressures had reached a value close to 50 mm. Hg. ×, Double-vessel segment; ●, Single-vessel segment.

2. **Response to Filling.**—

a. Pressure Relationships.—In the normally innervated distal ileum of the rabbit the pressures reached during simultaneous filling were significantly greater in single-vessel segments than those reached in double-vessel segments ($P < 0·001$) (*Fig.* 5).

In the vagotomized group pressures were significantly greater in double-vessel segments ($P < 0·01$). Sympathectomy had no effect on comparative pressures in single- and double-vessel segments of the distal ileum.

The wide variations in tone in normal and vagotomized single- and double-vessel segments of distal ileum are shown by the high standard deviations in these groups.

In the proximal jejunal groups comparative pressures were similar and there was a low variation in response to filling. *Fig.* 6 shows typical recordings in the normally innervated distal ileum of the rabbit during segmental filling.

Variations in behaviour in terms of tone which are shown collectively in *Fig.* 6 are individually demonstrated in *Fig.* 7, and the differences between the normally innervated and the vagotomized single- and double-vessel segments of distal ileum and the other four groups are clearly seen.

In the dog, as in the rabbit, the pressures reached in the normally innervated distal ileum during simultaneous filling were significantly greater in single-vessel segments than those reached in double-vessel segments ($P < 0·001$), but in the normally innervated proximal jejunum the values were not significantly different (*Fig.* 8).

b. Filling Times.—Filling time varies with segment length as well as with segment tone.

The time necessary to reach a standard pressure (5 mm. Hg in the rabbit and 8 mm. Hg in the dog) was measured and the effect of the length of the segment (L) was removed by considering this time (T) per unit length of segment (T/L). In the rabbit there was no significant difference in filling times between all normally innervated single- and double-vessel segments. Filling time following vagotomy in single-vessel segments of proximal jejunum is significantly greater than that in normally innervated single-vessel segments ($P < 0·01$), but there is no difference in times between sympathectomized and normally innervated single-vessel segments. The same significance values are found comparing double-vessel segments of proximal jejunum. Following vagotomy in the distal ileum, both single- and double-vessel segments relaxed and in both groups filling times were significantly greater than in the normally innervated groups ($P < 0·02$ for single-vessel segments; $P < 0·1$ for double-vessel segments).

Sympathectomy caused an increase in tone, shown by a decrease in filling time, in both distal ileum groups. The filling time was significantly less than that of the normally innervated groups ($P<0{\cdot}02$ in both groups compared with normal) (*Fig.* 9).

In the dog, contrary to the findings in the rabbit, there was a significantly increased filling time in single-vessel segments of distal ileum when compared with single-vessel segments of jejunum ($P<0{\cdot}005$). This difference was also seen between double-vessel segments of jejunum and ileum ($P<0{\cdot}01$) (*Fig.* 10).

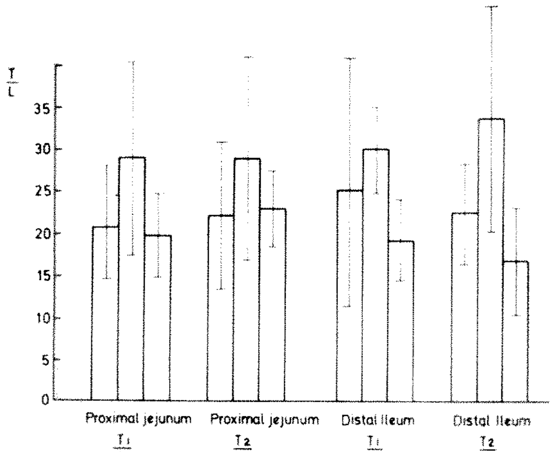

FIG. 9.—Filling times for the proximal jejunum and distal ileum of the rabbit to reach a pressure of 5 mm. Hg in single-vessel (T_1/L) and double-vessel (T_2/L) segments adjusted for length. The values for normally innervated segments are shown on the left, those after vagotomy in the centre, and those after sympathectomy on the right of each group of columns.

DISCUSSION

We believe our results can be fully explained by variations in the distribution of the autonomic system: if the parasympathetic and sympathetic systems were equally distributed to all parts of the gut, division of one or the other would be likely to have a similar effect in all regions.

Vagotomy decreased tone in both single- and double-vessel segments of proximal jejunum and also reduced motility. This might have been due either to the effect of the hypothetical extrinsic sympathetic system or to the intrinsic autonomic system. Since the intrinsic parasympathetic system is known to predominate over the intrinsic sympathetic system of the jejunum and a fall in tone was recorded following vagotomy, the vagus clearly exerted a considerable influence on tone. If extrinsic sympathetic innervation exists a reduction in filling time following sympathectomy owing to the unimpeded action of the vagus might be expected. This was not recorded. One can conclude therefore that there is no extrinsic sympathetic supply to the jejunum in the rabbit. This finding corroborates that of Kerwenter (1965) in the cat.

Our results in the distal ileum are markedly different. Unlike the proximal jejunum in which segmental behaviour was independent of differences in vascular supply, distal ileal segments exhibited marked variations in tone dependent on the number of vessels supplying them. The effect of sympathectomy was to decrease filling time in all distal ileal segments, indicating an increase in tone, and also to abolish the random behaviour, shown by variations in final pressures, of the single-vessel segments, indicating that the unimpeded vagal supply stabilized segmental tone. The greater tone in the vagotomized double-vessel segments of distal ileum shown by significantly greater group pressures over the single-vessel segments is unexplained.

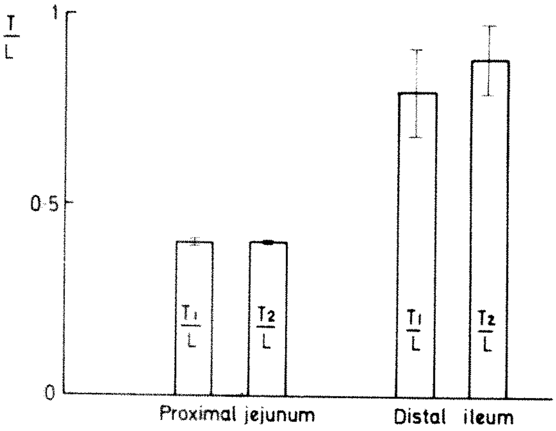

FIG. 10.—Filling times for the proximal jejunum and distal ileum of the dog to reach a pressure of 8 mm. Hg in single-vessel (T_1/L) and double-vessel (T_2/L) segments adjusted for length.

Segments of distal ileum of the dog appear to be dependent on the vascular supply in a manner similar to that of the rabbit. Unlike the rabbit, however, where tone, in terms of filling time, is the same in both parts of the small bowel, the tone in the distal ileum is greater than that in the proximal jejunum.

It is suggested that the vagus is regularly distributed to all parts of the distal ileum with the major branches of the superior mesenteric artery, but that the sympathetic supply is haphazardly distributed with some vessels. If by selecting a segment supplied by a single vessel one is isolating that segment from the sympathetic supply, a vagal effect, i.e., high tone, is to be expected, and is seen in our experiments. If, however, one selects segments supplied by two vessels, one or both of which are accompanied by a branch of the extrinsic sympathetic system, the tone is expected to be low. Some single-vessel segments will obviously be those to which the parent vessel brings sympathetic innervation.

From the results we conclude that while the vagus is supplied to all parts of the small intestine in a regular and orderly manner with each main branch of the superior mesenteric artery, the sympathetic supply is only distributed to the distal ileum, and there in a rather haphazard manner.

APPLICATION

From this and our earlier work we suggest that segments of the proximal jejunum will behave similarly and predictably according to length irrespective of the number of vessels supplying them. Segments of the distal ileum in the dog and the rabbit if selected solely by length will behave in an unpredictable manner, owing to the irregular extrinsic sympathetic distribution, and many of the short segments will exhibit an exceptionally high tone making them unsuitable for use where antiperistaltic segments causing low degrees of obstruction are required. The contraction of some short single-vessel segments of distal ileum observed on being isolated in the rabbit and the dog indicates that such segments will exhibit obstructive qualities out of all proportion to their short lengths. They will not be suitable for use as antiperistaltic segments in the treatment of short-bowel syndrome, but their use may be considered in operations of sphincter substitution.

SHORT NOTES OF RARE OR OBSCURE CASES

POST-IRRADIATION FEMORAL ANEURYSM TREATED BY ILIOPOPLITEAL BY-PASS VIA THE OBTURATOR FORAMEN

BY HARVEY B. ROSS AND JOHN E. L. SALES

DEPARTMENT OF SURGERY, ST. BARTHOLOMEW'S HOSPITAL, LONDON

SUMMARY

This unusual case is presented for two reasons. First, it illustrates the value of a long by-pass graft from the common iliac artery to the popliteal artery passing through the obturator foramen when there are complications which forbid operation through the femoral triangle. Secondly, it provides clinical and histological evidence of the late effects upon neighbouring large arteries of radiotherapy—given in this instance for a fibrosarcoma in a thigh muscle.

THE bifurcation of the common femoral artery is a convenient site for anastomosis in by-pass procedures and for arteriotomy in disobliteration. It may happen, however, as in the case reported here, that direct arterial surgery is necessary but some complication forbids the usual approach through the femoral triangle (*Table I*). If this is so, a by-pass may be established from the iliac vessels to the popliteal artery via the obturator foramen. The technique was first described by Shaw and Baue (1963), and since that date further reports of the successful use of the method have been made, and these, together with the original 3 cases, are summarized in *Table II*.

Table I—INDICATIONS for OBTURATOR BY-PASS

1. Infections of aortofemoral and femoropopliteal prostheses.
2. Large aneurysms of the iliac and femoral arteries.
3. Ulceration in the femoral triangle owing to carcinoma (primary or secondary), ischaemia of skin-flaps, and radiation necrosis.
4. Trauma with loss of soft tissue suitable for covering the femoral vessels.
5. Mycotic aneurysm of the femoral vessels (increasingly common in heroin addicts).

The case reported here is of additional interest because an aneurysm of the femoral artery is believed to have developed as an after effect of radiotherapy.

CASE REPORT

B. S., a woman aged 79 years, was admitted on 6 March, 1969, complaining of swelling in her right thigh, which was increasing in size.

In 1920 an undifferentiated fibrosarcoma had developed in her right adductor longus. The tumour had been

excised, together with the proximal two-thirds of the muscle. The following year a local recurrence had been excised and the area had been irradiated. In 1954 the scar tissue had broken down, and in 1955 the ulcerated area in the femoral triangle had been excised down to the femoral vessels. Troublesome infection had occurred, but healing had ultimately been achieved. Histological examination of the ulcer and underlying tissue showed post-irradiation changes, but no recurrence of the tumour.

Two months before the present admission the patient had slipped and fallen, and shortly after this she had noticed a swelling in the lower part of her right femoral triangle. The swelling had been asymptomatic, but she had also observed some swelling of the right ankle at this time.

On examination the patient's general health was good for her age. There were some crepitations at both bases. The blood-pressure was 210/130 mm. Hg and the pulse-rate was 84 with regular rhythm. There was an early systolic murmur in the aortic area, conducted to the neck. Examination of the local condition revealed a saccular aneurysm of the superficial femoral artery at the apex of the femoral triangle, measuring 5 cm. in diameter. The skin and scar tissue overlying the femoral triangle showed irradiation telangiectasia; all pulses were present in both lower limbs and there was minimal oedema of the right ankle.

The haemoglobin was 12·6 g. and the white blood count was 6000 per c.mm. The blood-urea was 39 mg. per cent and the serum cholesterol was 310 mg. per cent. Electrocardiograms showed ischaemic changes and a radiograph of the chest showed left ventricular enlargement. A plain film of the right thigh revealed extensive calcification in the femoral artery.

A right femoral arteriogram (*Fig.* 1) showed moderate diffuse dilatation of the common and superficial femoral vessels, with a somewhat crimped appearance. The aneurysm containing thrombus was also demonstrated, as well as the grossly abnormal femoral artery which terminated at the level of the adductor opening—this corresponded to the lower limit of irradiation. The collateral circulation was very poor.

On 18 March resection of the aneurysm and the establishment of a conventional iliopopliteal Dacron by-pass were carried out. A longitudinal incision was made from 5 cm. above the inguinal ligament down to the level of the proximal popliteal artery. The external iliac and the popliteal artery showed minimal arteriosclerosis, but the common, superficial, and profunda femoral vessels were dilated and very thin walled. There was a large amount of perivascular scar tissue resulting from the previous surgery and radiotherapy, and the arteries and veins were separated mainly by sharp dissection.

The lower half of the superficial femoral artery, including the aneurysm, was resected. The vessel was ligated above this level, but the upper half of the superficial femoral artery was not resected. This was because the profunda vessel was involved in the aneurysmal process and the benefits of resection did not justify the technical hazards and the additional time involved in this procedure. In order to isolate the common femoral bifurcation a ligature was tied around the common femoral artery just below the inguinal ligament. A Dacron prosthesis, 10 mm. in diameter, was then anastomosed end to side to the external iliac artery and end to end obliquely to the proximal part of the popliteal artery.

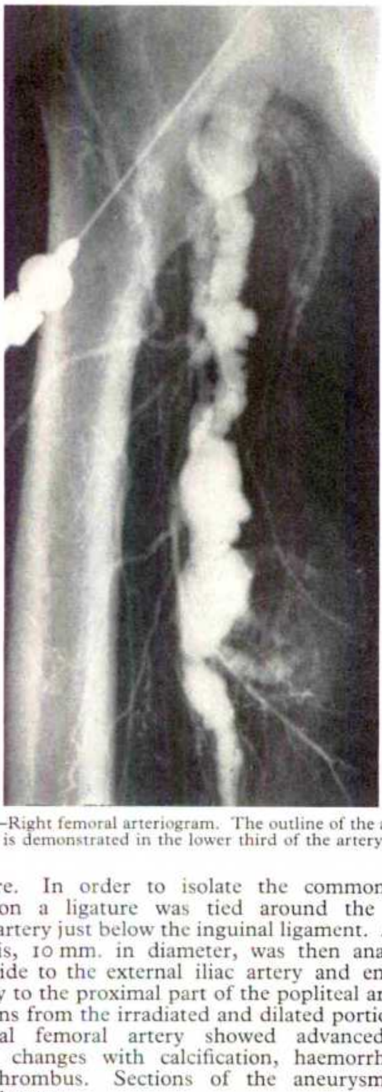

FIG. 1.—Right femoral arteriogram. The outline of the aneurysm is demonstrated in the lower third of the artery.

Sections from the irradiated and dilated portions of the superficial femoral artery showed advanced atherosclerotic changes with calcification, haemorrhage, and mural thrombus. Sections of the aneurysm showed similar changes.

Postoperatively the patient's initial progress was satisfactory, and both ankle pulses were palpable. However, on the seventh postoperative day the femoral wound broke down in the irradiated area and became infected. Culture revealed coliform bacilli and *Pseudomonas aeruginosa*. The patient was treated with systemic antibiotics and local irrigations, but the wound did not heal and the prosthesis became exposed. On 20 April she developed left-sided chest pain; radiographs of the chest showed elevation of the left dome of the diaphragm and a small left-sided pleural effusion. A pulmonary embolus was diagnosed, and she was treated with intravenous heparin, 5000 U. 6-hourly. On 26 April she developed a temperature of 40·1° C., and blood culture produced a growth of coliform bacilli, probably a result of infection from the exposed graft.

In view of the failure of the wound to heal and the continued exposure of the prosthesis a tube pedicle was raised from the anterior abdominal wall and swung down to cover the defect in the thigh. Initially the graft was satisfactory but by 7 Aug. the pedicle flap had become necrotic over the prosthesis, and the wound was discharging watery pus. The infection proved resistant to treatment. A left retrograde femoral arteriogram showed patency of the prosthesis with poor run-off to the anterior and posterior tibial arteries. The iliac vessels on both sides showed minimal atherosclerosis, as did the left femoral artery. It was therefore decided to insert another prosthesis using the obturator by-pass technique.

On 19 Aug. a femoral by-pass through the obturator foramen was performed. The operative technique has been described in detail by Guida and Moore (1969) and the procedure in this case differed only in detail. The patient was supine, with the right hip flexed 10° and externally rotated. Steridrape was used to seal off the infected area in the femoral triangle. The abdomen was opened through a right paramedian incision. While exploring the area of the iliac vessels and obturator foramen it became apparent, first, that an extraperitoneal approach was difficult and unsatisfactory, and, secondly, that in order to avoid angulation of the graft the upper end should be anastomosed to the common iliac artery and not to the external iliac artery (*Fig.* 2 A). The peritoneal cavity was therefore opened and, having identified the ureter at the iliac bifurcation, the posterior parietal peritoneum was incised to expose the common artery.

Synchronously with the abdominal operation a second operator exposed the popliteal fossa through the lower end of the recent by-pass incision, and the site of the previous anastomosis was identified. The popliteal artery was secured 4 cm. below this level for the new anastomosis.

In establishing the pathway through the obturator foramen and traversing the adductor compartment it has been advised that a third incision should be made on the posteromedial aspect of the thigh. We decided not to make this incision because of the after effects of the previous operation and radiotherapy, and because of the risk of infection from the femoral triangle.

The obturator membrane was incised by sharp dissection just below the obturator artery and nerve, and this incision was enlarged by digital dissection, thus making sure that there was no sharp fascial edge which might compress the graft. The tunnelling was then carried out using the graft passer employed in conventional by-pass procedures; this instrument has a long malleable shaft. Preliminary trials in a cadaver showed that the instrument tends to pass anteriorly and thus to enter the subsartorial canal. This tendency is corrected by defining the adductor magnus in the lower dissection, and the second operator was thus able to guide the instrument down along the posterior aspect of this muscle, using sponge-holding forceps. A 10-mm. Dacron prosthesis was attached to the end of the graft passer and was pulled up through the tunnel (*Fig.* 2B). End-to-side anastomosis was established to the common iliac artery above and to the popliteal artery below, using 00000 Dacron sutures; the anastomoses were made obliquely in order to minimize turbulence. When flow had been established through the new by-pass the peritoneum was closed over its upper end.

The ends of the previous graft were then defined and the external iliac artery was ligated just proximal and the popliteal artery just distal to the attachments of this graft. There was no evidence that the graft had become adherent to the surrounding tissues. The old anastomotic sutures were cut and unpicked. The abdominal and thigh incisions were closed without drainage. Finally the old Dacron by-pass was grasped with artery forceps through the defect in the pedicle skin-graft in the femoral triangle and was pulled out without difficulty. Five pints of blood were transfused during the operation, and 8000 U. of heparin were given to cover the period of insertion of the by-pass.

The patient's postoperative recovery was very good, both ankle pulses being present within 24 hours. She started to walk on the twelfth day, and developed some oedema of the foot and ankle but this did not interfere with her mobilization. The oedema was probably lymphatic and was partially controlled by an elastic stocking. She was discharged on the eighteenth postoperative day and was last seen exactly 6 months after leaving hospital when she was fully mobile. In view of the danger of late occlusion of the Dacron by-pass, long-term anticoagulant therapy was started 3 months after the operation and has been continued until the date of this report.

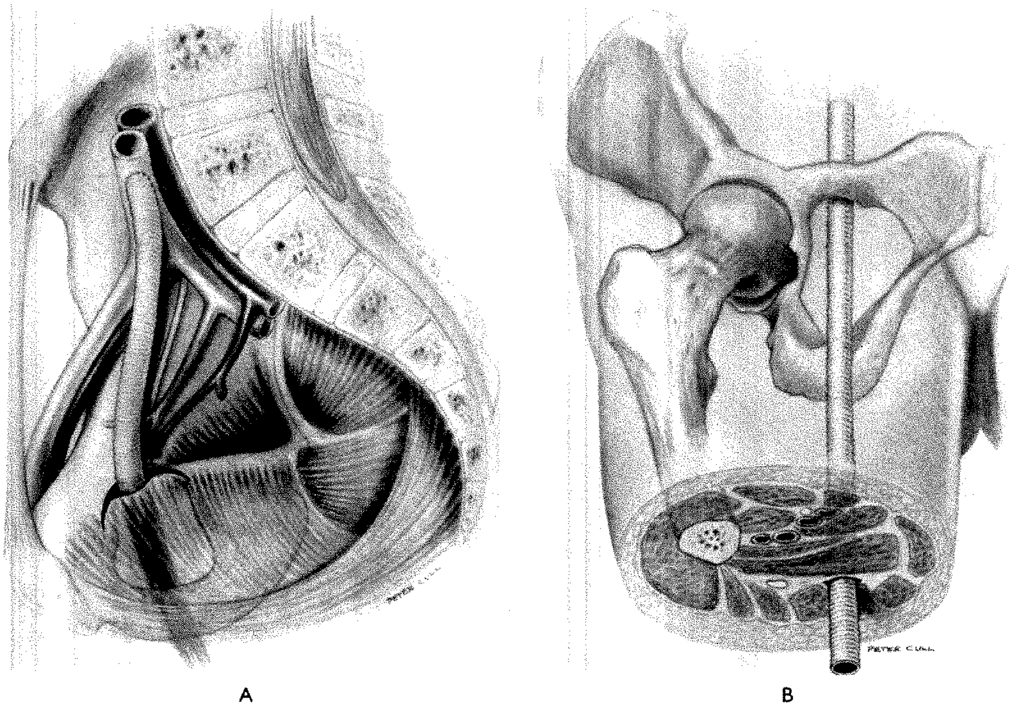

FIG. 2.—The pathway of the graft.

DISCUSSION

Clinical Management.—In view of the tissue damage in the thigh resulting from the previous operative treatment and radiotherapy, it was perhaps optimistic to hope for satisfactory healing in this area. In retrospect the obturator route for the by-pass should have been chosen at the outset. We also consider that we should have abandoned the first by-pass at an earlier date. The likelihood of salvaging an infected Dacron graft is very small, and although the pedicle skin-graft healed very well initially, as in *Case* 3 in *Table I*, it failed to maintain skin cover of the infected foreign material. Meanwhile, the infection gave rise to the danger of secondary haemorrhage from the anastomoses and was detrimental to general health, as shown by intermittent high fever, rigors, and a positive blood-culture. The failure of antibiotics and skin-grafting to combat the infection was partly due to the involvement of the entire length of the graft in the infection. Evidence of this fact was provided by the lack of adhesion of the Dacron to the surrounding tissues which facilitated its extraction through the skin defect at the end of the final operation.

The use of Dacron in both operations is open to question. In this case there was no right long saphenous vein, and the left long saphenous and the upper limb veins were of poor calibre. The extra length of the by-pass from the iliac segment instead of from the common femoral bifurcation would result in a very narrow channel if a vein were used, and it is likely that the advantages of a 10-mm. lumen more than offset the increased chance of late failure due to using Dacron. It is probable that a suitable autogenous vein would be the material of choice, but the fact that a vein was used only twice out of 22 cases in *Table II* suggests that a suitable vein is not usually available.

The Clinical Effect of Radiation on Large Arteries.—Radiation may damage an artery in two ways. First, by direct action on the elements of its wall and, secondly, by the indirect effect due to scarring and damage in the surrounding tissues (Sams, 1965). The pathological changes in the vessel are limited to the field of irradiation.

The acute and long-term effects of radiation on arterioles and capillaries have been well described (Woolbach, 1909; Warren 1942). As for larger vessels, Lindsay, Kohn, Dakin, and Jew (1962) have studied the short-term effects of radiation on segments of dogs' aortic walls. They showed that atherosclerosis appeared in the irradiated segments and was indistinguishable from natural atherosclerosis. They felt that this was due to selective injury of the internal elastic lamina leading to intimal fibrosis and plaque formation. Smith (1961) has suggested that this occurs as a result of damage to the vasa vasorum. From these experiments and others (Berdjis, 1960; Sams, 1965) it would appear that the effect of irradiation is to accelerate the natural degenerative process in the arterial wall. The mechanism of this process is not fully understood.

Clinically, large arteries can tolerate normal megavoltage radiotherapeutic schedules of 5000–6000 rad in 28–42 days without obvious immediate damage. However, Cade (1940) described a case of perforation of the aorta following radium therapy of a carcinoma of the oesophagus. Jones (1948) described a similar case after 1 MeV. X-ray therapy in which failure to repair the deficit caused by tumour invasion was the basic factor. Marcial-Rojas and Castro (1962) reported 11 cases undergoing irradiation of the neck in combination with surgery, and irradiation of inoperable neoplasms of the oesophagus in which the carotid artery or aorta ruptured during or shortly after treatment. There was associated mediastinitis from perforation of the neoplasm in all the cases with aortic rupture, and salivary fistulae with necrosis of the skin-flaps in all the cases with rupture of the carotid artery. It is probable that infection and salivary fistulae were the principal causes of the vessel ruptures and that irradiation potentiated their effect.

There are only scattered reports of the late effects of radiation on large arteries. In most instances major vessel occlusion has occurred. Thomas and Forbus (1959) described the case of a young man who developed localized necrosis of the aortic wall with associated thrombosis 2½ years after irradiation of a mediastinal lymphoma. Rubin and Casarett (1968) reported the case of a 38-year-old woman who thrombosed her aorta and common iliac arteries 4 years after internal and external irradiation for carcinoma of the cervix. Obliteration of the subclavian and narrowing of the common carotid and innominate arteries has been described by Heidenberg, Lupowitch, and Tan (1966). This occurred in a 21-year-old woman 11 years after irradiation for Hodgkin's disease. The artery was obliterated by a combination of vessel-wall damage and dense fibrosis in the surrounding tissues. Superficial femoral artery thrombosis was described by Gross (1969) after irradiation of nasopharyngeal carcinoma metastases in the groin.

Narrowing only of the major vessels following irradiation has also been reported. Selective constriction of the profunda femoris artery in a 23-year-old woman following irradiation of a labial haemangioma was found to be due to adventitial scarring (Pouliaf, Giannopoulos, and Frangagis, 1967). Johnson, Lane, Harding Rains, O'Connell, and Ramsay (1969) reported the case of a 61-year-old woman who had presented with intermittent claudication due to bilateral iliac artery stenosis 6 years after external irradiation for carcinoma of the uterus. The stenosis was caused principally by perivascular fibrosis. Why some arteries should occasionally be more susceptible to damage by normal therapeutic schedules is not known. Asscher, Wilson, and Anderson (1961) have shown experimentally that irradiation increases the susceptibility of blood-vessels to damage by hypertension and this may be a factor in some cases.

The case reported here had had irradiation of the right thigh for a recurrent sarcoma in 1921. We do not have a record of the dose that she received, but we do know that it was of low-quality irradiation and sufficient to produce severe skin and subcutaneous changes after 6 years, and a small area of frank skin necrosis after 24 years. Arteriograms showed that the left femoral artery was within normal limits for the age of the patient, whereas the right femoral artery showed gross irregularity of the arterial wall and a saccular aneurysm. The vessel wall was distorted by areas of dilatation and constriction, but an adequate lumen was maintained. The reason for these changes is that the effect of irradiation on the cells of the wall of a large artery is not uniform and therefore the subsequent degenerative processes are irregular within the field of irradiation.

Irradiation produces characteristic changes in small blood-vessels: namely, sausage-shaped segmentation of the arterioles and looping of the capillaries (Lindop, 1970). Some such changes could be seen in the present case, but the majority of the small vessels in the field of irradiation did not show advanced changes. This was probably due to the increased endothelial turnover and new vessel formation stimulated by the surgery to the thigh in 1954.

Histology of the arterial wall showed gross irregular thickening due principally to changes in the intima. This was thickened and composed mainly of hyalinized collagen focally calcified and showing atheromatous changes at intervals along its inner aspect. The media was thinned and in places completely absent. It showed almost complete disappearance of the muscle cells and marked loss and fragmentation of the internal elastic lamina with collagen replacement. There were thinning and patchy deficiency of the external elastic lamina. The aneurysm was filled with old and partially organized thrombus, and its wall was composed of attenuated layers of fibrous tissue. The vasa vasorum in the adventitia showed only slight hyalinization. These changes were considered to be consistent with chronic irradiation damage, the prominent features being the fragmentation of the elastic tissue and the replacement of the arterial wall by collagen.

There are several reasons why clinically the long-term effects of radiation on large arteries are rarely seen. First, the changes take years to develop owing to the very slow turnover of cells in the arterial wall. Secondly, damage to the artery may not become manifest unless it is subjected to some form of stress, such as further irradiation, infection, or physical trauma. These may precipitate thrombosis, embolism, or the development of an aneurysm, as occurred in this case after a fall.

Johnson and others (1969) have shown that such effects on arteries can be produced by normal therapeutic dosages. It therefore seems likely that as this damage is related to dose the clinical effects of post-irradiation arterial pathology will be seen more frequently in the future. One reason is that dosage used to be limited by skin tolerance but with modern techniques large doses can now be given to deep structures without damaging the skin.

Acknowledgements.—We would like to thank Dr. Arthur Jones and Professor P. J. Lindop of St. Bartholomew's Hospital, and Dr. H. S. ven den Brenk of the Dimbleby Laboratory, St. Thomas's Hospital, for their advice on the subject of irradiation changes in blood-vessels. We would also like to thank the Departments of Medical Illustration and Photography of St. Bartholomew's Hospital.

This case has been presented at the Clinical Section of the Royal Society of Medicine **63**, 624, 1970, and we are grateful for the Editor's permission to use some of the material in this publication.

RECTAL STONES

BY D. G. JAGELMAN
SURGICAL REGISTRAR, WESTMINSTER HOSPITAL, LONDON

SUMMARY

A case is reported of a rare complication of total cystectomy and ureterocolic anastomosis for carcinoma of the bladder. The patient suffered not only from some of the more common complications of this procedure but also developed bleeding per rectum, the cause of which was impaction of two calculi in the rectum. Analysis of these stones showed an inner core of mixed gall-stone and an outer shell of urinary struvite.

CASE REPORT

A 68-year-old blind ex-serviceman presented with a 4-month history of painless haematuria and was found on cystoscopy to have a papilliferous carcinoma of the bladder, which was treated initially with cystodiathermy. The patient was otherwise fit and had undergone retropubic prostatectomy for benign hypertrophy 18 months previously. Subsequent recurrences on routine-check cystoscopy over a 3-year period necessitated a course of radiotherapy with a good result and no evidence of recurrence of the tumour. Unfortunately the patient developed a severe post-irradiation cystitis, reduced bladder capacity, and persistent haematuria, these symptoms being so severe that total cystectomy and ureterosigmoid implantation were performed. At operation he was noted to have gall-stones but till then these had been quite asymptomatic.

The patient made a good postoperative recovery, but his subsequent follow-up was complicated by several admissions during the following 12 months for electrolyte imbalance and periodic episodes of ascending urinary infection. He was treated with long-term sulphonamides and potassium bicarbonate therapy with a reduction in the clinical attacks of pyelitis and better stabilization of his hyperchloraemic acidosis. On two admissions he also complained of mild upper colicky abdominal pain and vomiting, but he was never jaundiced. Cholecystitis was not diagnosed clinically, even with the knowledge of gall-stones being present at the time of his total cystectomy.

Five years following the cystectomy he presented in the out-patients' department with bright red bleeding per rectum, and on examination was found to have two calculi in the rectum that required an anaesthetic for their removal. They measured $3\cdot5 \times 2\cdot5$ cm. and 3×3 cm. (*Figs.* 1, 2). These stones were analysed and revealed a central core of mixed gall-stone (cholesterol and bile pigment) and an outer shell of struvite ($MgNH_4PO_4.6H_2O$) approximately 1·75 cm. thick.

The patient had no further bleeding per rectum, but his renal function deteriorated and he died at home some weeks later in uraemia, 5 years following his cystectomy. A post-mortem examination was not performed.

DISCUSSION

This case is reported as a rare complication of ureterocolic anastomosis with total cystectomy for carcinoma of the bladder. On reviewing the literature it would appear to be a unique case. The patient also demonstrates the more common complications of this operative procedure, the treatment of which may have had a bearing on the occurrence of this unusual complication.

At the time of total cystectomy it had been noted that gall-stones were present and under the circumstances they were not removed. The attacks of upper abdominal pain and vomiting would in retrospect be compatible with cholecystitis and subsequent ulceration of the stones into the intestine. They probably entered the large intestine as, owing to their size (approximately 1·75 cm. in diameter), gall-stone ileus might well have developed if they had entered the small bowel. The gall-stones therefore reached the large bowel and were bathed in urine and coated in struvite ($MgNH_4PO_4.6H_2O$) during their passage to the rectum. It is well documented that following ureterosigmoid implantation, urine passes backwards in the colon as far as the caecum, so that the stones would have close contact with urine during their passage. Struvite is only deposited in alkaline urine and is an uncommon cause of urinary calculi alone, usually being combined with calcium phosphate and carbonate. The urine excreted by this patient was presumably heavily alkaline as he was taking regular daily doses of potassium bicarbonate and there was an abundance of urea-splitting organisms in the bowel. Renal calculi are a known complication of ureterocolic anastomosis for the same reasons. The dual nature of these calculi can therefore be explained, and their size, in conjunction with a degree of anal stenosis due to the long-term passage of fluid faeces, prevented natural voiding per rectum.

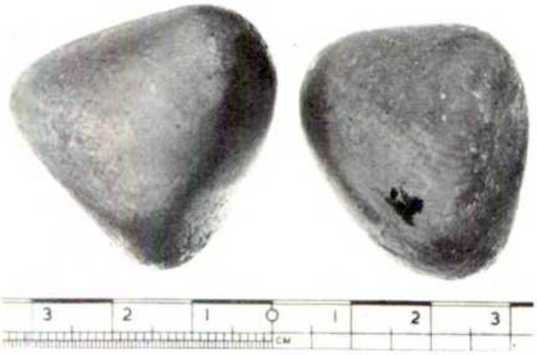

FIG. 1.—Rectal calculi.

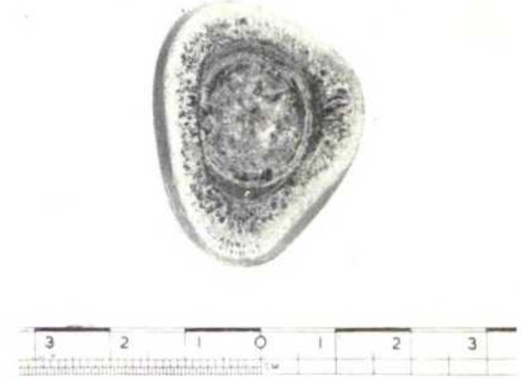

FIG. 2.—Cross-section of a rectal calculus, showing an inner core of mixed gall-stone and an outer shell of struvite.

Acknowledgements.—I wish to express my thanks to Mr. Robert Cox for permission to publish this case. I am grateful to the Department of Medical Photography, Westminster Medical School, for assistance with the photographic reproductions.

HAEMANGIOSARCOMA OF THE SPLEEN

BY P. J. TOGHILL, C. C. RIGBY, AND G. F. M. HALL
THE GENERAL HOSPITAL, NOTTINGHAM

PRIMARY splenic tumours are extremely rare and because of this are not usually considered in the differential diagnosis of splenomegaly. We report here a patient with a primary haemangiosarcoma who presented with splenomegaly and unusual haematological findings and in whom spontaneous rupture of the spleen occurred.

CASE REPORT

A 72-year-old joiner was admitted to hospital with left upper abdominal pain of 10 days' duration. Apart from some shortness of breath in previous weeks he had otherwise been in good health. The patient had not had serious illnesses in the past and he had never had radiological examinations involving the use of Thorotrast. On examination his general condition was satisfactory but he was clinically anaemic. The spleen was tender and enlarged, being easily palpable 6 cm. below the left costal margin. The liver was not enlarged and there was no ascites. There was no significant lymphadenopathy.

The following investigations were performed: haemoglobin, 8·1 g. per 100 ml.; white cell-count, 5500 mm.^{3}, with neutrophils, 59 per cent, lymphocytes, 32 per cent, monocytes, 7 per cent, eosinophils, 1 per cent, basophils, 0 per cent, myelocytes, 1 per cent; reticulocyte count, 6·5 per cent; platelet count, 50,000 mm.^{3}; the red cells showed anisocytosis and mild anisochromia, and there were fairly frequent schistocytes and burr cells with occasional microspherocytes; Howell Jolly bodies were frequent; normoblasts formed 5 per cent of the total nucleated cell count; direct anti-human globulin (Coombs) test was negative; red-cell osmotic fragility showed small 'tails' of cells of both increased and decreased fragility. The blood-urea was 22 mg. per 100 ml.; serum sodium, 138 mEq./l.; chloride, 102 mEq./l.; potassium, 4·4 mEq./l.; CO_2 content, 27 mEq./l. Serum alkaline phosphatase was 84 I.U.; total serum bilirubin, 0·1 mg. per 100 ml.; S.G.P.T., 10 I.U.; flocculation tests, negative; total serum proteins, 6·2 g. per 100 ml.; albumin, 3·6 g. per 100 ml. A chest radiograph showed emphysematous changes in the lung fields with marked unfolding of the aorta. A straight radiograph of the abdomen showed the spleen to be grossly enlarged, extending downwards as far as the iliac crest.

Six days after admission the patient collapsed with generalized abdominal pain. He was shocked, there was generalized distension of the abdomen, and paracentesis from the right flank revealed fresh blood. A diagnosis of spontaneous rupture of the spleen was made. At laparotomy 4–5 litres of blood were found in the peritoneal cavity. The spleen was grossly enlarged, being approximately six times normal size, with a deep 8-cm. tear on the convex surface. The liver was normal. The spleen was extremely friable and was removed piecemeal after ligation of the splenic pedicle.

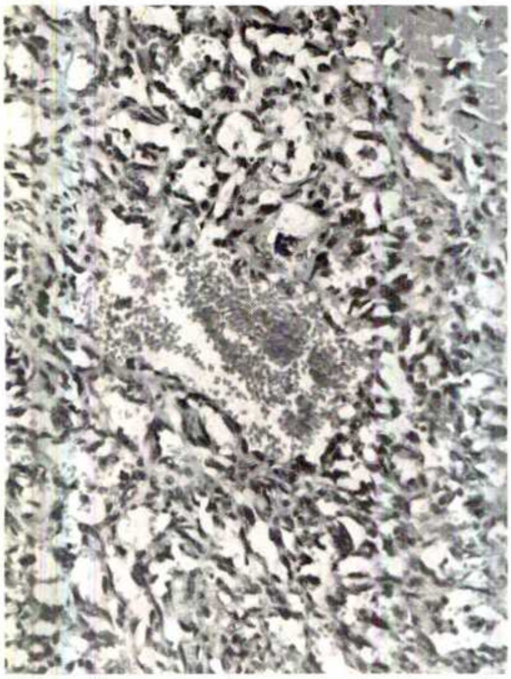

FIG. 1.—The normal splenic structure is replaced by a capillary network with a cavernous channel in the centre of the picture. H. and E. (× 198.)

Pathological examination of the excised spleen showed it to consist of two ragged masses, together weighing 1125 g. The tissue was firm with innumerable black haemorrhagic areas up to 1 cm. in diameter. In an intact subcapsular area there was a yellowish infarct, 2 × 1·5 × 1 cm., and several tiny infarcts were present elsewhere; there was no evidence of infarction in the area of the laceration. Sections showed the spleen to be the site of a diffuse haemangiosarcoma. Only traces of normal splenic structure could be identified. The tissue was composed of a capillary network with multiple large cavernous spaces, most of which were thrombosed (*Fig.* 1). The capillary network lay in a stroma of hyperchromatic oval and spindle cells of endothelial type with quite frequent mitoses and occasional more bizarre cells including tumour giant cells, some being multinucleate. Several of the cavernous spaces were partially lined by several layers of these malignant cells.

Postoperatively the patient made an immediate satisfactory recovery. However, after 2 months he became ill again with anaemia, jaundice, and enormous hepatomegaly. He died at home 5 months after his admission to hospital. A post-mortem examination was not performed.

DISCUSSION

Haemangiosarcomas of the spleen are extremely rare tumours and few have previously been recorded (Bauer and Stanford, 1946; Wright, 1949; Wilkinson, Lucas, and Foote, 1968). There is some doubt about their histogenesis, but it is thought by some authors (Hastings-James, 1949) that they arise from malignant change in pre-existing haemangiomas. Wright (1928) considered that they were primary malignant splenic tumours which metastasized secondaries to the liver. In the present case it is of interest that at laparotomy the liver was macroscopically normal, but that within a few weeks it had enlarged enormously and was obviously the site of secondary malignant deposits. This rapidly fatal course with widespread metastases to the liver, peritoneum, lymph-nodes, and bones has been stressed by other authors (Wright, 1949; Blix and Jacobsen, 1963; Wilkinson and others, 1968). Haemangiosarcomas of the liver have been described following the use of contrast media containing thorium dioxide (Thorotrast) (MacMahon, Murphy, and Bates, 1947; Silva Horta, Abbatt, Da Motta, and Roriz, 1965), but there was no evidence of this patient having had previous radiological examinations.

The haematological findings in the present case share many features of similarity with the syndrome of micro-angiopathic haemolytic anaemia delineated originally by Brain, Dacie, and Hourihane (1962). They regarded the basic disorder of this syndrome, seen in such diseases as malignant hypertension and disseminated carcinoma, as being direct erythrocyte damage by irregular vascular endothelium and fibrin strands. As a result, features of haemolysis with large numbers of damaged red cells presenting as burr cells and schistocytes may be seen. Certainly the racemose structure of a large splenic haemangiosarcoma could provide the appropriate mechanism for such a micro-angiopathic haemolytic anaemia, and other authors have commented on this type of haematological change (Baker, Paget, and Davson, 1956; Alpert and Benisch, 1970). A consumptive coagulopathy has also been described in patients with giant haemangiomas (Zervos, Vlachos, Karpathios, and Mantas, 1967; Thatcher, Clatanoff, and Stiehm, 1968) and in a haemangiosarcoma of the spleen (Blix and Jacobsen, 1963). In these cases the thrombocytopenia and fibrinogen deficiency resulted in widespread bleeding presumably due to consumption of platelets and fibrinogen during haemostasis within the tumour.

Apparent spontaneous rupture of the diseased spleen is now a well-recognized entity, having been described in arteriosclerosis of the splenic vessels (Jones, 1944), splenic abscess (Gelfand, 1947), infective mononucleosis (Rawsthorne, Cole, and Kyle, 1970), sarcoidosis (Roberts and Rang, 1958), leukaemia (Cooray, 1952), and actinomycosis (Sperling, Heredia, and Gillesby, 1967). Primary splenic tumours are not usually considered in the diagnosis of spontaneous splenic rupture, but this complication may occur in a splenic haemangioma (Ingham and Thompson, 1960) and in haemangiosarcoma as in the present case.

LEIOMYOSARCOMA OF THE SPERMATIC CORD

A CASE REPORT

By D. G. JENKINS and S. G. SUBBUSWAMY

NEWCASTLE GENERAL HOSPITAL

Summary

A case of leiomyosarcoma of the spermatic cord is presented, the twenty-sixth case in the world literature. The tumour metastasized to the skin and to the lungs, and had to be differentiated from a neurofibromatous lesion. There was histological evidence to suggest that the lesion had originated as a benign leiomyoma and then had undergone malignant change. The primary tumour was excised. The secondary deposits were radioresistant but showed some response to chemotherapy. It is suggested that the most suitable form of treatment is wide excision of the primary tumour with close follow-up and chemotherapy when recurrence or metastasis occurs.

Tumours of the spermatic cord are of infrequent occurrence. We have been able to find only 25 cases of leiomyosarcoma of the spermatic cord in the literature. We have recently come across a case which had metastasized to the skin and thereby presented a peculiar problem in histological diagnosis.

CASE REPORT

A 55-year-old white male attended a surgical clinic in May, 1966, complaining of a swelling in the right groin which had been present for 3 months.

Physical examination revealed a hard, round, non-tender, irreducible mass in the right groin below the internal inguinal ring.

Laboratory investigations revealed nothing of consequence. A chest radiograph showed no lesion.

A diagnosis of encysted hydrocele was made. However, at operation 1 month later the lesion was found to be a solid tumour lying beside the spermatic cord within the external spermatic fascia. The entire spermatic cord with the tumour and the right testis was excised below the internal inguinal ring.

In January, 1969, the patient developed a small brown nodule in the middle of the chin. The lesion was about 1 cm. in diameter and was raised above the skin surface. He also had a small nodule behind the left ear. The nodule on the chin was excised and was found to be histologically similar to the spermatic cord tumour.

In June, 1969, the patient developed pain in the right side of the chest, breathlessness, and loss of weight. A chest radiograph showed extensive patches of increased density throughout the right lung, and a diagnosis of metastases to the lung was made.

The patient was given a course of actinomycin D, a total dose of 5 g. being administered in 10 days. While there was no change in the skin nodule or chest radiograph, there was considerable subjective improvement and the patient remained reasonably fit for about 6 months.

In January, 1970, the patient developed more skin nodules (on his scalp) and some deeply placed nodules in the soft tissues of the right thigh. He was given a course of X-ray therapy to his leg to relieve the pain from the latter lesions and a course of Oncovin, 1·5 mg., intravenously at weekly intervals for 4 weeks. Little response was obtained by X-ray therapy despite a total dose of 5000 rad in 50 days by Tele caesium unit.

In May, 1970, the patient had developed more skin nodules and had pains over his sacrum. He was also becoming emaciated. His condition deteriorated rapidly and he died in August. No autopsy was performed.

Pathology.—The mass from the spermatic cord consisted of a hard, multilobular, rounded tumour, 8 × 6 cm. Histologically, it appeared well encapsulated and was composed of interlacing strands and sheets of spindle-shaped cells with elongated nuclei (*Fig.* 1). The cells were arranged compactly and appeared to be benign over the greater part of the tumour. However, a sharply defined focus of obviously malignant change was seen involving about one-fifth of the tumour (*Fig.* 2). The cells in this region were much larger than in the rest of the mass, and were arranged in an irregular manner, though in places a pattern of interlacing strands was seen. The nuclei too were larger, with marked variation in size and chromatin distribution. A large number of mitotic figures was seen. A few small areas of necrosis were present in this zone. The tumour showed no attachment to the vas deferens.

The nodule from the chin was made up of tissue very similar to that in the spermatic cord (*Fig.* 3). The tumour lay in the deeper dermis, being separated from the epidermis by a layer of collagenous tissue.

Both tumours showed similar staining characteristics. Very little collagen or reticulin could be demonstrated. The tumour cells did not stain with the Glees and Marsland technique, but stained red with Masson's trichrome stain and the Lissamine fast-red technique.

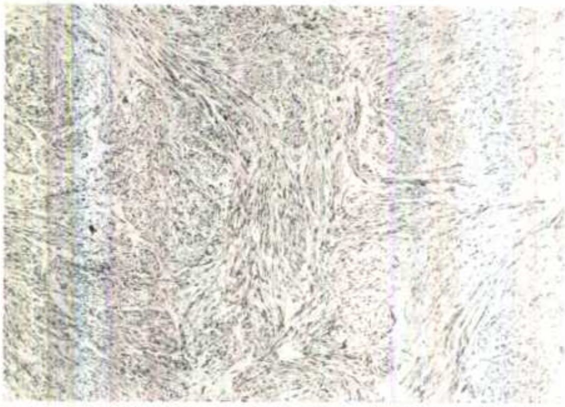

FIG. 1.—Section from the benign part of the tumour, showing interlacing bundles of smooth-muscle fibres. H. and E. (× 32.)

DISCUSSION

As Stout (1953) has pointed out, the criteria for recognizing some of the varieties of sarcoma are not sufficiently well established to make the published diagnoses reliable. We would, therefore, like to make clear the factors that led to the diagnosis of leiomyosarcoma in the present case.

When the spermatic cord tumour was first seen, the histology of the benign-looking areas was considered typical of a smooth-muscle tumour; no dianosis other than that of a leiomyoma with malignant change was entertained. However, the occurrence of skin nodules later suggested three possibilities: (1) the tumour in the spermatic cord was a leiomyosarcoma and the skin nodules were secondaries; (2) the skin and spermatic cord lesions were both manifestations of neurofibromatosis with malignant change in the spermatic cord tumour; (3) the skin and the spermatic cord lesions were independent of each other, the former being a neurofibroma.

The occurrence of the nodules in the chin and behind the ear 2 years after removal of the spermatic cord tumour, followed some months later by nodules on the scalp, suggested that the skin lesions were secondaries rather than neurofibromas.

Histologically the lesions in the chin and the spermatic cord appeared identical and showed identical staining characteristics. The positive reaction with the Lissamine fast-red technique and the negative reaction with the Glees and Marsland technique were in favour of a diagnosis of leiomyosarcoma. There was no evidence of palisading to support a diagnosis of neurilemmoma. The stroma was compact and did not have the loose oedematous appearances commonly seen in neurofibromas. Myofibrils could be seen in the better differentiated areas. Thus, the diagnosis of leiomyosarcoma with metastasis appears to be well established.

Patel and Chalier (1907) reported the first case of leiomyosarcoma of the spermatic cord. Kyle (1966) reviewed the literature, which then included 21 cases, and added 1 of his own. We have found 3 more cases in the subsequent literature (Lundblad, Mellinger, and Gleason, 1967; Weitzner, 1967; Arlen, Grabstald, and Whitmore, 1969). Our case is therefore the twenty-sixth reported in the literature.

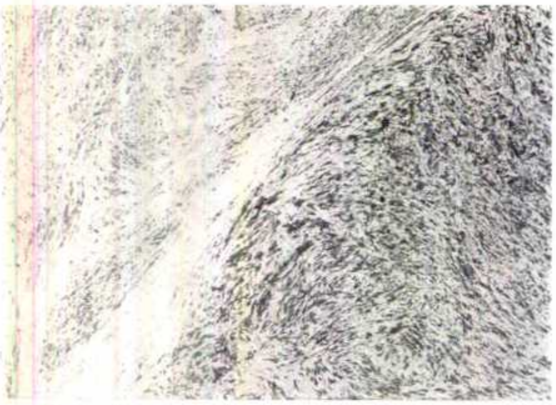

FIG. 2.—Junction of the benign and malignant parts of the tumour, showing an abrupt transition to large cells with hyperchromatic nuclei. H. and E. (× 32.)

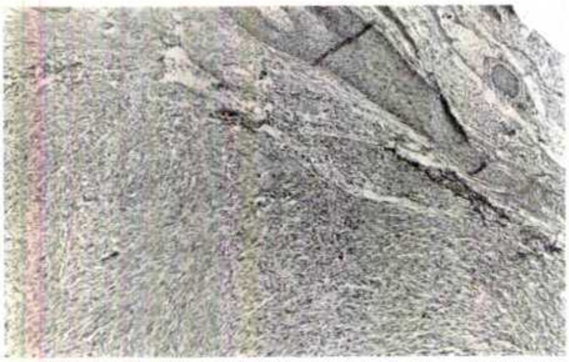

FIG. 3.—Section of a skin nodule, showing compactly arranged interlacing strands of spindle-shaped cells, some of the nuclei being large and hyperchromatic. Masson's trichrome stain. (× 32.)

The exact site of origin of leiomyosarcomas of the spermatic cord is unknown. Undifferentiated mesenchymal cells, smooth-muscle cells in the cremaster, walls of blood-vessels, and the vas deferens have all been suggested as possible sites of origin (Weitzner, 1967). In the present case the tumour was quite free of the vas deferens. The ubiquity of leiomyomas and leiomyosarcomas suggests that primitive mesenchymal cells or walls of blood-vessels are the likely sites of origin.

As Kyle (1966) has pointed out, distant metastasis, when it occurs, is much more likely to be haematogenous than lymphatic. The presence of skin and pulmonary involvement in this case is in favour of haematogenous spread. This is the first case of leiomyosarcoma of the spermatic cord in which skin metastasis has been recorded. The presence of the skin metastases presented a peculiar problem in diagnosis, both clinically and histologically.

The age of the patients with leiomyosarcoma of the spermatic cord reported in the literature ranges from 15 to 78 years, with the majority being over the age of 50 years. As Gowing and Morgan (1964) have pointed out, paratesticular tumours of connective tissue can be divided into two groups based on the age of onset. The first group consists of the embryonic sarcoma and the rhabdomyosarcoma which occur almost exclusively in children and adolescents. The second group, into which the leiomyosarcomas fall, occurs in older subjects. The present case occurred at the age of 55 years, thereby being consistent with the other cases in the literature.

One of the features of the present case was that malignancy was confined to a small part of the tumour, which was sharply distinct from the remaining benign-looking tissue, suggesting that the lesion had started as a benign leiomyoma with subsequent malignant change. This has been a feature in 6 of the cases in the literature (Dreyfuss and Goodsitt, 1940; Wessel, 1953; Bevan, 1954; Meinardi, 1961; Kyle, 1966; Weitzner, 1967).

The treatment of leiomyosarcomas in general is by wide surgical excision, which produces a 25–30 per cent 5-year survival rate. In the case of leiomyosarcoma of the spermatic cord, metastases often seem to arise after a long period of apparent freedom from disease. Since spread is mainly haematogenous as distinct from other sarcomas of the spermatic cord (Banowsky and Shultz, 1970) there is no place for retroperitoneal node dissection or postoperative irradiation. In the present case the secondary deposits appeared to be radioresistant, no response being obtained to a large dose of radiotherapy.

The effect of chemotherapy with antimetabolites on this disease has not so far been reported. In the present case a course of treatment with actinomycin D led to subjective improvement and arrest of progression of the disease for 6 months. Thus it would appear that the most suitable form of treatment is wide local surgery and a close follow-up with the use of chemotherapy when metastasis or recurrence occurs.

DOES SQUAMOUS CARCINOMA OF THE COLON EXIST?

By TOM W. BALFOUR

WESTERN GENERAL HOSPITAL, EDINBURGH

SUMMARY

A patient with a histologically unusual carcinoma of the colon had a successful surgical resection and primary anastomosis. The tumour showed certain squamous features. It is doubtful if any of the previously reported cases of 'squamous carcinoma' represents more than squamous metaplasia with variable degrees of differentiation in existing adenocarcinomas.

To find 'squamous' malignant tissue in the colon is not necessarily to imply that the tumour is metastatic or inoperable.

Four cases of 'squamous carcinoma' of the colon have previously been reported. Of these, only 1 involved the left half of the colon. The rarity of this type of tumour may be of critical importance when, as in the case described here, the preliminary colonic biopsy might be incorrectly interpreted as indicating spread of tumour into the colon from a more typical 'squamous' territory.

CASE REPORT

A 63-year-old unmarried assistant school matron was admitted to the Gastro-intestinal Unit of the Western General Hospital, Edinburgh, in June, 1969, for investigation of an episode of rectal bleeding 1 month previously. The bleeding had been dark red, had lasted for 2 weeks, and had been associated with bowel movements and an occasional 'twinge' of pain in the left iliac fossa. Her bowel action was regular and the stools were well formed. She took no drugs apart from oral supplements of iron. Her general health was good and she had not lost weight.

Thirty years previously the patient's anaemia had been investigated and found to be of an iron-deficiency type. In 1945 a routine appendicectomy had been done for acute appendicitis, and in 1957 a barium meal and cholecystogram carried out after several episodes of vomiting were reported as normal.

Examination on Admission.—The patient looked well and showed no signs of weight-loss. The abdominal examination was normal and her previous scar had healed well. There were no abnormal lymph-nodes and no palpable abnormality on rectal examination.

Investigations.—The haemoglobin was 83 per cent (red cells 'normocytic and normochromic'), and the erythrocyte sedimentation rate was 23 mm. in the first hour (Westergren). Liver-function tests and plasma proteins were normal. Faecal occult blood was slightly positive on repeated examinations.

At sigmoidoscopy an ulcerated mass was biopsied at 16 cm. The histology report indicated that the tumour was 'unlike a primary growth of colon, but had the appearance of a poorly differentiated squamous carcinoma'. The pathologist further suggested that metastasis from a primary source in the uterus or the urinary tract would be most likely to produce such an appearance.

A chest radiograph was normal, but a barium enema showed a 'small area of narrowing in the sigmoid colon' (arrowed in *Fig.* 1).

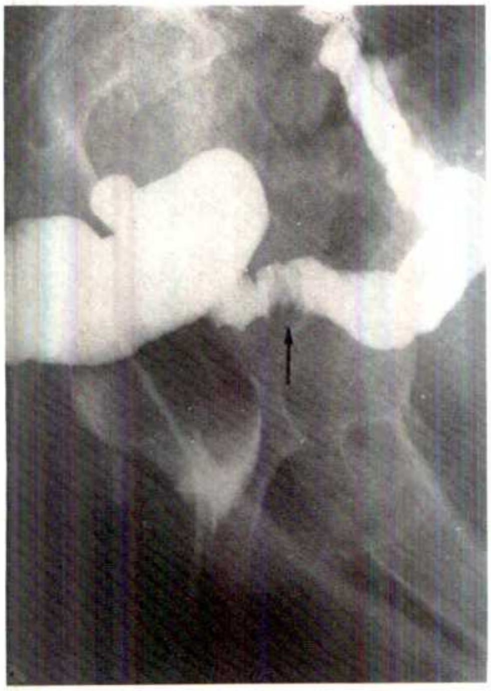

FIG. 1.—Barium-enema photograph showing localized narrowing in the low pelvic colon.

Examination of the urine was normal; the blood-urea was 33 mg. per cent and an intravenous pyelogram detected no abnormality in the kidneys, ureters, or bladder.

Examination under anaesthesia and endometrial curettage showed no abnormality in the genital tract.

OPERATION.—On 10 July, 1969, laparotomy (Mr. W. P. Small) confirmed the presence of a discrete tumour in the pelvic colon (*Fig.* 2). The colon was fully mobile and the tumour was palpated as an irregular nodule entirely within the lumen of the bowel. There was no evidence of hepatic metastases. The bladder, kidneys, and uterus appeared normal. A primary resection and anastomosis were completed.

PROGRESS.—The patient recovered well apart from a localized wound infection, and was discharged home on the eighteenth day. Six weeks after the operation she was enjoying a normal day's activity, her wound was healed, and her bowel action was normal. Eighteen months after her operation she remains well with no abnormal bowel symptoms. There is no clinical evidence of 'squamous carcinoma' elsewhere.

PATHOLOGY.—The macroscopic appearance (*Fig.* 2) was of a rounded, sharply demarcated, nodular plaque of yellowish tumour tissue. The serosa was not involved but one pericolic lymph-node was enlarged, firm, and whitish.

Microscopically the tumour (*Fig.* 3) was quite unlike a colonic adenocarcinoma. It was composed mainly of masses of closely packed cells with, in places, peripheral palisading. Some of the cells contained eosinophilic material which could have represented developing keratin. However, there is no specific stain for keratin and the same appearance could have been caused by colonic mucin.

There were no obvious prickle cells nor any classic epithelial 'pearls'. Therefore a diagnosis of pure squamous carcinoma could not be made. The most

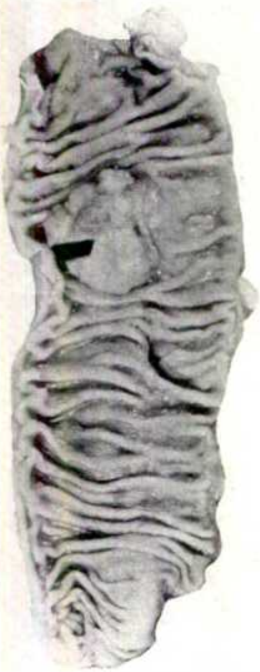

FIG. 2.—Resected specimen of pelvic colon showing localized tumour.

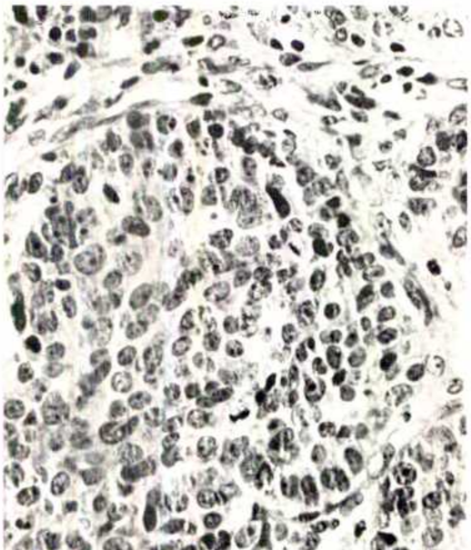

FIG. 3.—Photomicrograph of a section of the tumour showing a discrete mass of typical cells with early peripheral palisading. H. and E. (× 375.)

likely diagnosis was 'squamoid' degeneration in poorly differentiated adenocarcinoma. The possibility of an atypical carcinoid tumour was also considered, but specific staining did not support this.

The enlarged pericolic lymph-node showed infiltration with tumour cells of a similar type.

DISCUSSION

The only previous case of squamous carcinoma of the left colon was described by Thompson (1940). A 32-year-old woman with 'ulcerating squamous carcinoma' of the sigmoid flexure and no evident metastases underwent colonic resection and died 21 months later of local recurrence. However, his case fails as an example of pure squamous carcinoma since the author also reported adenocarcinoma in the neighbouring mucosa. It therefore represents 'squamous metaplasia', though of a mature form with keratinization and epithelial pearls.

Schmidtmann (1919) reported a 65-year-old man with an advanced 'keratinised squamous cell cancer' of the ascending colon with necrotic metastases in the inguinal lymph-nodes. No surgical treatment was attempted and accurate histological details are not available for this case. It may again represent squamous metaplasia, or, in view of the unusual spread to the inguinal lymph-nodes, it may be a rare example of squamous-cell carcinoma at another undiagnosed site which had metastasized both to the colon and to the superficial lymph-nodes.

A squamous tumour of the ascending colon was found by Hicks and Dowling (1955) in a 90-year-old woman. Again no surgical treatment was attempted and the tumour was later shown to have metastasized widely to the liver and intra-abdominal lymph-nodes. The histological features of this tumour were very similar to those of our patient. It too most likely represents squamoid degeneration in a poorly differentiated adenocarcinoma.

No squamous carcinoma of the transverse colon has ever been recorded, although Sanerkin (1968) described a poorly differentiated adenocarcinoma with prominent squamous metaplasia and also stromal ossification.

The longest surviving patient with a squamous carcinoma of the colon was described by Gaston (1967). A 65-year old man had a right hemicolectomy for a tumour of his caecum. No metastases were detected and the patient was in good health 2 years after the operation. Here again typically squamous features coexist with poorly differentiated adenocarcinoma.

The aetiology of such 'squamous' tumours in 'columnar' territory is unknown. The concept of an origin in embryonic cell rests seems to have been largely discredited. The theory of developmental error carries some weight in the region of the transitional epithelium (derived from the cloacogenic membrane) lying between the squamous epithelium of the anal canal and the columnar epithelium of the rectum. Certain 'squamous' cells might extend cephalad beneath the rectal mucosa, and even into the distal colon, but it is difficult to visualize them reaching the ascending colon or caecum. The remaining possibility is that of squamous metaplasia, which occurs frequently in the rectum, usually in response to chronic infection or trauma. Drennan and Falconer (1959) described a patient whose entire rectal mucosa had undergone squamous metaplasia with malignant change in places. However, such metaplasia has never been reported in the colon except in association with a poorly differentiated adenocarcinoma.

Although Hicks and Dowling (1955) did not attribute their case to squamous metaplasia, they did admit that it lacked the features of a well-differentiated mature squamous carcinoma. There was no clear gradation from basal cells to prickle cells with intercellular bridges to keratinous cell nests. They described birefringent areas which were suggestive of keratin and which could be accentuated by fluorochromes. Our case shows a similar cellular pattern. Histological uncertainty will always be found in such tumours until fresh tissue from them can be examined for squamous cells by the electron microscope, or until a stain is found which is entirely specific for keratin.

In 3 of the 4 cases described in the literature the tumour seems to have been advanced. By contrast, our patient had a very localized plaque of tissue in the bowel wall. She had a short history of 1 month and can be classified as 'early' despite the one involved lymph-node.

Surgical treatment was attempted in only 2 previous patients. One patient died of recurrence after 21 months and the other was well after 2 years. Our patient remains alive and well after 18 months with no indication of recurrence and no evidence of primary squamous carcinoma at any other site as far as can be determined.

CONCLUSION

Primary squamous carcinoma of the colon probably does not exist in a form which would satisfy modern histological criteria. The few cases reported to date in the literature probably represent squamous metaplasia or cellular degeneration in atypical adenocarcinomas.

Whether or not squamous carcinoma can affect the colon is to some extent academic. The practical importance is that when a patient is found on sigmoidoscopy to have a tumour of the distal colon with the appearance of squamous carcinoma the diagnosis becomes uncertain. There is a danger of unnecessary delay while searching for a primary site, which in a woman is often suspected to be the cervix. There is even the chance that operation may be denied on the grounds of presumed inoperability.

Acknowledgements.—I thank Mr. W. P. Small for his advice and encouragement, Dr. J. M. Drennan for his histological expertise, and Dr. J. McManus for permission to study a patient under his care.

REVIEWS AND NOTICES OF BOOKS

Hirschsprung's Disease. By THEODOR EHRENPREIS, M.D., F.A.A.P., Stockholm. 8¾ × 5¾ in. Pp. 175, with 44 illustrations. 1971. Chicago: Year Book Medical Publishers. £6·30.

IT is 85 years since Harald Hirschsprung, Professor of Paediatrics at Copenhagen, reported the clinical features of 2 infants who died of the disease which now bears his name, and which has become the most important and possibly the commonest cause of acute intestinal obstruction in the newborn. The control which paediatric physicians have established over gastro-enteritis has allowed other causes of diarrhoea and vomiting to be recognized more often in the small baby, and of these, Hirschsprung's disease is the most important. This book comes at an opportune time and there is no doubt that it will become the most important and comprehensive source of information about this disease. The whole subject is treated in the well-balanced manner which one would expect from Dr. Ehrenpreis, who for so long has been the foremost European authority on Hirschsprung's disease. He has reviewed the huge mass of published material on the historical aspects, morphology, aetiology, and clinical features, and has appraised calmly the various types of operative treatment on which so much controversy has been lavished since before Swenson and Bill introduced the first effective definitive method of treatment in 1948. There is still much to learn about this disease and its management. In this book what is known so far is collected, arranged, and judged, and no surgeon or physician who has to deal with the newborn infant can afford not to read it again and again.

A Short Textbook. Ear, Nose and Throat. By R. PRACY, F.R.C.S.; J. SIEGLER, F.R.C.S., D.L.O.; and P. M. STELL, F.R.C.S. 8½ × 5¼ in. Pp. 155 + iv. Illustrated. 1971. London: The English Universities Press Ltd. 95p.

THIS is a useful and cheap pocket-book on the surgery of the ear, nose, and throat. It is written in a clear and concise style and is illustrated by some interesting line drawings, many of which are original.

The authors have concentrated throughout the book on those diseases with which the doctor will often have to deal during general practice. Students can carry this book in their coat pocket for ready reference while attending the out-patient clinic on diseases of the ear, nose, and throat.

Die gynäkologischen Operationen. Ninth edition. By HEINRICH MARTIUS, Göttingen, and HUGO HUSSLEIN, Wien. 10¼ × 7 in. Pp. 274 + xi. Illustrated. 1971. Stuttgart: Georg Thieme Verlag. DM.98.

THE first edition of this book by Martius appeared in 1942, and the ninth edition, revised by Husslein, was printed in 1971, which proves that this book is popular among gynaecologists in German-speaking countries. A complete survey of gynaecological operations, abdominal and vaginal, repair of fistulae, etc., is presented, accompanied by many instructive illustrations.

Though urinary incontinence may belong to the working area of the urologist, the descriptions of plastic operations in cases of sphincteral incompetence are of a striking comprehensibility. The technique of resection of the small intestine, colostomy, herniotomy, and appendicectomy can be found in this book; these operations should, if possible, be delegated to the general surgeon. The author rightly does not recommend systematic appendicectomy following abdominal gynaecological operations.

Laparoscopy is regarded as a very valuable diagnostic technique, which is more trustworthy than culdoscopy.

This book is without doubt an excellent technical handbook for everybody interested in operative gynaecology.

Trauma to the Liver. Second edition. By GORDON F. MADDING, M.D., M.S., F.A.C.S., Stanford, and PAUL A. KENNEDY, M.D., F.A.C.S., Stanford. 9½ × 6 in. Pp. 186 + xiv. Illustrated. 1971. London: W. B. Saunders Co. Ltd. £4·05.

THE experience gained during the Second World War and the multiple injuries caused by motor accidents have caused a spate of articles on trauma to the liver both in this country and in America. Added to this, American surgeons have also had extended experience over the years in Korea and Vietnam.

The authors of this monograph had practical experience of cases of liver trauma in the Second World War and this experience was well reported in the first edition of this book. This second edition is a most useful book, for it gives all the facts on liver trauma and the treatment that is required.

The problems of liver haemostasis, lobectomy and liver resection, the use of Gelfoam, and bile peritonitis are all covered in a very practical way.

The line drawings are clear and they enhance the value of the book. There is an excellent bibliography at the end of each chapter.

This book will be of real value to all abdominal surgeons, and as a reference volume on trauma of the liver it could not be bettered. It is Volume III in the series 'Major Problems in Clinical Surgery'.

Die einfachen Kreislaufgrössen beim chirurgischen Patienten. By C. BURRI. 9 × 6 in. Pp. 130 + viii. Illustrated. 1971. Berlin: Springer-Verlag. DM.48.

THIS book offers a survey of the average standards of the blood circulation in normal and pathological conditions. These standards include: the pulse-rate, the systolic blood-pressure, the shock index, which is the quotient of pulse-rate/systolic blood-pressure, the central venous pressure, the blood-volume, and the haematocrit.

Combination of these standards enables the surgeon to regulate the intravenous substitution therapy. Experience proves that overdosing is needed in cases of severe blood-loss to compensate for the lowered central venous pressure. This central venous pressure is measured by intravenous PVC catheters connected with the infusion system in order to regulate the infusion speed in coordination with the central venous pressure.

Thoracic injuries are more quickly accompanied by a lowered arterial tension (and here the venous pressure is an unreliable standard) than abdominal injuries and crushed extremities.

The author demonstrates convincingly that the standards as described are indispensable in the fight against shock, in cases of blood-loss, burns, and septicaemia, and are a great help in the prevention of overdosing.

Bailey and Love's Short Practice of Surgery. Fifteenth edition. Revised by A. J. Harding Rains, M.S. (Lond.), F.R.C.S. (Eng.), Professor of Surgery, University of London; and W. Melville Capper, F.R.C.S. (Eng.), Consulting Surgeon, Bristol Royal Hospital. 9¾ × 6¼ in. Pp. 1296 + xii, with 1592 illustrations. 1971. London: H. K. Lewis & Co. Ltd. £6·50.

This most popular book on surgery has enjoyed a wonderful reputation for over 30 years and more than 259,000 copies have been published. This new fifteenth edition has been most thoroughly revised and new illustrations have made their appearance. There are 1592 illustrations, of which 241 are in colour. This is the ideal surgical book for the student, and we have nothing but praise for it. It is also popular abroad and there are Italian, Spanish, and Turkish editions.

A great credit to British medical literature.

Total Hip Replacement. Edited by Malcolm Joyson, Department of Medicine, University of Bristol, Royal National Hospital for Rheumatic Diseases, Bath, and Winford Orthopaedic Hospital. 9¾ × 6 in. Pp. 152. Illustrated. 1971. London: Sector Publishing Limited. £3·60.

This book contains a series of original papers by experts dealing with total hip replacement.

These authors discuss at some length the design, clinical results, complications, and follow-up of the various forms of hip replacement. Separate chapters deal with Ring, McKee-Farrar, Charnley, and total hip arthroplasty.

Each operation is explained, discussed, and illustrated with radiographs taken before and after the operative procedure.

John Charnley has written a foreword to the book.

The layout of the book is quite original, the main subject being tabulated in bold print at the side of each page; this makes for easy reading.

A useful book for all those who are interested in the reconstruction of the osteo-arthritic hip-joint.

Kurzer Leitfaden der praktischen Infusionstherapie. By W. Seifart. 7½ × 4¾ in. Pp. 179, with 5 illustrations. 1971. Berlin: VEB Verlag Valk und Gesundheit. DM.12.60.

One is pleased to find a good description of fluid and electrolyte disturbances and the measures to be taken to cure them. The tables giving normal values and the standard solutions that ought to be available in a hospital are extremely useful.

The dangers and implications of transfusions of whole blood get the attention that they need; counter-measures are briefly described.

The price is very moderate. The book with its pliable cover is apparently meant—and rightly so—to be carried in the pocket of hospital dresses.

Manuel de l'Aide en Chirurgie. By P. Orsoni. 8⅝ × 6⅝ in. Pp. 126, with 89 illustrations. 1971. Paris: Masson et Cie. 38F.

A most attractive little book that gives us a thorough survey of the surgical assistant's craft. The technique of the various ligatures and sutures is described in considerable detail, simple line drawings illustrating and reinforcing the text. The author also expounds ways of manipulating instruments, such as dressing forceps, scissors, artery forceps, and retractors. Anyone who can master all the variations described will have the legerdemain of a conjuror. The greatest merit of this book is that it gives the beginner a theoretical background, from which he can make a personal selection. It is to be hoped that an English translation will appear before long.

Idiopathic Ischemic Necrosis of the Femoral Head in Adults. Edited by W. M. Zinn, F.M.H., Ragaz. 9½ × 6½ in. Pp. 220 + xii. Illustrated. 1971. Stuttgart: Georg Thieme Verlag. DM.78.

This important paperback is the most comprehensive study of idiopathic ischaemic necrosis of the femoral head in adults that has so far been published. It is the outcome of an international meeting in Switzerland in June, 1968, and the contributors to this book come from far and wide. The book is superbly illustrated throughout; the photomicrographs are excellent.

Every facet of ischaemic necrosis is discussed in detail. Biopsy drilling as a means of early diagnosis of idiopathic ischaemic necrosis of the femoral head is set out in an interesting and practical way.

Legg-Perthes' disease in dogs is debated. Cases of avascular necrosis of the femoral head in rheumatoid arthritis, lupus erythematosis, athrombocytosis, ankylosing spondylitis, gout, cirrhosis of the liver, and kidney transplantation are discussed.

This study of osteonecrosis seems to provide an exciting bridge between clinical orthopaedics, general metabolic abnormalities, and basic science.

Here is an intriguing book full of interesting facts and figures which should prove of interest to all practitioners and clinicians.

Gynaecological Cancer. Edited by T. J. Deeley, M.B., Ch.B., F.F.R., D.M.R.T., Cardiff. 8½ × 5½ in. Pp. 324 + xi. Illustrated. 1971. London: The Butterworth Group. £5.

This book is one of a series of volumes under the general title of 'Modern Radiotherapy'. Since the Second World War the use of radiotherapy in the treatment of various forms of cancer has greatly increased, and this is especially so in the treatment of cancer of the female genital tract.

This volume, with its nineteen chapters contributed by radiotherapists and pathologists from well-known centres in Britain, Sweden, Germany, and America, contains a wealth of information regarding the most modern methods of radiotherapy used in the treatment of gynaecological cancer. The use of hyperbaric oxygen and radiotherapy in advanced carcinoma of the cervix is discussed in detail. A chapter on the value of computers in pelvic dosimetry makes interesting reading.

All who are interested in the treatment of malignant disease of the genital tract in the female will find much of value in this book. The book is a most useful reference volume.

Nouvelle Practique Chirurgicale illustrée. Vol. 4. Edited by Jean Quénu. 10½ × 7 in. Pp. 251. Illustrated. 1971. Paris: Dion Editeurs. 50F.

The present volume is the fourth to appear in the second series of Jean Quénu's illustrated operative surgery. In it we find successively: excision of a cervical rib, Blalock's operation for Fallot's tetralogy, surgical treatment of an arteriovenous fistula, portacaval anastomosis in portal hypertension, correction of a colpocele, and Bricker's transileal cutaneous ureterostomy.

The series is probably familiar to the majority of the surgical readers: pictorial handbooks in which the consecutive stages of an operation are illustrated by serial drawings. The steps taken are small, so that the operation can be followed very easily. The drawings are perfect gems and if operating could be learned from any book this one would have to be compulsory. It can be thoroughly recommended to those preparing an unfamiliar operation, or incidentally to those preparing a demonstration. In the latter case the short introductory remarks preceding each chapter will also be of great help. The value of these books could be definitively improved by giving short bibliographies justifying the particular technique favoured.

Carcinoma of the Bronchus. Edited by T. J. DEELEY, M.B., Ch.B., F.F.R., D.M.R.T., Cardiff. 8½ × 5½ in. Pp. 358 + xi. Illustrated. 1971. London: The Butterworth Group. £7.

CARCINOMA of the bronchus is a very common condition today and the majority of cases are far advanced when they are diagnosed. This being so most cases are treated by some form of radiotherapy. This multiple-author book covers the subject of radiotherapy in cancer of the lung in a comprehensive way. The contributors mostly come from centres in the British Isles but there are also some from Holland, America, Japan, Finland, and New Zealand. The book therefore has a definite international flavour.

This book is one of the 'Modern Radiotherapy' Series, designed to give the established clinician up-to-date knowledge of advances in this field. The contributors are from groups of pathologists, cytologists, physicians, diagnostic radiologists, radiobiologists, and radiotherapists.

Mr. Cleland, the only surgical contributor, writes on the place of surgery in the treatment of cancer of the bronchus. He considers that fewer than 20 per cent of all cases are suitable for surgical excision.

The use of adjuvant chemotherapy and hyperbaric oxygen is discussed at some length. All who are concerned with the treatment of patients suffering from carcinoma of the bronchus will find much of value in this book. As a reference volume it will take pride of place.

Intestinal Absorption and its Derangements. Edited by A. M. DAWSON, St. Bartholomew's Hospital, London. 9¾ × 7½ in. Pp. 161. Illustrated. 1971. London: British Medical Journal, B.M.A. House. £2.

THIS volume contains the papers which were presented at a symposium organized by the Royal College of Pathologists and delivered in London in February, 1971.

The papers cover a wide range, from carbohydrate digestion and absorption to microbiology and immunology.

Protein, iron, fat, and salt and water absorption are all discussed at length. There is a comprehensive list of references at the end of each chapter.

This is a most useful volume for gastro-enterologists. Surgeons who are interested in ulcerated colitis and Crohn's disease will find this a valuable reference book.

Tumors of Bone and Cartilage. Vol. 5. By HARLAN J. SPJUT, M.D., Texas; HOWARD D. DOFFMAN, M.D., New York; ROBERT E. FECHNER, M.D., Texas; and LAUREN V. ACKERMAN, St. Louis. 10 × 7¾ in. Pp. 454. Illustrated. 1971. Washington: Armed Forces Institute of Pathology. No price given.

THIS atlas of tumour pathology is Volume 5 in the second series, and is devoted to tumours of bone and cartilage. A team of pathologists too numerous to mention has been responsible for this excellent book.

Nearly 500 pictures illustrate this atlas and all are of a high quality, but the photomicrographs are superb. The common tumours and the rare ones are all described. Osteoid osteoma is discussed in detail and is well illustrated. Synovial cysts and aneurysmal bone cysts are described and illustrated.

This is an excellent atlas which all pathologists and orthopaedic surgeons will want to possess. A first-class production.

Les Entretiens de Bichat 1971. Edited by P. L. CHIGOT, Trousseau, and A. BELLIN, Bichat. 8½ × 6¾ in. Pp. 408. 1971. Paris: Expansion Scientifique Française. No price given.

IN this book the papers given at the annual conference in Bichat Hospital have been gathered together. As usual there were sessions in general surgery, with eight subdivisions, radiology, gynaecology, and sundry others. As there are about 80 articles dividing 400 pages between them, each article averages a few pages. This allows for no more than rather short summaries. If there were discussions they certainly are not given. There are no illustrations and no references to the relevant literature. Consequently the group of potential buyers of this book will probably be limited to those who actually attended the conferences. In a way this is a pity, for the subjects chosen are certainly topical and cover a wide range. It seems probable that they would arouse keen interest if the nature of these articles could be changed; the great fame of some of the contributors would certainly guarantee that. As it is, the book is no more than a rudimentary attempt at recent advances in surgery and allied subjects.

An Aid to Clinical Surgery. By PETER R. SCOTT, M.B., B.S., F.R.C.S., F.R.C.S. (Edin.), F.R.A.C.S., F.A.C.S., Melbourne. 9½ × 7½ in. Pp. 324 + x, with 60 illustrations. 1971. Edinburgh: Churchill Livingstone. £4.

THIS is a useful book for the student, although its size is rather too large for comfortable reading in a chair. The text is concise and lucid and the illustrations—line drawings—are clear and informative. Much of the subject-matter is considered in relation to commonly encountered symptoms, such as upper abdominal pain, rectal haemorrhage, or nipple discharge.

The price of this book is reasonable.

Clinical Organ Transplantation. Edited by R. Y. CALNE, M.A., M.S., F.R.C.S., Professor of Surgery, University of Cambridge. 9 × 6 in. Pp. 539 + xi. Illustrated. 1971. Oxford: Blackwell Scientific Publications. £8.

THIS book is born of popular demand, for in many countries organ transplantation is becoming more common as the years go by.

Professor Calne is the right person to edit such a book as this, for his experience in kidney and liver transplantation is second to none. He has collected a band of contributors all of whom are known for their interest in the many-sided problem of organ transplantation.

The book is divided into seven parts. Part 1 deals with the general considerations, such as allograft reaction, immunosuppression, organ preservation, tissue typing, and cancer and transplantation. Part 2 is concerned with kidney transplantation, including living-donor nephrectomy, pathology, complications, long-term care and follow-up, and the results of operation.

Part 3 deals with liver transplantation, including the selection of donors, the technique of liver transplantation, haematological management, and postoperative care.

Part 4 is devoted to heart transplantation and describes the operative technique. There are less than 200 cardiac transplants reported from the world literature at the present time.

Part 5 is concerned with lung transplantation. There are far less lung transplants than heart transplants, although the first successful reimplantation of the right lung was carried out over 20 years ago. The technical problems are the main cause of a large number of graft failures.

In Part 6 other organs such as the pancreas, the endocrine organs, and the alimentary tract are considered as possible transplantable organs. Part 7 is devoted to the question of ethics, the law, and the future, and Professor Calne is at his best dealing with these knotty problems.

This volume is a practical guide to organ grafting and it will prove of great value to all those scientists and surgeons who are interested in organ transplantation.

The Polycythemic Disorders. By BARUCH MODAN, M.D., D.Ph., Tel Aviv. $9\frac{3}{4} \times 6\frac{1}{2}$ in. Pp. 177+ix. Illustrated. 1971. Springfield, Ill.: Charles C. Thomas. $26.

THIS is an important monograph which comprises a review of the aetiological, clinical, therapeutic, laboratory, and epidemiological features of the various forms of polycythaemia.

The book is divided into four parts. Part 1 is concerned with the regulation of erythropoiesis and a classification of the polycythaemic disorders. Part 2 deals in considerable detail with polycythaemia vera. The treatment of this disease is not crystallized at present. Some pathologists still believe in phlebotomy, because there are no complications. Others believe in suppression of the bone-marrow. Many substances have been advocated, including benizol, Fowler's solution, Thiotepa, uracil mustard, and Daraprim. Radioactive phosphorus has also been tried.

In Part 3 secondary polycythaemia comes under review, and Part 4 is concerned with pseudopolycythaemia and benign erythrocytosis. Special attention is paid to the nature and degree of association between polycythaemia vera and leukaemia, and to the association with other entities, particularly renal and pulmonary disorders, and benign and malignant neoplasms.

Some excellent photomicrographs are included in this volume.

The author is to be congratulated on writing this monograph because he has covered the subject of polycythaemia disorders in a most interesting way.

There is a very comprehensive list of 849 references at the end of the book.

Diagnosis and Treatment of Abdominal Abscesses. By IRVING M. ARIEL, M.D., F.A.C.S., New York, and KIRK K. KAZARIAN, M.D., New York. 9×6 in. Pp. 322+xxiii. Illustrated. 1971. Edinburgh: Churchill Livingstone. £8.

THIS book presents a comprehensive survey of the various abdominal abscesses and their treatment. The whole wide field comes under consideration, from subphrenic to pelvic abscesses.

The picture has completely changed since Barnard's classic description of the surgical aspects of subphrenic abscess in 1908. Today with the use of antibiotics, modern laboratory tests, radioactive scanning, and improved techniques the diagnosis and treatment of abdominal abscesses have vastly improved and the mortality rate is low.

The various chapters in this book deal with every facet of abdominal abscesses, including those arising from the genito-urinary tract and the female genital organs.

The pros and cons concerning the use of drainage tubes and wicks are discussed at length.

The illustrations throughout the book are well produced and informative.

A useful reference volume.

Angiography. Techniques and Procedures. By JOSEPH E. WHITLEY, M.D., and NANCY O'NEIL WHITLEY, M.D., North Carolina. Pp. 122+x. 1971. Missouri: Warren H. Green. $12.50.

TODAY angiography is one of the essential branches of special diagnostic radiology. This large monograph with an excellent atlas of clear angiograms will be most useful to all clinicians who are interested in vascular diseases or conditions. Neurosurgeons depend to a large extent on cerebral angiograms for the exact orientation of various tumour formations.

Angiography of ischaemia is an important aid in the diagnosis of diseased blood-vessels.

This monograph with its excellent angiograms will take its place as one of the essential books in any medical library.

As a reference volume it could not be bettered.

A Textbook of Nursing. A Compendium of Nursing Knowledge. Eighteenth edition. By EVELYN PEARCE. Pp. 800+xxxvii. Illustrated. 1971. London: Faber & Faber. £3.

IT is sad that Evelyn Pearce did not see this eighteenth edition published, but she died just before it came out. For nearly 35 years Miss Pearce had been concerned in teaching the principles of nursing to a large number of student nurses. Miss Pearce wrote five other books on anatomy, and instruments, and a medical and nursing dictionary. Her name was well known among the medical profession as well as by generations of student nurses.

This eighteenth edition has been entirely revised and rewritten, though the basic pattern of the book has been maintained.

An important new feature is the inclusion of thirty-eight distinguished contributors, all specialists in their particular fields.

Although this textbook does not contain a large number of illustrations, the ones that are included are excellent.

There can be no doubt whatever that this textbook will still retain pride of place in the nursing world.

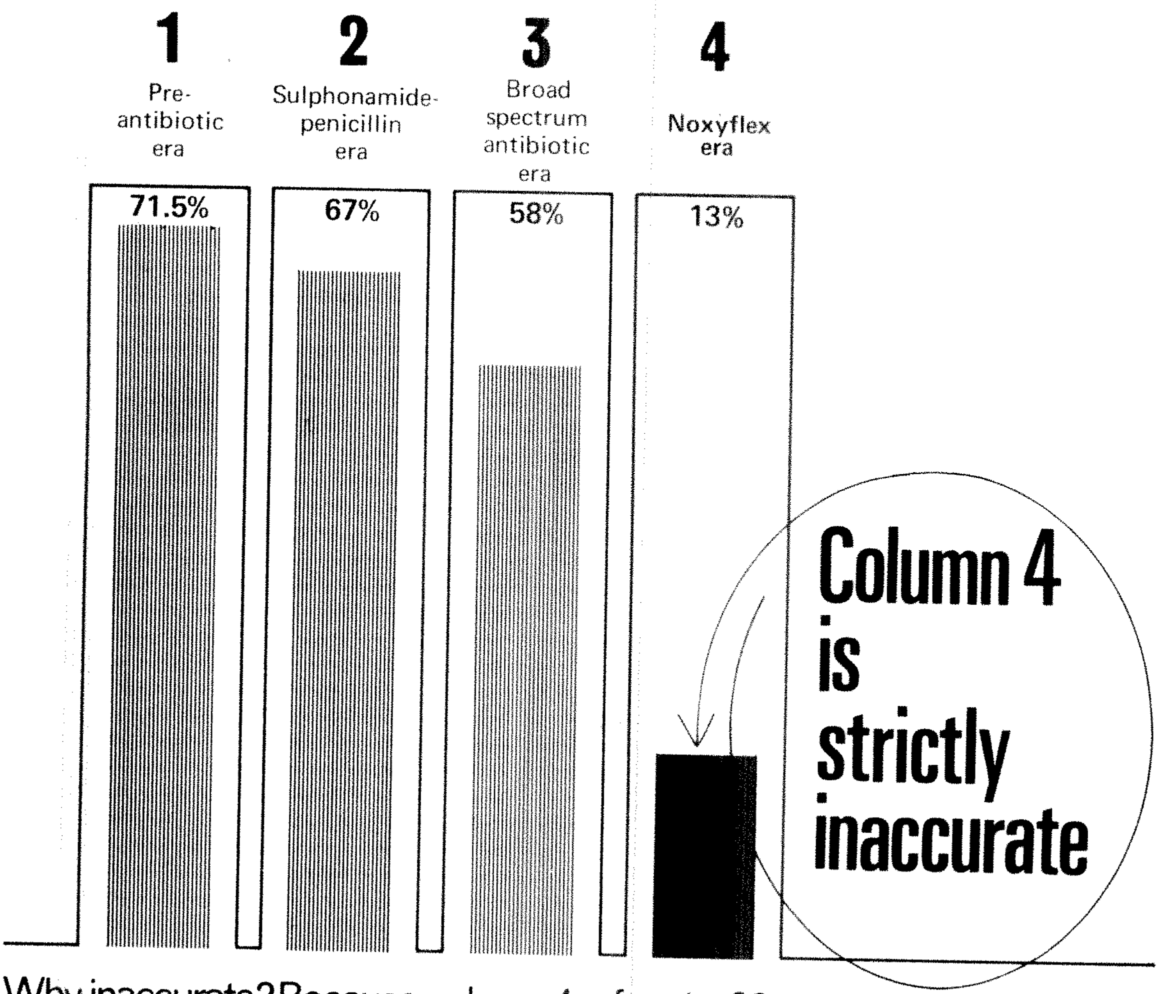
Mediastinoscopy. Edited by OTTO JEPSEN and H. RAHBEH SØRENSEN, Odense. 10×7 in. Pp. 167. Illustrated. 1971. Odense: Odense University Press. $16.50.

THIS volume contains the proceedings of an international symposium which was held at the Odense University in Denmark in June, 1970.

Mediastinoscopy was devised by Professor Carlens of Stockholm in 1959; it is a method of exploration of the superior mediastinum employing a mediastinoscope and biopsy. Its use is mainly in the assessment of resectability in cancer of the lung. It may also be used in the evaluation of sarcoidosis and carcinoma of the stomach.

This book covers the whole range of usefulness of mediastinoscopy and there is an excellent bibliography on this subject covering the years 1959–69.

The graph below compares mortality rates due to faecal peritonitis, era by era.
It is not pedantically accurate because its sources differ. But the point is fairly made.



Why inaccurate? Because column 4 refers to 23 cases of faecal peritonitis which were treated successfully with Noxyflex. But the *3 deaths which occurred were due to causes other than peritonitis - as post-mortem revealed. **The mortality rate due to peritonitis can therefore be regarded as zero.**

* The whole graph, and the causes of the deaths referred to are the subject of the new Noxyflex folder "Why three deaths?" You will receive at least one copy!

When bacterial contamination of the peritoneum is diagnosed or suspected: **Noxyflex**

Geistlich Chester

To Authors . . .

JOHN WRIGHT & SONS LTD., being Printers as well as Medical Publishers, are able to issue works on medicine and kindred sciences with unusual advantage to authors.

They are always pleased to receive for consideration manuscripts of a medical character, and these, if accepted, will be given the special care in their preparation for which the house of John Wright & Sons Ltd. is noted.

They have at their command in their modern factory the finest machinery, processes, materials, and skill essential for the perfect production of books and periodicals, and at the same time they possess every facility for introducing medical works to the Profession.

THE PARAGON
STAINLESS STEEL
STERILE
SURGICAL BLADE

STERILISED BY GAMMA RADIATION (2·5 M-RADS)

- In foil peel-pack. Pattern number clearly marked and blade shape in relief.
- Pack can be auto-claved.
- Pack can be stored in most fluids.
- Full range of blades and 6 handles available.
- One gross ready-for-use dispenser packs.

OBTAINABLE FROM YOUR USUAL SUPPLIER
Made by **THE PARAGON RAZOR CO.,** Little London Rd., Sheffield, England.

COMPUTERS IN MEDICINE

Edited by J. ROSE, *M.Sc., Ph.D., F.R.I.C., F.I.L., A.M.B.I.M., Director-General of World Organisation of General Systems and Cybernetics, Blackburn College of Technology, Blackburn.*

This symposium is devoted to recent developments in the field of medical computing and will be of interest to medical consultants, staff of clinical faculties of universities, medical practitioners; others concerned with the preparation and evaluation of data obtained in laboratories, hospitals, research centres, and in general medical practice

172 Pages 33 Illustrations **£3·00**

WRIGHTS of BRISTOL

Blood Disorders in the Elderly

By J. H. THOMAS, *M.R.C.P. (Lond.), D.C.H., Consultant Physician (Geriatric Medicine), Bridgend General and Morgannwg Hospitals; Formerly Federal Adviser, British Caribbean Territory;* and D. E. POWELL, *M.D. (Edin.), M.R.C.P. (Lond.), M.R.C.Path., Consultant Pathologist, Bridgend General and Morgannwg Hospitals; Formerly Senior Registrar, United Bristol Hospitals*

This book will be useful to senior students, membership candidates, and those dealing with sick elderly people, whether at home or in hospital. The book will help to bridge the present gap between the specialties of geriatrics and haematology, and emphasizes the close co-operation between doctors needed in the care of elderly patients.

CHURCHILL LIVINGSTONE

MANUAL OF SURGICAL THERAPEUTICS

Edited by R. E. CONDON and L. M. NYHUS

1970 *390 pages 48 illustrations*

Spiral bound **£3·25**

The authors provide comprehensive information on the diagnosis and treatment of shock, trauma, and cardiac disorders. Preoperative and postoperative care are covered in detail. Surgical infections, bacteriology, and complications are discussed with complete sections on drug usage, side effects, and administration.

EMERGENCY-ROOM CARE

Edited by CHARLES ECKERT

1972 *Second Edition 450 pages*

66 illustrations **£4·50**

This practical handbook demonstrates methods for handling a variety of emergency-room situations, from severe accident cases to psychiatric crisis. Emphasising immediate treatment and care, special discussions include methods for the logical evaluation of patient complaints and the efficient examination of findings. Step-by-step procedures for making rapid decisions for immediate treatment are also assessed.

THE MANAGEMENT OF LIVER INJURIES

J. M. LITTLE

1971 *134 pages 44 illustrations* **£2·00**

'This book is a most valuable and successful attempt to clarify a difficult field of traumatic surgery and as such should be studied by all surgeons with an interest in this field.'—*Journal of the Royal Naval Medical Service.*
'I can thoroughly recommend this very readable and excellent treatise on liver injuries as a most useful "vademecum" for all those involved in this field.'—*Journal of the Royal College of Surgeons in Ireland.*
'This is an excellent monograph on the management of liver injuries.'—*The British Journal of Surgery.*

SURGICAL DISORDERS OF THE PERIPHERAL NERVES

Sir HERBERT SEDDON

1971 *352 pages 325 illustrations* **£8·00**

The author gives a thorough and detailed account of surgical disorders of the peripheral nerves. No attempt has been made to describe the many reconstructive operations that may be required, though they are mentioned.

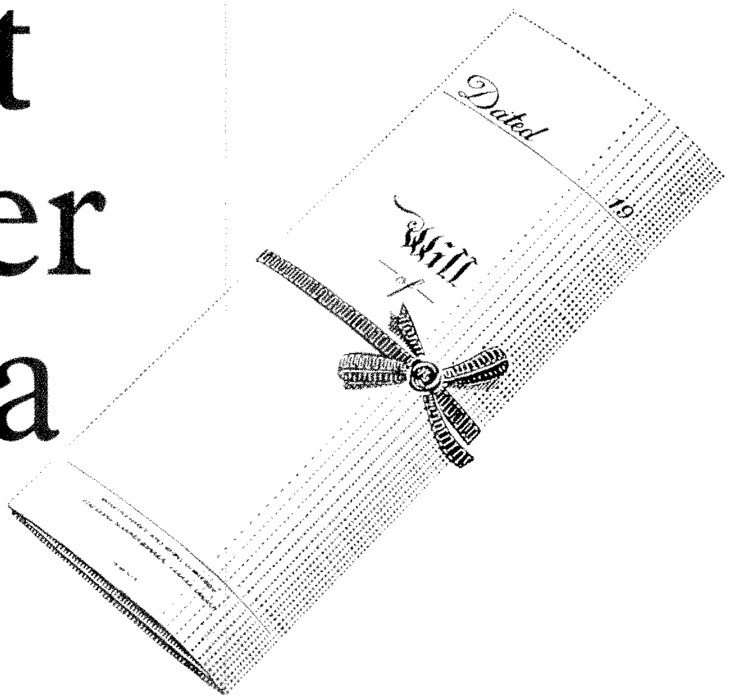
WRIGHTS of BRISTOL

Fight cancer with a will



When testators ask your advice, please remind them of the urgent work of the Imperial Cancer Research Fund. In the Fund's up-to-date laboratories trained minds are using every weapon of modern science to fight all forms of cancer, including leukaemia.

Now one of the world's great research centres, the I.C.R.F. relies entirely on public support. The cancer problem *must* be solved. Please help now.

Patron:
H.M. THE QUEEN
President:
The Honourable Angus Ogilvy

Form of Bequest

I hereby bequeath the sum of..........................pounds free of duty to the Imperial Cancer Research Fund, Lincoln's Inn Fields, London, WC2A 3PX for the purpose of scientific research, and I direct that the receipt of the Honorary Treasurer or Secretary shall be a good discharge for such legacy.

Please write for further information to: The Secretary, I.C.R.F. (Dept 164),
PO Box 123, Lincoln's Inn Fields, London WC2A 3PX

THE ENGLEWOOD HOSPITAL, ENGLEWOOD, N.J.

Straight surgical internships are offered starting July 1972 at a salary of $8220 annually (includes food allowance). Living quarters are provided for single and married interns.

Englewood Hospital is a 400-bed community hospital, twenty minutes from New York City, offering a detailed program of bedside rounds, clinical conferences and lectures.

ECFMG certification is required. Advancement is possible through subsequent AMA approved four-year residency program in surgery satisfying requirements for surgical board certification.

Interested applicants please contact:
Director of Medical Education, Englewood Hospital,
Englewood, New Jersey 07631.

DANGEROUS DRUGS REGISTER

Eleventh Edition, 1965

Designed particularly for Medical Men who dispense their own medicines. The register is used to record all Purchases, Sales, and Stocks of Dangerous Drugs. In this latest edition the number of separate sections for each drug has been increased, and the whole is thumb-indexed. The register also contains extracts giving the salient points of the Dangerous Drugs (No. 2) Regulations, 1964, together with a comprehensive list of all drugs subject to control under the Dangerous Drugs Act, 1964. **Strongly bound.**

5¾ × 8½in. **184 pp. £1·63 inclusive of p. tax.**

Are the dried and twisted intestines of a dead animal really the best material for sutures in 1972?

A DEXON suture is absorbable, inert, strong and supple. And will meet every demand you could make. This isn't surprising, as DEXON is the first and only material created in the laboratory for use as a suture.

Man-made, absorbable homopolymer of polyglycolic acid. Supplied non-needled, or on DAVIS+GECK †ATRAUMATIC needles.

After 3,500 years, don't catgut sutures belong in the museum?

Isn't it extraordinary that catgut sutures, which were used in Egypt in Tutankhamun's day, are still found in theatres in 1972?

Today, there is a scientific alternative. DEXON was created in the Davis and Geck laboratories specifically for use as a suture. It is absorbable, inert, strong and supple.

If you aren't using DEXON sutures in your theatre, shouldn't you find out about them? Before someone accuses you of living in the past.

Man-made, absorbable homopolymer of polyglycolic acid.
Supplied non-needled, or on DAVIS – GECK
†ATRAUMATIC needles.

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·10	£2·80	£3·20	£3·80	£4·30	£4·80	£5·90	£6·90
4	2·70	3·90	4·60	5·40	6·16	6·90	8·40	9·90
6/8	4·50	5·80	7·10	8·30	9·60	10·80	13·40	15·90
10/12	7·20	9·80	11·70	13·70	15·70	17·70	21·80	25·40
14/16	8·70	11·10	13·50	15·90	18·30	20·70	25·50	30·30
18/20	11·40	15·10	18·20	21·30	24·50	27·70	33·90	39·00
COVERS	1·50	2·10	2·70	3·30	3·90	4·50	5·70	6·90

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 58. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St. Martin's House,* 159 *Clapham High Street, London, S.W.*4.

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

Now, now, now, what's going on
down here?

To be precise, sir, unnecessary bleeding. That's why we're "topping him up" – he's lost a litre or more[1,2].

Transfusion is costly and not without risk. By using EPSIKAPRON, post-prostatectomy blood loss can be cut by 80 per cent or more[3,4]. Moreover, "... blood transfusions can be avoided and draining catheters kept patent without difficulty and removed earlier, which makes the post-operative course smoother and shorter"[4].

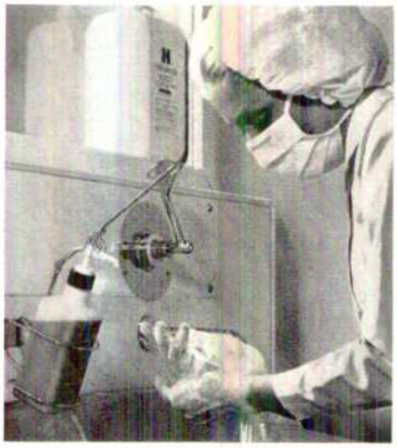
Now ICI bring to surgical scrubs the proven advantages of Hibitane in

hibiscrub

TRADE MARK



Antibacterial Activity

From the bacteriological point of view the demand is for a surgical scrub which combines maximum antibacterial activity with pronounced residual effect.

'Hibiscrub' fulfills these requirements. It is not only rapidly effective against both gram positive and gram negative organisms but also exhibits good residual activity – a major advance in the development of surgical scrubs.

Hand Care

The effect of prolonged usage on the hands of surgical staff is a critical factor in the acceptability of any surgical scrub. Sensitivity reactions, excessive detergency etc., can lead to the abandonment of certain scrub regimes.

'Hibiscrub' is positively pleasant to use – nurses using it regularly have reported on the excellent condition of their hands.

Now, to simplify treatment of pseudomonas urinary infections:

Pyopen

Penicillin safety and a published 76% success rate in 543 patients of varying renal status confirm Pyopen as a simple solution to a difficult problem.
For patients with normal kidneys 5G. 6 hourly is easily given using Pyopen infusion. For patients in renal failure or with impaired renal function a simple dosage of 2G. 8 hourly, by infusion or into the dialysate, is often sufficient.
Whether the kidneys are impaired or not, Pyopen provides the answer in pseudomonas urinary tract infections.

Adult dosage: Chronic urinary tract infection: 5G. 4–6 hourly
Acute uncomplicated infections: 2G. 6 hourly
Contra-indications: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins. In rare cases spontaneous skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen–by infusion or injection

BRL

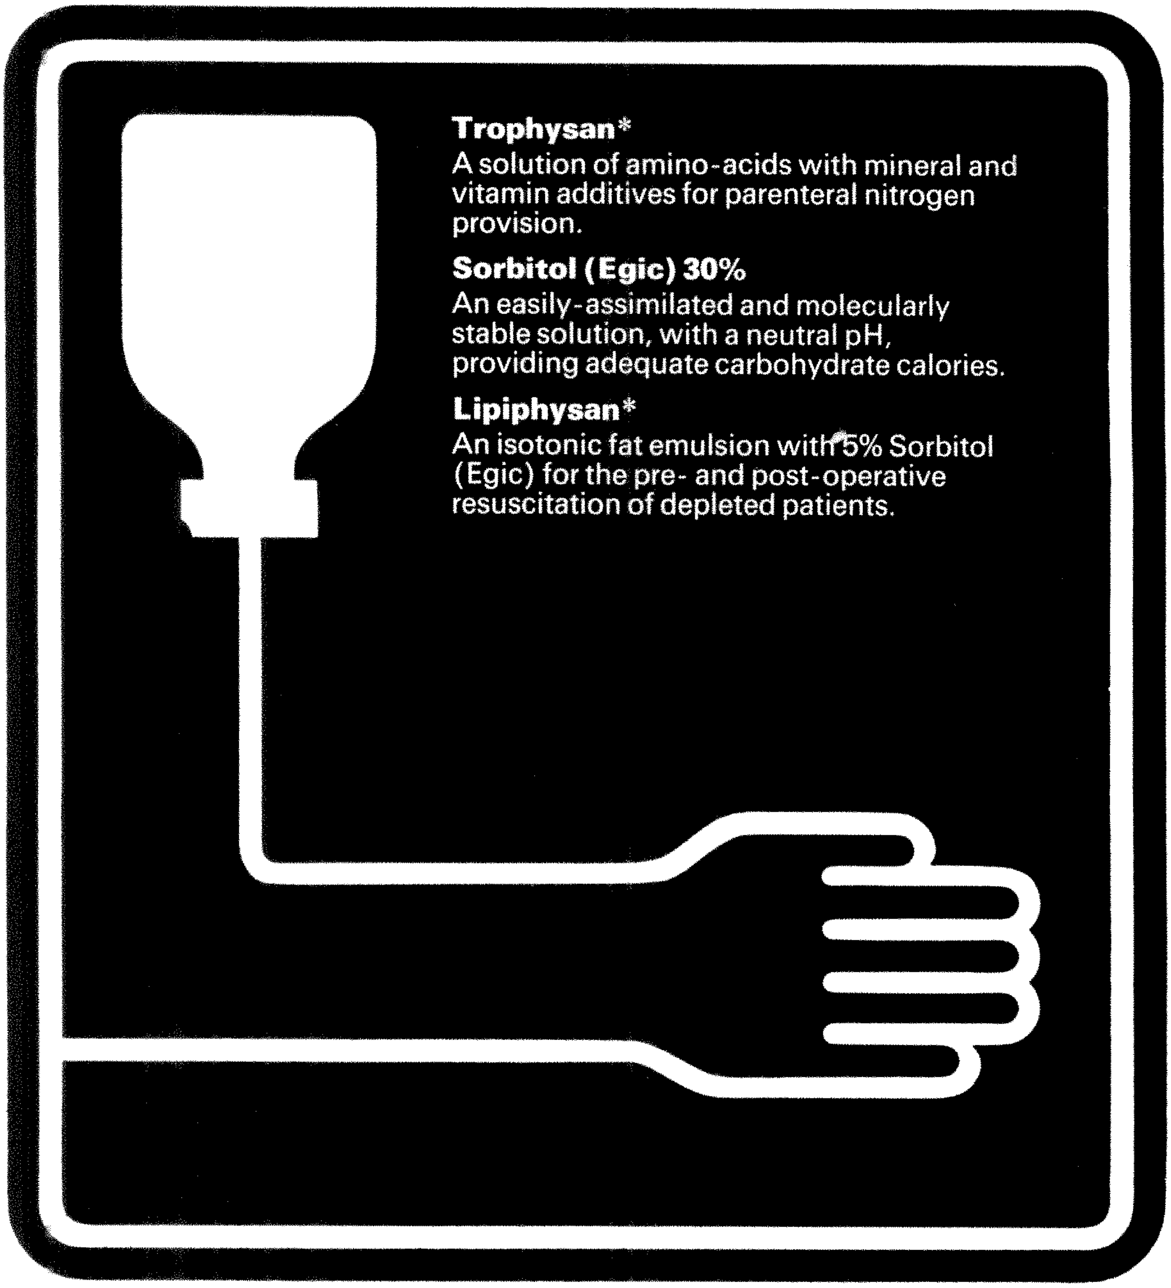
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England. *regd.

The problem of nutritional deficiency in surgery

In surgery of the GI tract the malnourished patient is a poor surgical risk. Pre-operative parenteral nutrition ensures adequate provision of nitrogen and calories and the correction of any electrolytic imbalance. This is best achieved by the use of SERVIER intravenous nutritional solutions.



Trophysan*
A solution of amino-acids with mineral and vitamin additives for parenteral nitrogen provision.

Sorbitol (Egic) 30%
An easily-assimilated and molecularly stable solution, with a neutral pH, providing adequate carbohydrate calories.

Lipiphysan*
An isotonic fat emulsion with 5% Sorbitol (Egic) for the pre- and post-operative resuscitation of depleted patients.

When nutritional deficiency is a problem, Servier has the solution.

THE
BRITISH JOURNAL OF SURGERY

Vol. 59 JUNE, 1972 No. 6

SIR CECIL WAKELEY, Bt., K.B.E., C.B.

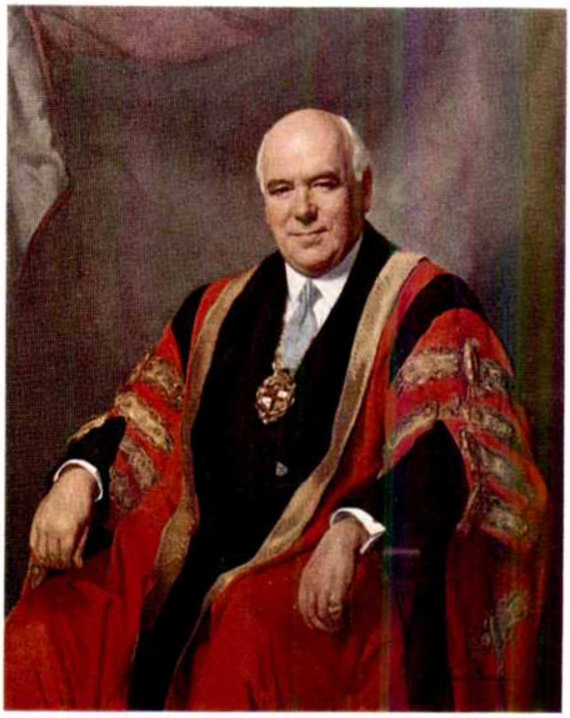
On 24 May, 1972, Sir Cecil Wakeley retired from his office as Editorial Secretary of THE BRITISH JOURNAL OF SURGERY. Some phrases are used so frequently that their meaning becomes dulled, but no alternative will suffice other than to describe this occasion as 'the end of an era'.

Mr. Wakeley was elected to the Editorial Committee in 1933 and to the Executive Committee in 1937. Surgeon Rear-Admiral Wakeley became Editorial Secretary in 1941 and now after thirty-one years the well-loved figure of Sir Cecil Wakeley, Baronet, has attended his last Executive Committee meeting.

Readers of the JOURNAL will be aware of Sir Cecil's multitudinous activities which must have absorbed much of even his indefatigable energy. These were described in a special article in the JOURNAL to commemorate a quarter of a century of service as Editorial Secretary and they need not be related again on this more sorrowful occasion. Nevertheless, the appreciation of the many high offices which he has held and the devotion which he has given to each one of them leaves the ordinary mortal with an overwhelming admiration for the dedication which his whole life has exemplified.

How, one may ask, with all these demands upon his services, has he been able to carry the immense burden which the secretaryship of the JOURNAL entails and how has he been able to do so with the impression that this was his only preoccupation and that he had no other distractions? The question is unanswerable but the facts are these: For thirty-one years Sir Cecil has visited the offices of the JOURNAL once a week and generally more often than that. Last year three hundred and seventy-five articles (more than one for each day of the year) were submitted for approval and, as was his wont, Sir Cecil read them all before circulating them to the appropriate member of the Editorial Board. Furthermore, his remarkable memory enabled him to discuss any article which he might have read some months before with comprehension and critical appraisal.

In addition to this he has taken on the sometimes tedious task of reviewing many of the books presented to the editorial office. In an average year Sir Cecil will have reviewed more than a hundred books with a clarity of perception which might well be emulated by the more discursive reviews in other journals. Last year his total was one hundred and fifty.



Photograph of the painting of Sir Cecil Wakeley which hangs in the Royal College of Surgeons of England (*painted by James Gunn in June, 1957*).

THE BRITISH JOURNAL OF SURGERY has been notable for its insistence on the philosophy of understatement rather than hyperbole and this is what Sir Cecil himself would have wished. It is in keeping with this philosophy to say that Sir Cecil will be missed. He will be missed not only because of his devotion to the duties of his office, for his undeviating service to the objectives of surgery, and his untiring activities in its interest, but because he is a friendly man of kindly understanding, a lovable man, radiating cheerfulness. From the Editorial Committee we bid farewell with grateful thanks to Cecil Wakeley—friend and counsellor.

ORIGINAL PAPERS

SIMULTANEOUS FLOW AND PRESSURE MEASUREMENTS IN INTERMITTENT CLAUDICATION

BY J. D. LEWIS, C. PAPATHANAIOU, S. T. YAO,* AND H. H. G. EASTCOTT
BLOOD FLOW LABORATORY, ST. MARY'S HOSPITAL, LONDON

SUMMARY

In a series of 12 normal and 68 atherosclerotic patients a relationship between flow and pressure changes following moderate exercise correlates well with the anatomical level of the disease. Both flow and pressure studies provide a good objective assessment of the extent of the disease and of the functional results of reconstructive surgery.

MEASUREMENTS of haemodynamic alterations of pressure and flow following exercise in patients suffering from intermittent claudication are essential in achieving a better understanding of the pathophysiology of the disease.

Resting flow values in patients with an occlusion or stenosis of the major vessels in the lower limb have been shown to be of little diagnostic or prognostic value (Landowne, 1942; Edholm, Howarth, and Sharpey-Scharer, 1951; Hillestad, 1963; Yao, Needham, and Irvine, 1970). In order to demonstrate the presence of arterial lesions it is necessary to produce a period of hyperaemia in the limb such that any factor which may limit the arterial inflow via the main vessels or through the collaterals will be revealed. This hyperaemia occurs following ischaemia or, more physiologically, following exercise which produces maximal dilatation of the muscle's intrinsic vascular bed. Reactive hyperaemia following a period of total inflow occlusion is a simple and reproducible method but has mechanical and physiological drawbacks.

The measurement of ankle systolic pressure by means of ultrasound has been shown to be a simple and safe procedure (Yao, Hobbs, and Irvine, 1968). The resting ankle pressure is reduced by the presence of occlusive arterial disease affecting the major vessels (Winsor, 1950; Strandness and Bell, 1965; Carter, 1968; Yao, Hobbs, and Irvine, 1969). This fall of pressure is related to the severity of the disease process (Sumner and Strandness, 1969; Yao, 1970). Furthermore, post-exercise pressure changes are directly related to the severity of the disease and these changes are reproducible (Yao, 1970).

Reliability of measuring muscle blood-flow using the ^{133}Xe-clearance technique has been well established (Lassen, Lindbjerg, and Munck, 1964; Lindbjerg, 1967). Changes in post-exercise clearance have been demonstrated to correlate with the anatomical level and the severity of the occlusive process.

The present study was designed to investigate the relationship between flow and pressure changes occurring in normal limbs and in the limbs of patients who experience intermittent claudication following moderate exercise. The changes of pressure and flow were recorded simultaneously using the Doppler ultrasound and ^{133}Xe-muscle-clearance methods. An indication of the value of objective assessment following reconstructive surgery will be demonstrated. These pressure/flow changes will also be correlated with the anatomical level of the disease.

Table I.—PATIENTS STUDIED GROUPED ACCORDING TO THE ARTERIOGRAPHIC EVIDENCE OF THE LEVEL OF DISEASE

Patients and Level of Disease	*No. of Limbs*
Normal adults (age 30–80 years)	12
Patients with atherosclerotic arterial disease	
Superficial femoral artery	14
Femoropopliteal artery	16
Isolated iliac artery	7
Multiple-segment disease	17
Pre- and postoperative studies	14
Total	80

MATERIALS

Eighty limbs of 75 patients were studied. Twelve limbs were normal and had neither clinical nor ultrasound evidence of arterial disease in either limb. The age range was 30–80 years. The other 68 limbs were of patients who presented with intermittent claudication and were classified according to the anatomical level of the disease as determined by arteriography. A further group of patients who were undergoing reconstructive surgery was examined both before and after operation. *Table I* tabulates the number of limbs according to the anatomical level of the lesion.

METHODS

1. Doppler Ultrasound.—A transcutaneous flow-velocity meter (Parks Doppler Model 806) was used as in the technique described by Yao and others (1969). By placing the flow probe over the dorsalis pedis or posterior tibial arteries a sphygmomanometer cuff was applied just above the ankle. During deflation of the cuff the return of the flow signal indicated the level of the systolic pressure at the ankle.

---

[*] Present address: Department of Surgery, School of Medicine, Wayne State University, Detroit, Michigan, U.S.A.

A pressure index was obtained by comparing the ankle and brachial pressures.

2. ^{133}Xe Muscle Clearance.—Muscle bloodflow was measured using the ^{133}Xe-clearance technique as described by Lassen, Lindbjerg, and Dahn (1964); 0·5 mc. of ^{133}Xe dissolved in isotonic saline was injected into the centre of the lateral head of the gastrocnemius muscle of the limb under study, the site having been defined by palpation with the muscle actively contracted. Clearance of the isotope was measured with the Pitman 235 isotope localization monitor. The scintillation probe fitted with a shield was centred over the injection site and was just in contact with the limb but did not distort the skin. Its position was marked for ease of probe replacement. The probe was supported in a clamp and counting could be carried out both in the upright and horizontal positions.

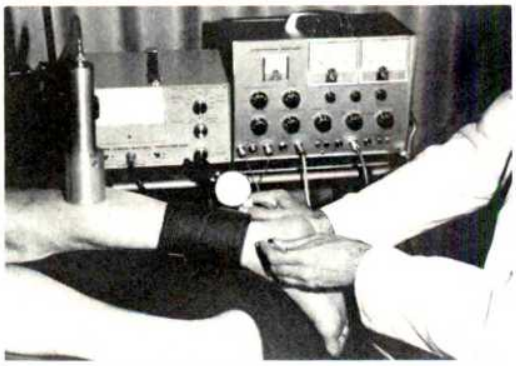


FIG. 1.—Technique of patient monitoring using ultrasound and a Pitman ratemeter.

The particular feature of the ratemeter used was the provision of a percentage scale. Thus, having obtained an initial reading in counts per second, it was possible to adjust the ratemeter so that this count corresponded to 100 on the percentage scale, this then being taken as the starting point for the resting count. The maximum counting rate was 3000 counts per second with time constants of 2 and 12 seconds. Counts were recorded on a linear scale and curves of clearance were drawn.

All patients rested in a supine position for a period of half an hour before any recordings were made. An initial count in counts per second was obtained and converted to 100 on the percentage scale; 4–5 minutes of the resting count were then recorded. The count rarely dropped below 98 per cent, and during this period the resting pressure was also measured. A standard exercise test was used employing a treadmill (Jaeger-Ergotest) without incline set at a constant speed of 4 km. per hour and subjects walked to their maximum walking distance, i.e., the point at which they were forced to stop because of claudication, or they were stopped at 5 minutes.

On completion of the exercise the subjects returned to the supine position. Readings were obtained within a few seconds of stopping the exercise. Recording of ankle systolic pressure was performed simultaneously with muscle clearance until both returned to the pre-exercise level. *Fig.* 1 demonstrates the arrangement of the apparatus.

RESULTS

In all the normal limbs at rest the ratio of the ankle to brachial pressure was equal to or greater than 1; in all the limbs with evidence of arterial disease the ratio was less than 1.

To correlate with the changes of percentage of muscle clearance the ankle-pressure changes were also expressed as a percentage of the resting pressure. The clearance curves were plotted on a linear scale; absolute flow values have not been calculated. *Fig.* 2 demonstrates a typical curve obtained from a normal limb. The ankle pressure showed no change or only a small initial rise following exercise. The Xe-clearance curve showed that during the period of moderate exercise 80 per cent or more of the injected dose was cleared from the muscle and that little further clearance at the end of the exercise period occurred. The curve reached a resting state within 2 minutes in all the normal limbs which were studied.

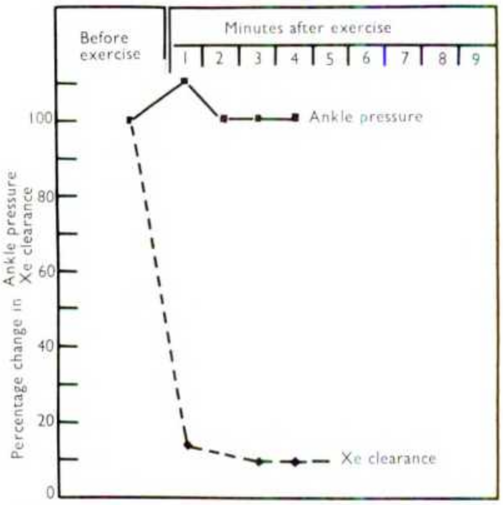

FIG. 2.—Curves showing percentage ankle-pressure change and Xe clearance following 5 minutes' exercise in a normal subject (*Case* R. L., aged 65 years; branchial pressure, 140 mm. Hg; ankle pressure, 140 mm. Hg; initial count, 2400 counts per second; maximum walking time, > 5 minutes).

In all the cases where occlusive arterial disease was present the resting ankle pressure was less than the brachial pressure. Following exercise the Xe-clearance and the ankle-pressure changes departed from the normal pattern. Different types of pressure/flow patterns were observed. When the disease involved a single segment such as a superficial femoral artery occlusion of long duration the changes from normal were only slight. However, when the disease was of recent onset these changes were characterized by a drop of 50 per cent following exercise with recovery to the resting level after 6 minutes. Clearance was reduced to 50 per cent of the resting level during the period of exercise and a further 20 per cent decrease occurred in the next 3 minutes; there was a period of continued hyperaemia before the rise of ankle pressure (*Fig.* 3). A similar situation was seen with an isolated iliac artery lesion (*Fig.* 4).

The flow and pressure patterns obtained from patients with two segments of disease showed more pronounced changes in both parameters (*Fig.* 5). In the presence of femoropopliteal arterial disease the pressure dropped to 40 per cent of the resting level and remained low for a period of 3 minutes, returning to the resting level 8 minutes after exercise. The clearance of Xe during the exercise period (lasting for 5 minutes) was much reduced, 85 per cent remaining at the end of walking, and then there was a period of rapid clearance which lasted for 8 minutes. Again the maximum clearance occurred before the ankle pressure began to return to the pre-exercise level.

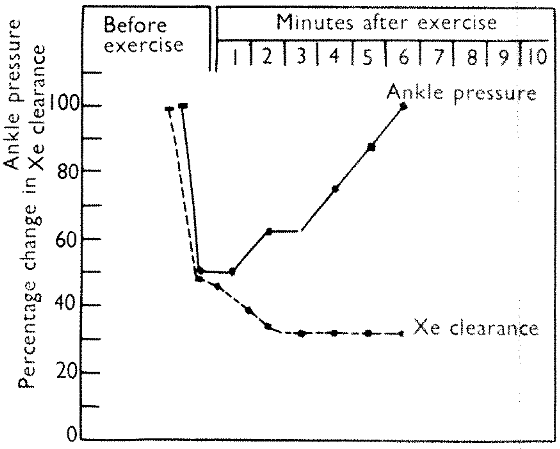

FIG. 3.—Clearance and pressure curves in single-segment disease (*Case* J. S., with a short history of left superficial femoral occlusion; brachial pressure, 120 mm. Hg; ankle pressure, 80 mm. Hg; initial count, 2800 counts per second; maximum walking time, 3 minutes).

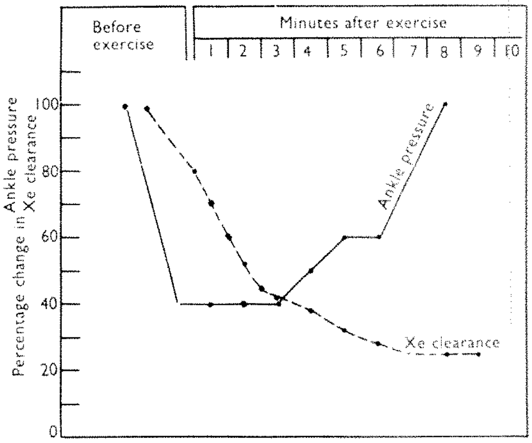

FIG. 5.—Clearance and pressure curves in double-segment disease (*Case* F. D.; left femoropopliteal occlusion; brachial pressure, 180 mm. Hg; ankle pressure, 100 mm. Hg; initial count, 2100 counts per second; mamxium walking time, 5 minutes).

An example of multiple-segment disease where the more severe clinical disability is reflected in the objective measurements is shown in *Fig.* 6. Not only was the maximum walking time reduced markedly but also a greater pressure gradient was seen between the ankle and brachial levels. The pressure dropped to zero after exercise and remained so for 4 minutes and the recovery time was prolonged. At the same time there was minimal clearance of Xe in the initial period followed by a prolonged post-exercise hyperaemia with a return to the resting level 14 minutes after walking had ceased. A similar reciprocal relationship between the Xe-clearance curve and the recovery of ankle pressure was present as seen in the preoperative tracings in *Fig.* 7, where the clearance again increased before there was any marked rise of ankle pressure.

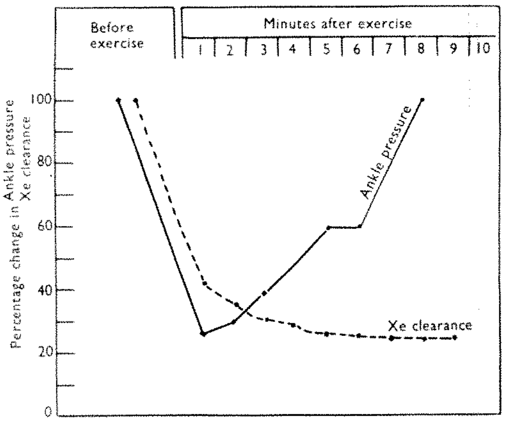

FIG. 4.—Clearance and pressure curves in single-segment disease (*Case* I. M.; left iliac stenosis; brachial pressure, 110 mm. Hg; ankle pressure, 80 mm. Hg; initial count, 2000 counts per second; maximum walking time, 5 minutes).

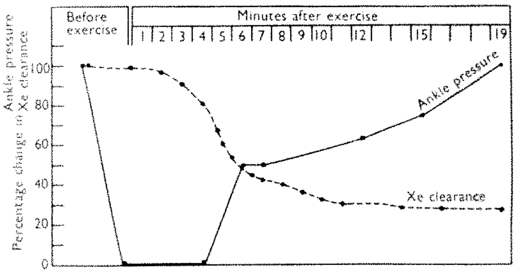

FIG. 6.—Clearance and pressure curves in multiple-segment disease (*Case* E. F.; left common iliac occlusion and superficial femoral artery stenosis; brachial pressure, 140 mm. Hg; ankle pressure, 40 mm. Hg; initial count, 2900 counts per second; maximum walking time, 1 minute).

Both methods provided good objective assessment of the results of surgical treatment of arterial disease. *Fig.* 7 demonstrates the clearance and pressure changes before and after reconstructive surgery in a patient with aorto-iliac occlusion. The preoperative curves indicated moderate disease with delayed recovery of both indices. After successful aorto-femoral artery bifurcation grafting the pressure/flow pattern had reverted to normal. *Fig.* 8 shows the results obtained in a patient with severe two-segment disease which was converted to a single-segment lesion by surgery. The patient had an iliac artery occlusion plus a femoropopliteal artery occlusion and the inflow was increased by insertion of a femoro-femoral cross-over graft which resulted in marked subjective improvement. This was confirmed by the improvement of the pressure and flow patterns although some impairment remained. The benefit of changing a multiple lesion to a single lesion is well documented by these studies.

Fig. 9 demonstrates the distribution of the Xe-clearance patterns according to the anatomical level of the disease.

DISCUSSION

In the normal limb the blood-flow through muscle tissue during a period of moderate exercise is such that there is a minimal post-exercise hyperaemia and little or no change in the distal pressure. Normally a slight increase is seen. These facts were confirmed by the Xe-clearance curves and ankle-pressure patterns obtained in the normal subjects in this study. Maximum clearance occurred during the exercise period with minimal post-exercise hyperaemia and the resting level was reached within 2 minutes. These findings confirm that muscle blood-flow is always adequate during a period of moderate exercise in normal limbs.

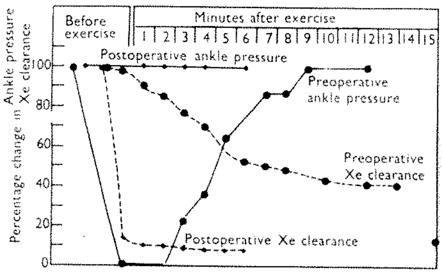

FIG. 7.—Pre- and postoperative curves showing reversion to a normal pattern following an aortofemoral bifurcation graft (*Case* F. A.; aorto-iliac disease corrected with an aortofemoral bifurcation graft. Before operation: brachial pressure, 160 mm. Hg; ankle pressure, 80 mm. Hg; initial count, 2800 counts per second; maximum walking time, 1 minute 15 seconds. After operation: brachial pressure, 150 mm. Hg; ankle pressure, 150 mm. Hg; initial count, 2800 counts per second; maximum walking time, 4 minutes).

In the presence of arterial occlusion an increased resistance to flow is present. Flow in the limb during or after exercise is distributed inversely according to the resistance: maximum resistance to flow is provided by an occlusion in the major artery; minimal resistance occurs in the muscle bed proximal to the diseased segment. With the demand by the proximal exercising muscle the resistance is lowered so that there is a fall of the distal pressure. Patients with a single anatomical level of occlusion in this study all showed a fall of distal ankle pressure together with a reduced muscle clearance of 50 per cent. When there are two anatomical levels of occlusion the picture becomes more complex. Following exercise, blood-flow has to traverse two collateral networks which have a relatively high resistance to flow as compared with the normal inflow tract. A profound drop of ankle systolic pressure and cessation of muscle clearance in the initial period were the common findings. This pattern invariably indicates the presence of severe arterial insufficiency.

The method of measuring muscle blood-flow using ^{133}Xe clearance has been widely applied for studying the effect of occlusive vascular disease affecting the lower limb (Lassen and others, 1964; Lassen and Kampp, 1965; Lindbjerg, 1965, 1967). The method has shown good correlation with venous occlusion plethysmography and with direct blood-flow measurements in the isolated gastrocnemius muscle of the cat (Lassen and others, 1964; Prerovski, Kjellmer, Tonnesen, and Lindbjerg, 1967). Using the ^{133}Xe-muscle-clearance method Alpert, Larsen, and Lassen (1968) were able to show a similar ability to distinguish between single- and multiple-segment disease by using the clearance patterns obtained following exercise. The changes of ankle systolic pressure measured by digital plethysmography in patients with occlusive arterial disease have also been reported by Strandness and Bell (1965).

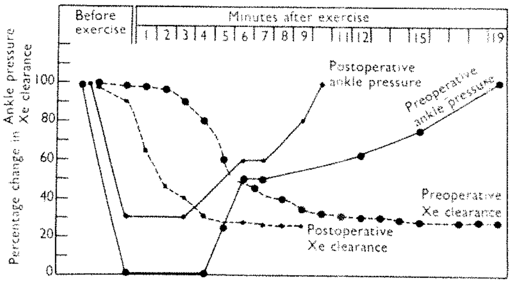

FIG. 8.—Pre- and postoperative curves with single-segment correction in double-segment disease (*Case* E. F.; details of the preoperative state are shown in *Fig.* 6. After a femorofemoral cross-over graft: brachial pressure, 140 mm. Hg; ankle pressure, 100 mm. Hg; initial count, 2700 counts per second; maximum walking time, 4 minutes).

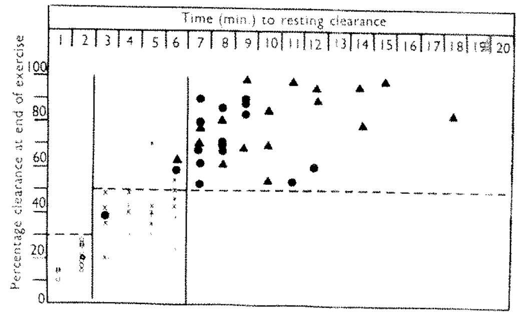

FIG. 9.—Distribution of Xe clearance related to the anatomical level of disease: ×, superficial femoral; i, isolated iliac; ●, femoro-popliteal; ▲, aorto-iliac; ○, normal limb.

The present study has demonstrated the relationship between Xe clearance from the calf and the ankle-pressure changes occurring in the lower limb using two independent techniques but measured simultaneously. Previous work (Yao, 1970) has shown the ability to separate normal legs from those with single- and multiple-segment disease using the ultrasound technique to measure ankle pressure alone before and after exercise. The present work has shown that there is also a good correlation between the clearance patterns using radioactive Xe and the anatomical levels of the disease, with clear distinctions between normal legs, and those with single- and multiple-segment disease. In patients with intermittent claudication this shows that progressively less flow occurs during the exercise period, as represented by the percentage clearance of Xe at the end of this period, and that with more extensive disease the onset of the hyperaemia becomes increasingly delayed and of greater duration. When there was extensive disease the flow was grossly inadequate, sometimes ceasing, and the subsequent recovery was very delayed. The relationship between calf Xe clearance and ankle pressure following exercise is constant and reproducible. In the presence of a stenosis or occlusion there was a fall of both flow and pressure distal to the lesions following a period of exercise. The magnitude of such a fall in both parameters was related to the anatomical level and to the extent of the disease process, being least in single-segment disease and more pronounced as the number of segments involved increases or the disease extends proximally. With extensive disease there is little or no clearance from the calf muscle during or for some minutes after the cessation of exercise, this being associated with a profound and prolonged drop in ankle pressure. The converse is seen in localized disease.

The sequential relationship between flow in the calf and pressure at the ankle following exercise in claudicants has recently been studied by Sumner and Strandness (1969) using venous occlusive plethysmography. Distal pressure measured simultaneously at the ankle by a strain gauge placed around the toe was found to have an inverse relationship with the calf blood-flow. Three types of pressure and flow patterns were obtained which correlated well with the anatomical level and severity of the disease. As in their study an inverse relationship between pressure and flow was also demonstrated in the present report. The onset of maximum clearance (being directly related to the maximum hyperaemic flow) appeared to commence and reach the maximal level before any appreciable rise in ankle pressure occurred. Thus the changes in the two parameters are related to each other and in the same way to the extent of the disease process.

Successful reconstructive surgery converts these clearance patterns to normal and is an indication of the value of this method for assessing the results of surgery. It is apparent that useful information about the effect of the arterial lesion may be obtained from the study of the clearance curves without the need for the measurement of absolute flow values. Because of the simplicity of the Doppler ultrasound method and its close relationship with muscle clearance the Doppler ultrasound method of measuring systolic pressure would appear to be the method of choice as a non-invasive technique to study the functional status of the occlusive process.

ATROPHY FOLLOWING TESTICULAR TORSION

By JAMES A. BURTON

MEDICAL OFFICER, STUDENT HEALTH SERVICE, UNIVERSITY OF SHEFFIELD

SUMMARY

A personal series of 17 cases of torsion of the testis collected over a 3½-year period is reviewed. The incidence is seen to be low in the general population but misdiagnosis is common in the acute condition. The relevant embryology, histology, and signs and symptoms of the condition are described. A number of the patients had unilateral testicular atrophy following a previously misdiagnosed torsion years earlier. Their subsequent management is described. The differential diagnosis is briefly mentioned.

Surgical textbooks would have us believe that torsion of the testis is not a common condition. Indeed, Wheeler and Clark in 1952 collected only 9 cases out of 40,000 admissions to an American hospital. In a further study of 100,000 admissions to a general hospital over a 13-year period only 10 cases of torsion were seen and treated. Reviews from this country would suggest a higher incidence than this and it would perhaps be more correct for the textbooks to state that the condition is fairly uncommon but is much more likely to be incorrectly diagnosed than correctly diagnosed and treated. The situation is really quite serious, for if the condition is not recognized for what it is at the first consultation it may well be too late to initiate effective treatment at the second or subsequent consultation even if it is then recognized. In one of the studies mentioned previously the time at which hospital presentation was made ranged between 24 hours and 6 months, i.e., in all cases the condition had been present certainly longer than 20 hours.

Over the past 3½ years, both in hospital and student health practice, I have been impressed by the number of times that I have seen the acute condition incorrectly diagnosed and also by the results of misdiagnosis years previously in men with unilateral testicular atrophy. As medical officers to a student health service of 5500 students, we have an annual intake of some 1500 new students, about 70 per cent of whom are male. The students register with us as their general practitioners and we therefore receive their National Health Service record from the family doctor. We thus draw on this large number of practices from all over the country each year. We do not undertake routine medical examination of all new students and the real incidence of atrophy following torsion in this population is therefore unknown. From the figures quoted previously it will be apparent that the number of cases of testicular torsion that any one general practitioner may see in a year or even in a lifetime of practice will be very small. This preamble might serve to explain the origin of the cases presented here.

The condition of torsion was first described by a Frenchman, Delasiauve, in 1840, who found gangrenous changes in an undescended right testis which he had mistaken for a strangulated hernia. At operation he noted that the blood-supply to the testis had been compromised by the torsion of the cord. The condition was first described in this country some 50 years later (Nash, 1893).

EMBRYOLOGY

It may be helpful at this stage to review the relevant embryology since this will help in understanding the condition and the rationale of its treatment.

Between the third and ninth months of foetal life the retroperitoneal testis descends from a lumbar to a scrotal position and follows the preformed pathway of the processus vaginalis through the anterior abdominal wall into the scrotum.

During its entire descent it lies dorsal to the posterior peritoneum of the abdominal cavity and the processus vaginalis but ventral to the posterior lining fascia of the abdominal cavity. The descent occurs as a result of (1) differential growth at various levels of the trunk, (2) actual descent, and (3) pull on the inferior pole by the gubernaculum.

On reaching the scrotum it is usually held firmly by the scrotal ligament, which is the remnant of the gubernaculum. Most of the testis becomes surrounded by the tunica vaginalis, but the posteromedial portion remains outside the sac and becomes adherent to the scrotal septum by means of loose areolar tissue. This forms two stabilizing attachments: the scrotal ligament and the extravaginal testicular attachment to the scrotal septum.

Torsion in the normally related testis therefore rarely occurs. The mesorchium is the posteromedial extravaginal attachment of the testis to the scrotal septum. It contains the blood-vessels and the vas deferens. It extends from the superior pole of the testis to approximately 2 cm. from the inferior pole. The tail of the epididymis is usually a part of the mesorchium and therefore has tunica vaginalis on only a portion of its anterior surface. It has been shown that when torsion occurs the tunica vaginalis invests not only the testis but also the epididymis and the spermatic cord above the attachment of the cord to the testis. This condition is usually found on both sides.

Anatomically, the causes of torsion are:—

1. An unusually capacious tunica vaginalis.
2. Absence of the gubernaculum testis and a posterior mesorchium.
3. Absence of the scrotal ligament.
4. Abnormal length and loose attachment of the intravaginal portion of the cord.
5. A combination of these anomalies with imperfect testicular descent.

A review of the literature reveals that 90 per cent of the patients with torsion of the testis lose the testis: 80 per cent by orchidectomy and 10 per cent by subsequent ischaemic atrophy. The main reason for this excessive wastage is delayed or incorrect diagnosis. This is certainly confirmed by the present series.

HISTORY

In the acute episode there is a sudden onset of severe testicular pain. In most acute cases there is a history of recurrent testicular pain, not of such severity as in the acute episode but affecting the same side, and this is probably due to self-limiting, incomplete torsion previously. Urinary symptoms are usually absent. The patient may present with a history of recurrent pain when actually free from discomfort and it is important to diagnose correctly the origin of the pain if the acute episode is to be avoided later.

SIGNS AND SYMPTOMS

The testis of the affected side is usually drawn up towards the inguinal canal and will be tender to a variable degree.

A diagnostic physical sign in recurrent cases is a transversely lying testis when the patient is examined standing up. In the acute case, if the patient is examined standing the testis of the other side will probably be found to be lying transversely also. The onset of the pain may be related to varying degrees of trauma, riding a bicycle, or falling in the bath, or may awaken the patient from sleep. Determination of the position of the epididymis may be helpful. In torsion it will usually be found in some position other than the posteromedial position in relation to the testis. Elevation is said to accentuate the pain in torsion and to relieve it in epididymitis (Prehn's sign). The pain may be cited as being in the scrotum or may be experienced as referred pain along the ilio-inguinal nerve distribution. This is particularly important to recognize in intermittent cases as this seems to be one of the clues to the correct diagnosis which is frequently misinterpreted. The pain is usually very severe and is of sudden onset. It becomes more severe and within an hour or so the testis starts to swell and the scrotum of the affected side becomes red and oedematous. This is the most misleading of all the physical signs and gives rise to the most frequent diagnosis of epididymitis. Interestingly, the longer the torsion is not recognized the more it comes to look like an epididymitis, which lulls the doctor into a false sense of security. He thus exhibits antibiotics and waits. This is then the beginning of the end as far as the testis is concerned. After several hours the patient usually develops a low-grade pyrexia which again falsely confirms the doctor's suspicions of an infection. In some of the cases of proved torsion that I have seen there has been pyuria and microscopic haematuria in a sterile urine. In 2 acute cases there was also an acute mucoid urethral discharge, probably a feature of congestion. Dysuria and frequency, however, were not present except in 1 case during the acute episode.

THE MECHANISM OF TESTICULAR INFARCTION

Ormond (1938) showed that the first effects of rotation of the testis are flattening of the veins of the cord and partial obstruction of the venous return; then as the rotation continues there is obliteration of the veins followed by obliteration of the artery. The effect on the testis depends on the degree of rotation. If there is incomplete obliteration there will be congestion and oedema, especially of the epididymis which is more distensible than the testis. If venous return is entirely obstructed congestion is greater and necrosis occurs in a short time. Prompt infarction occurs if the artery is obliterated.

Dog experiments have shown the following results:—

1. Spermatogenic cells were slightly damaged after 2 hours, severely damaged after 4 hours, and eliminated after 6 hours of ischaemia.
2. Leydig cells were severely damaged after 8 hours of ischaemia and eliminated after 10 hours.
3. Ten hours or more of ischaemia resulted in nearly complete fibrotic replacement of the testis.

At this point it should be recalled that the time of presentation at hospital of the cases quoted previously ranged between 24 hours and 6 months.

The following are summaries of the case histories in the present series. The first 8 cases are of acute torsion seen in both hospital and student health practice, the remainder being non-acute problems at the time seen.

CASE REPORTS

Case 1.—J. K., aged 15 years. This patient presented complaining of sudden onset of left testicular pain 3 hours previously whilst in bed. He had a 6-month history of intermittent pain on the same side which had been presented to the doctor but had not been recognized. On examination acute torsion was present and was manipulated. Bilateral fixation was done later.

Case 2.—R. H., aged 19 years. This patient presented complaining of sudden onset of left testicular pain 1 hour previously following a fall in the bath. On examination he had a very swollen, red, tender scrotum requiring intravenous morphine to allow palpation. The testis was very high in the scrotum. It was manipulated with immediate descent and relief of the pain. The testis was normal the next morning apart from a small secondary hydrocele. The patient was readmitted later for bilateral fixation.

Case 3.—K. D., aged 23 years. This patient was admitted complaining of right testicular pain of 1 hour's duration. A twist could be felt in the cord and this was manipulated. The patient subsequently had bilateral fixation.

Case 4.—T. L., aged 16 years. This patient was seen 6 hours after he had experienced acute onset of left testicular pain whilst standing at a bus stop. The testis was manipulated and subsequently both sides were fixed. A large mesorchium was found at operation.

Case 5.—C. B., aged 21 years. This patient presented complaining of left testicular pain of 36 hours' duration. The testis was manipulated and subsequently fixed. The patient emigrated 6 weeks later so that no follow-up has been possible.

Case 6.—R. N., aged 22 years. This patient developed acute right testicular torsion whilst on teaching practice. He was taken to hospital where he was given paracetamol and ampicillin and sent home by ambulance. *En route* the pain became worse and he was seen 3 hours after onset when the testis was manipulated and subsequently fixed. Urine examination at time of the acute episode showed: epithelial cells, +; leucocytes, ++; red blood-cells, +; hyaline casts, +; the urine was sterile on culture.

Case 7.—A. B., aged 20 years. This patient had experienced sudden onset of left testicular pain 4 hours previously. On examination there was a tender swelling at the upper pole of the testis. This was clinically diagnosed as a torsion of the hydatid of Morgagni, which was proved at operation.

Case 8.—D. H., aged 17 years. This patient presented complaining of sudden onset of right testicular pain 4 days previously. This had been treated at this time as an infection. On examination a very swollen and oedematous scrotum was seen. The patient had a temperature of 37° C. on admission. At operation the testis was necrotic and was removed. The other side was fixed.

Case 9.—C. H., aged 20 years. This patient presented with a history of intermittent right testicular pain over the previous 4 years. On examination both testes were found to be lying transversely. These were fixed and there has been no further pain.

Case 10.—I. F., aged 20 years. This patient presented with a history of intermittent left testicular pain, the right testis having become atrophic following a 'right epididymitis' at the age of 15 years. The remaining testis was lying transversely and was fixed. There has been no further pain.

Case 11.—J. C., aged 24 years. This patient presented complaining of intermittent right testicular pain for 6 months. The left testis was atrophic and the right side was fixed as this was lying transversely. There has been no further pain.

Case 12.—J. S., aged 21 years. This patient presented complaining of intermittent left testicular pain on walking for 3 weeks. The pain was referred along the ilio-inguinal nerves and disappeared on lying down. The testes were lying transversely and he has had no further pain following bilateral fixation.

Case 13.—B. M., aged 21 years. This patient presented with right testicular atrophy following 'epididymo-orchitis' at 15 years. The patient was seen on the third day of the episode at hospital where this diagnosis was again made. Examination showed a transversely lying left testis which had not been fixed. This was then done.

Case 14.—J. H., aged 22 years. This patient presented complaining of left testicular pain following a vacation job which had involved lifting. No hernia was present. The right testis was atrophic following a torsion at the age of 13 years which had been diagnosed as such and had been treated conservatively. It had been hoped 'that the resolution of his large hydrocele would fix the testicle to the scrotum to prevent a recurrence'. The left testis was fixed urgently at the age of 22 years.

Case 15.—M. P., aged 22 years. This patient presented with right testicular atrophy. He had had a painful swelling of the right testis at the age of 14 years and had been given chloramphenicol. He had then developed some dysuria and had been sent to hospital where it was thought that he had a 'cellulitis of the scrotum' and chloramphenicol had therefore been continued for a further 5 days. When next seen 10 days after the onset, the swelling had become much larger. The swelling had then been aspirated but no fluid had been obtained. Subsequently it had been incised, when again no fluid had been found. The patient had been readmitted 10 days later for exploration when a necrotic testis had been found and removed. The correct diagnosis had then been made and it had been suggested that he should wait and see if pain developed on the other side and if it did, he should be admitted urgently for fixation. He had had no pain, but underwent prophylactic fixation the week after he had been seen on the present occasion.

Case 16.—J. L., aged 21 years. This patient complained of intermittent left testicular pain over a 2-year period and was found to have bilateral transversely lying testes which were subsequently fixed at operation.

Case 17.—D. A. B., aged 19 years. This student complained of a painful swollen right nipple of sudden onset. He had a tender subareolar plaque. On questioning about testicular swelling he said he had not noticed any since he had had 'orchitis' at the age of 16 years. He now has an atrophic right testis, and a transversely lying left testis. The diagnosis in hospital at that time had been 'non-specific orchitis' and it had been hoped that it would settle on antibiotics. This was undoubtedly a missed torsion.

DISCUSSION

In Angell's (1963) series of 16 acute cases all had a fever which ranged from 36·7° C. (99° F.) to 39° C. (103° F.). Dysuria and urethritis were absent in all the cases. In only 2 acute cases in the present series where the testes were necrotic was a fever seen (*Cases* 8, 15). In 1 case there was a history of dysuria and this was only in the acute episode (*Case* 6). In the acute cases a mucoid discharge commonly appeared at the urethral meatus and this was probably a congestive effect.

In Angell's (1963) series those cases that were admitted with 'epididymitis' and subsequently were seen to have torsion were 7 in number. These had the urine cultured, only 1 of which contained pus cells, and all the specimens were sterile. In the present series 2 of the 3 acute cases that had the urine examined immediately after manipulation had pyuria; one also had microscopic haematuria. Both these patients had previously taken an aspirin-containing compound and the urinary findings may be simply the result of this. When re-examined 24 hours later the urines contained no such cells and remained sterile throughout.

DIFFERENTIAL DIAGNOSIS

1. **Acute Epididymitis and Orchitis.**—In epididymitis the pain is not so sudden or so severe as in torsion. There is usually evidence of infection in the urine or prostate, or a history of recent urethritis.

In epididymitis the tenderness is maximal at the epididymis whereas in torsion the whole mass is uniformly tender. There is usually tenderness and swelling of the vas deferens in epididymitis whereas in torsion this may not be a feature. Furthermore, at the age at which torsion is common, epididymitis is uncommon.

2. **Mumps Orchitis.**—There will be no previous history of mumps. There may be a history of recent parotitis, but mumps in adults and adolescents may present initially as orchitis. However, in mumps orchitis the swelling does not involve the cord.

3. **Hydrocele, Spermatocele, and Haematocele.**—The first two of these should not present much difficulty in the differential diagnosis. In traumatic haematocele a torsion may be present as well and careful examination is required clinically or subsequently at operation.

4. **Strangulated Hernia.**—Intestinal obstruction will supervene as will clinical shock.

5. **Thrombosis of the Pampiniform Plexus.**—Here there are signs of haematoma and a history of slow development of the pain.

6. **Testicular Neoplasm.**—The history will usually rule out torsion as the cause of the pain and swelling.

7. **Torsion of the Hydatid of Morgagni.**—Swelling is much less than in testicular torsion and the tenderness is localized to the upper pole of the testis. In the only 2 cases that I have seen the infarcted hydatid could be clearly observed beneath the skin as a pea-sized, black mass.

MANAGEMENT

From the cases quoted it is clear that the management in the majority of acute cases could be improved. The correct management depends initially on the doctor of first contact making the correct diagnosis or at least suspecting the condition.

Having made the correct diagnosis in the acute case, the testis must be untwisted immediately and fixed so that the condition does not recur. The opposite side should be similarly fixed since the abnormality is bilateral.

The testis may be untwisted at urgent operation or may be manipulated into the normal position and subsequently fixed electively. Manipulation is described below. Where the testis is obviously non-viable, orchidectomy is the only course, but the opposite side should undergo prophylactic fixation.

In recurrent cases bilateral fixation is the only way of conserving the testes and avoiding the acute episode.

In the acute cases in this series it was possible to manipulate the affected testis into the normal position and therefore restore its blood-supply. This has obvious advantages. It immediately relieves the patient of his symptoms, the pain disappears dramatically, and the testis descends in the scrotum. It is effected by rotation of the testis on the affected side, towards the midline, i.e., clockwise on the left side and anticlockwise on the right side when viewed from the front.

This is advantageous to the patient when awaiting anaesthesia and converts the operation from an emergency to an elective procedure. Intravenous morphine was necessary in 1 case only. Even under narcotic analgesia there was no doubt from the physical signs that the testis had been untwisted.

There are no fatal cases of torsion of the testis recorded in the literature, the most serious and earliest complication of the condition being necrosis following misdiagnosis.

SECONDARY ENLARGEMENT OF THE MANDIBULAR CORONOID PROCESS

BY P. A. BRAMLEY AND J. E. DEB. NORMAN

DEPARTMENT OF DENTAL SURGERY, UNIVERSITY OF SHEFFIELD

SUMMARY

Enlargement of the coronoid process of the mandible is a rare cause of limited jaw movement.

Primary causes fall into two categories: benign tumours and developmental hyperplasia.

Two cases of clinically important enlargement of the coronoid process secondary to other long-standing causes of difficulty in opening the mouth are described.

It is suggested that significant appositional bone growth secondary to abnormal stresses mediated by the tendon of the temporalis muscle does occur.

IF the coronoid process of the mandible becomes enlarged its anterior surface may strike the posterior surface of the malar process of the maxilla causing an obstruction to mouth opening. Attention to this unusual cause of limited mouth opening was first drawn by Shackleford and Brown (1943). Since that time at least 25 other cases have been reported. Osteoma, osteochondroma, hyperplasia, exostosis, and developmental enlargement are all mentioned as primary causes for coronoid enlargement.

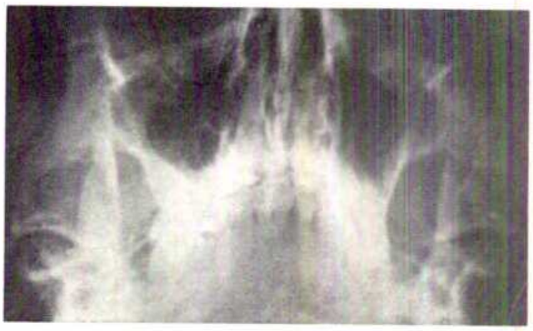

FIG. 1.—*Case* 1. Occipitomental radiograph showing enlargement of both coronoid processes of the mandible. The right side is much larger than the left.

Two cases are presented here which suggest that significant enlargement of the coronoid process of the mandible may occur secondary to another cause of limited movement of the mandible. It will be contended that secondary enlargement of the coronoid process should be considered as a possible complication in cases of long-standing limitation of movement due to other causes.

CASE REPORTS

Case 1.—D. G. was a 24-year-old pharmacist who had been perfectly fit and had had regular and uneventful dental treatment over the years. Neither he nor his dental surgeon had ever noticed any limitation of jaw movement until February, 1965. At this time he had developed an 'abscess' in relation to a left mandibular molar tooth. Although the tooth was extracted under general anaesthesia the inflammatory swelling increased, as did the pain and trismus. The patient was admitted to hospital for drainage of the submandibular abscess. He was

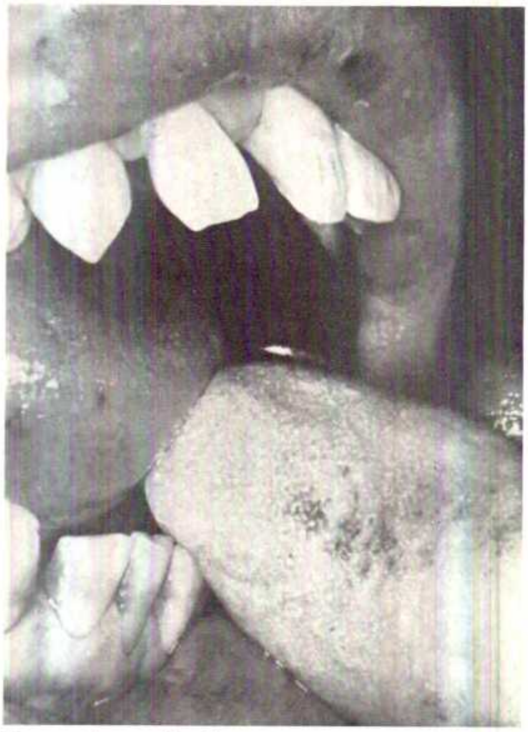

FIG. 2.—*Case* 1. Mouth opening of 35 mm. obtained after removal of the right coronoid process.

discharged after 7 days but with minimal jaw movement. A course of short-wave diathermy followed, together with active and passive jaw exercises, over several months but with little effect on jaw opening. In the autumn of 1965 he was readmitted to hospital for two further dental extractions and jaw manipulation under anaesthesia. No improvement in jaw movement was obtained. Manipulative exercises were continued on an out-patient basis.

The patient next presented for dental treatment in October, 1969, in another town. His new dental surgeon was unable to undertake treatment on account of difficult access and he was referred for investigation.

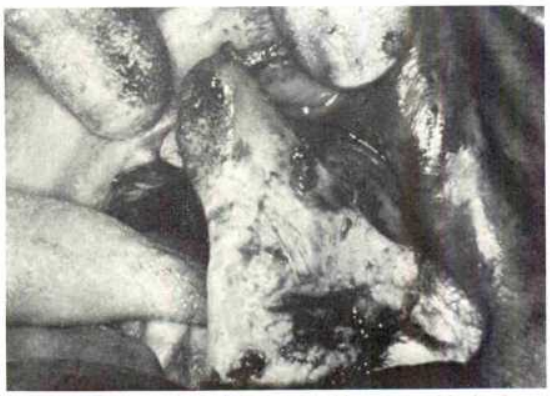

FIG. 3.—*Case* 1. The enlarged coronoid process with the facet on its anterior border.

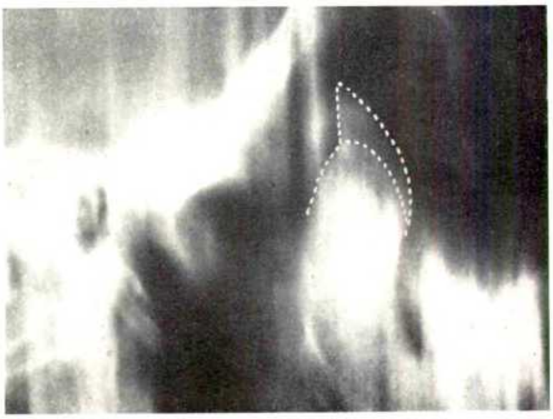

FIG. 5.—*Case* 2. Tomogram of the left coronoid process. The area of new bone formation is outlined.

We first saw this patient in March, 1970. He was a healthy-looking young man with no facial asymmetry or oral abnormalities. Maximal opening of the mouth was 17 mm., measured between the tips of the upper and lower incisor teeth. There was deviation to the right side on protrusion of the mandible. Radiographs suggested that both mandibular joints were not abnormal but that there was enlargement of both coronoid processes, the right being much larger than the left (*Fig.* 1).

A diagnosis of impeded jaw movement due to right-sided coronoid enlargement was made.

OPERATION.—The right mandibular coronoid process was removed via the intra-oral route under endotracheal anaesthesia. As a mouth opening of 35 mm. was obtained the left coronoid process was not touched (*Fig.* 2). Post-operative progress was uneventful and the patient was discharged on the fifth day. In the period following operation the patient practised mouth opening using wooden tongue spatulae. One year later full jaw movements had been maintained.

SPECIMEN.—The specimen of the enlarged coronoid process (*Fig.* 3) was lacking in distinction. It had a facet on its anterior border which articulated with a similar facet palpable at operation on the posterior aspect of the zygomatic process of the maxilla.

MICROSCOPIC APPEARANCE.—Histological sections (*Fig.* 4) showed an enlarged coronoid process of normal tissue with a fatty marrow. The growth appeared to be due entirely to normal bone apposition. No special features were present. There was no evidence of chondroid bone or cartilage.

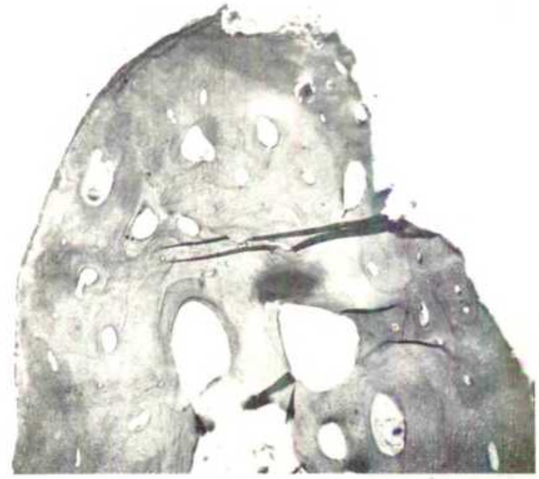

FIG. 4.—*Case* 1. Photomicrograph showing normal tissue structure, enlargement being entirely caused by normal bone apposition. (× 23.)

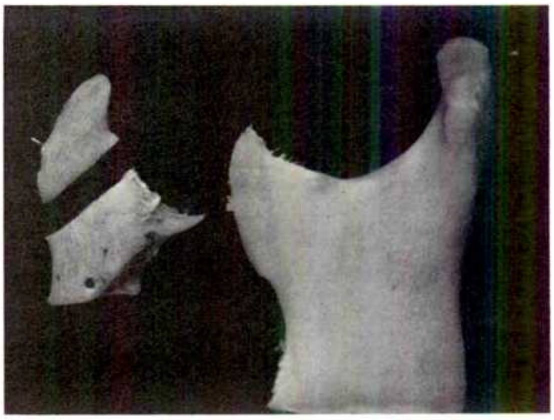

FIG. 6.—*Case* 2. Operative specimen shown adjacent to a specimen taken from a normal subject of similar age, build, and sex.

Case 2.—J. H., a 17-year-old girl, had an attempted extraction of the left maxillary third molar tooth in 1964. The tooth was apparently dislodged into the temporal fossa but was recovered at a second operation through an incision in the scalp transverse to the direction of the fibres of the left temporalis muscle. After the dislodgement of the tooth she had difficulty in opening the mouth. After the operation for the recovery of the tooth, jaw opening was minimal. Six weeks later the patient was readmitted for manipulation of the jaw under general anaesthesia as she was still unable to open her mouth. She was again admitted 4 months later for a similar manipulation and intensive physiotherapy. Short-wave diathermy and jaw exercises were continued on an out-patient basis for several months.

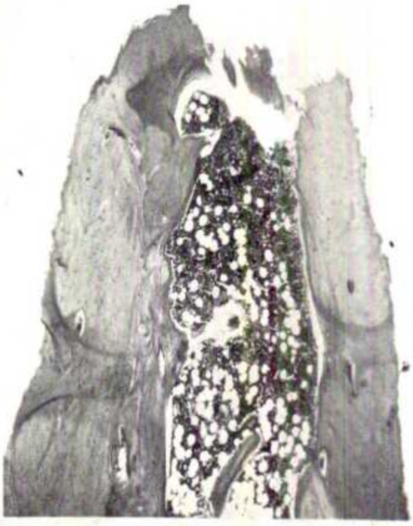

FIG. 7.—*Case* 2. Photomicrograph showing enlargement caused by lamellar and non-lamellar bone apposition. There is rimming with osteoblasts. Haemopoietic bone-marrow is present. (× 23.)

In April, 1967, the patient had some mandibular teeth extracted using a transalveolar approach, in addition to a further attempt at jaw manipulation under general anaesthesia. In February, 1970, she presented complaining of generalized toothache. She was admitted to hospital and 10 grossly carious teeth were removed with great difficulty. The incisal opening at this time was less than 1 cm.

On 6 April, 1970, we saw this patient for the first time. The incisal clearance was less than 1 cm. and the mandible deviated to the left side on protrusion. A 5-cm. long scar was present on the left temporoparietal region. There was no apparent cause for the limitation of mandibular movement other than the presumed shortening by fibrosis of the left temporalis muscle.

Radiographs (*Fig.* 5), however, suggested an overgrowth of the left coronoid process. New bone formation appeared to be sitting on the original outline of the coronoid process like a dunce's cap.

A diagnosis of limited jaw movement caused by left-sided temporalis shortening was made. It was also recognized that hypertrophy of the left coronoid process might be a complicating factor.

OPERATION.—In order to by-pass the effects of the shortened temporalis fibres and at the same time to relieve the possible physical obstruction of the enlarged coronoid process, a left mandibular coronoidectomy was carried out by the intra-oral route under endotracheal anaesthesia. The fibres of the temporalis were freed from the coronoid process with little improvement in opening. Removal of the coronoid process, however, resulted in considerably increased opening. The patient failed to persevere with exercises in the postoperative period and it was necessary to manipulate the jaw under general anaesthesia on the eighth postoperative day.

The patient failed to attend for further appointments and has been lost to follow-up.

SPECIMEN (*Fig.* 6).—The coronoid process was elongated and a conical portion of bone rather like a cap was seen at the tip of the process.

MICROSCOPIC APPEARANCE (*Fig.* 7).—Sections showed lamellar bone of the coronoid process with haemopoietic marrow, some non-lamellar bone apposition on external surfaces, and in some places there was rimming by osteoblasts. The tip showed remnants of the temporalis muscle attachment.

The coronoid process seemed to have enlarged by appositional growth; no cartilage or chondroid bone was present.

DISCUSSION

The coronoid is recognized to be one of the 'muscular' processes of the mandible. The temporalis is an extremely powerful muscle with a tendinous insertion into and around the coronoid process. It is not unreasonable to postulate that abnormal stresses transmitted by the temporalis muscle could result in appositional bone growth at the point of its insertion. Well-known examples of this are 'Rider's spur' and the Pellegrini-Steida syndrome where there is excessive bone formation at the insertion of the adductor longus and the adductor magnus respectively in some devoted horsemen.

Animal experiments emphasize the relationship between temporalis function and coronoid size. Sarnat and Engel (1951) showed that the coronoid process of the growing monkey became larger, thicker, and extended above the zygomatic arch following condylectomy on the ipsilateral side. They concluded that this was the result of the unopposed action of the temporalis not counterbalanced by condylar growth and support. Washburn (1947) resected the temporalis in rats but preserved the coronoid process on the same side. After 3–5 months he found the coronoid process to be absent. Similar work by Avis (1959), who resected portions of the temporalis on one side in young cats, showed that the process on the operated side was smaller than that on the unoperated side.

In the present *Case* 2 it is suggested that the surgical interference to remove the displaced wisdom tooth resulted in scarring and shortening of the temporalis muscle-fibres which were the original causes of the inability to open the mouth. Repeated attempts to open the mouth by manipulation under anaesthesia and by active and passive physiotherapy served merely to stress the tendinous insertion of the temporalis muscle with resulting functional hyperplasia of bone. That this secondary growth of bone was of clinical significance was noted at operation. Jaw movement was obtained not after detachment of the temporalis insertion but after removal of the enlarged coronoid process. The significance of the presence of haemopoietic marrow in the coronoid process at this age is not known.

In *Case* 1 we postulate a similar mechanism of secondary coronoid hyperplasia, but with less direct evidence.

There was no histological evidence of primary tumour growth.

Symptoms relating to developmental hyperplasia are usually detected at puberty with a gradually increasing inability to open the mouth.

Case 1 had reached the age of 24 with no difficulties with jaw movement until the infective episode. Then over a period of 5 years he had manipulations under general anaesthesia and much active and passive physiotherapy. When we saw him in 1970 both coronoid processes were enlarged, but the right was much larger than the left. Histological examination confirmed that appositional bone growth accounted for the enlargement. We were not able to establish whether the other areas of insertion of the masticatory muscles were subject to secondary hyperplasia.

In both cases the absence of chondroid bone suggests that the process of hypertrophy of the coronoid had been slow.

The 26 cases of coronoid enlargement reported in the literature are all of primary origin: either some form of benign tumour or developmental hyperplasia. There is little agreement on the criteria for the histological diagnoses of these cases, being variously described as exostosis, osteocartilaginous exostosis, osteochondroma, and osteoma, with little justification in some of the cases.

Nickerson, Graft, and Sazima (1969) have made a useful and critical review of the problem with an extensive survey of the literature.

Incontrovertible examples of true primary tumours, however, do exist, such as the osteoma reported by Lewars (1959) and the osteochondroma reported by Levine, Chessen, and McCarthy (1957). These illustrate the true nature of the tumour group. They are unilateral, appearing mostly in males over a wide age range. They are sometimes productive of facial asymmetry and are characterized by a mushroom-shaped mass which virtually fills the space between the zygomatic arch and the temporal bone.

Developmental hyperplasia accounts for the other group of primary enlargements. Good examples are described by Lyon and Sarnat (1963), Rowe (1963) and Nickerson and others (1969). Developmental hyperplasia is bilateral, confined to males, and starts at puberty. The coronoid process, although enlarged, retains its normal form.

In addition to these two primary groups of enlarged coronoid process of the mandible we suggest that enlargement can be due to functional hyperplasia secondary to other causes of inability to open the mouth fully. It is important to consider this possibility in the differential diagnosis of the causes of impeded jaw movements.

Acknowledgements.—We wish to thank Professor J. J. Hodson for the histological studies and reports, and Mr. R. Cousins for his photographic work.

MUSCLE BLOOD-FLOW FOLLOWING INSERTION OF A BY-PASS VEIN-GRAFT IN FEMOROPOPLITEAL OCCLUSIVE DISEASE

BY GRAHAM BELL AND DOUGLAS W. SHORT

UNIVERSITY DEPARTMENT OF SURGERY, THE ROYAL INFIRMARY, GLASGOW

SUMMARY

Muscle blood-flow has been measured by the local clearance of ^{133}Xe in 32 patients (34 limbs) following arterial replacement with a by-pass vein-graft for atherosclerotic occlusive disease affecting the femoropopliteal segment.

In 27 cases (29 limbs) in which the graft was functioning satisfactorily there was a marked improvement in muscle blood-flow with a return to within normal range in most instances. In 5 patients the graft occluded within 3 months of operation and in these cases there was no significant alteration in the muscle blood-flow following operation. The measurement of muscle blood-flow therefore provided objective corroborative evidence of the success or failure of the procedure.

Seventeen of the group had muscle blood-flow measurements carried out at 3-monthly intervals for a year or more after operation. The postoperative flow tended to remain stable throughout this period, and did not show any tendency to return to the preoperative levels as has previously been reported for thrombo-endarterectomy. This lends further support for the view that in reconstructive surgery for femoropopliteal occlusive disease the long-term results are better with by-pass vein-grafts than with thrombo-endarterectomy.

THE blood-flow through a tissue can be measured by injecting a radioactive substance directly into the tissue and measuring the rate of disappearance of the isotope. This technique was introduced for the measurement of the blood-flow through the calf muscle in man by Kety (1949), who used the isotope ^{24}Na. Subsequently, Lassen (1964) showed that the radioactive inert gas ^{133}Xe had several advantages over ^{24}Na as the radioactive tracer.

The xenon-clearance technique has been shown to be useful in the detection of peripheral arterial disease (Lassen, Lindbjerg, and Munck, 1964; Lindbjerg, 1965; Webster, 1966; Bell and Short,

1968) and in the postoperative assessment of patients following surgery (Garcia Del Rio, Welsh, and Repetto, 1969; Bell and Short, 1971).

PATIENTS STUDIED

Thirty-two patients with atherosclerotic occlusive disease of the femoropopliteal artery have been studied. Two patients had a vein-graft inserted in both legs and thus 34 limbs had blood-flow measurements before and after operation.

The level of the occlusion present is shown in *Table I*. The grafts were inserted across the diseased segment and ranged between 12·5 and 35 cm. in length. A minimum diameter of 4 mm. was considered desirable and with 3 exceptions this was achieved.

Table I.—LEVEL OF ARTERIAL OCCLUSION IN 32 PATIENTS (34 LIMBS)

Lesion	*No. of Legs*
Occlusion of superficial femoral artery, either partial or complete	18
Occlusion at the adductor magnus hiatus	10
Stenosis at the adductor magnus hiatus	3
Occlusion of the popliteal artery	3

In 5 patients the graft failed within the first 3 months. At the follow-up 1 year after operation 22 limbs were available for study, 3 patients having been lost to follow-up and 4 patients being within a year of operation. Of this group, 4 developed late occlusion of the graft and 1 patient developed stenosis at the proximal end of the vein-graft with a return of symptoms. This left for study 17 limbs who were symptom-free at the end of 1 year.

METHODS

Muscle blood-flow was measured from the local clearance of ^{133}Xe as described by Lassen and others (1964); 30–60 μc. of ^{133}Xe dissolved in 0·1–0·2 ml. of 0·9 per cent saline were injected directly into the anterior tibial group of muscles. The radioactivity was detected using a NaI crystal connected to a ratemeter and recorder. Following the injection of ^{133}Xe the arterial inflow to the limb was occluded and the patient was asked to exercise his ankle. The exercise was continued until the patient was forced to stop on account of ischaemic pain; in each case a minimum of 60 movements was carried out and the ischaemic period was never less than 2 minutes.

Following release of the cuff a clearance curve was obtained and the muscle blood-flow (M.B.F.) was calculated using the formula:—

$$\text{M.B.F.} = D \times 161 \text{ ml. per 100 g. per min.,}$$

(Lassen and others, 1964), where D is the decrease in 1 minute of a tangent drawn to a logarithmic plot of the clearance curve.

From each curve the following three calculations were made:—

1. The peak blood-flow (P.B.F.).
2. The time taken from release of the occluding cuff to reach this peak blood-flow.
3. The duration of peak blood-flow.

By drawing a tangent to the logarithmic plot of the clearance curve at any moment in time a D factor can be calculated for that time and a flow pattern obtained. In the present paper the flow patterns illustrated were made from blood-flow calculations at minute intervals after release of the occluding cuff.

RESULTS

In 5 patients the graft failed within the first 3 months. In all these cases the postoperative blood-flow at 3 months showed no statistically significant change from the preoperative levels (*Table II*). The pre- and postoperative blood-flow results in the remaining 27 patients (29 limbs) in whom a vein-graft was functioning satisfactorily at 3 months are shown in *Table III*. The peak blood-flow increased by 77 per cent, the duration of peak blood-flow was reduced by 46 per cent, and the time from release of the occluding cuff to reach peak blood-flow was reduced by 73 per cent ($P < 0·001$ in all 3 cases).

Table II.—PRE- AND POSTOPERATIVE MUSCLE BLOOD-FLOWS IN PATIENTS WITH A FAILED VEIN-GRAFT (5 LIMBS)*

TIME	PEAK BLOOD-FLOW (ml. per 100 g. per min.)	TIME TO PEAK BLOOD-FLOW (min.)	DURATION OF PEAK BLOOD-FLOW (min.)
Before operation	24·7 ± 5·9	1·4 ± 1·5	2·9 ± 3·0
After operation	22·5 ± 5·1	2·0 ± 1·8	2·8 ± 1·5

* Mean ± S.D.

Table III.—PRE- AND POSTOPERATIVE MUSCLE BLOOD-FLOWS IN PATIENTS WITH A SUCCESSFUL VEIN-GRAFT (29 LIMBS)*

TIME	PEAK BLOOD-FLOW (ml. per 100 g. per min.)	TIME TO PEAK BLOOD-FLOW (min.)	DURATION OF PEAK BLOOD-FLOW (min.)
Before operation	30·6 ± 12·9	1·5 ± 0·7	2·8 ± 1·2
After operation	54·2 ± 14·1*	0·4 ± 0·2†	1·5 ± 0·6†

* Mean ± S.D.

† $P < 0·001$.

Table IV.—POSTOPERATIVE MUSCLE BLOOD-FLOW IN PATIENTS WITH A SUCCESSFUL VEIN-GRAFT (29 LIMBS) COMPARED WITH THAT IN NORMAL SUBJECTS (68 LIMBS)*

PATIENTS	PEAK BLOOD-FLOW (ml. per 100 g. per min.)	TIME TO PEAK BLOOD-FLOW (min.)	DURATION OF PEAK BLOOD-FLOW (min.)
Normal group	55·9 ± 12·7	0·5 ± 0·3	1·1 ± 0·4
Postoperative group	54·2 ± 14·1	0·4 ± 0·2	1·5 ± 0·6

* Mean ± S.D.

When the postoperative results in the group with patent grafts are compared with the muscle blood-flow results obtained from a group of 36 normal subjects (68 limbs) of the same age-group who had no clinical evidence of peripheral arterial disease, there is a close correlation between the two groups (*Table IV*).

The muscle blood-flow patterns before and after surgery for the successful group are shown in *Fig. 1*. The postoperative flow pattern is compared with that of the normal group in *Fig. 2*. The postoperative blood-flow pattern closely resembles that of the normal group.

At the follow-up 1 year after operation 17 out of the 22 limbs available for study were symptom-free and clinically the graft was functioning satisfactorily.

Fig. 3 illustrates the mean peak muscle blood-flow results at 3, 6, and 12 months after operation. It is apparent, in general, that the increase in muscle blood-flow is well maintained during the first post-operative year.

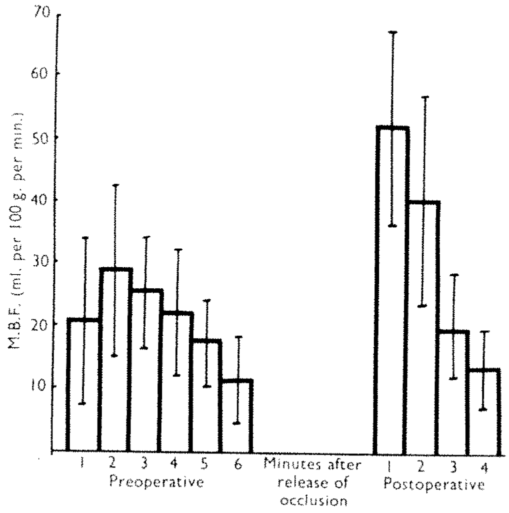

FIG. 1.—Pattern of muscle blood-flow (M.B.F.) calculated at minute intervals after the release of the cuff. Comparison of the pre- and postoperative flow patterns in 29 limbs with a patent graft (mean ± S.D.).

DISCUSSION

In most instances it is not difficult on clinical grounds to determine whether a graft is functioning or not, particularly when distal vessels are patent and pedal pulses are palpable. It is not so easy to determine clinically how well a graft is functioning or to be certain that no inherent defect is present which might lead to early failure. Angiography provides a useful assessment of the anatomical function of a vein-graft, especially when it is performed at the time of insertion of the graft, but it is not suitable as a routine follow-up procedure. The measurement of muscle blood-flow by the ^{133}Xe-clearance technique not only has the merit that it is less traumatic and is easily performed on out-patients, but also it is a more direct and more accurate measurement of the adequacy of blood-supply to the limb in the management of intermittent claudication (Alpert, Larsen, and Lassen, 1968). Alterations in postoperative muscle blood-flow as shown by ^{133}Xe studies may be an indication for further angiography.

In the series reported here there was a good correlation between the clinical picture and the muscle blood-flow estimations. In the 5 patients whose graft failed there was no significant improvement in the blood-flow following operation (*Table II*).

In the 29 limbs with an open graft at 3 months only 3 failed to show a rise in muscle blood-flow. One of these 3 patients had stenosis of his graft demonstrated by arteriography and developed a late occlusion of the graft. In the second case the pre-operative peak muscle blood-flow was 67·6 ml. per 100 g. per minute and this falls well within the normal range (in 68 limbs in patients over 40 years of age the mean peak muscle blood-flow was 55·9 ml. per 100 g. per minute, S.D. ± 12·7).

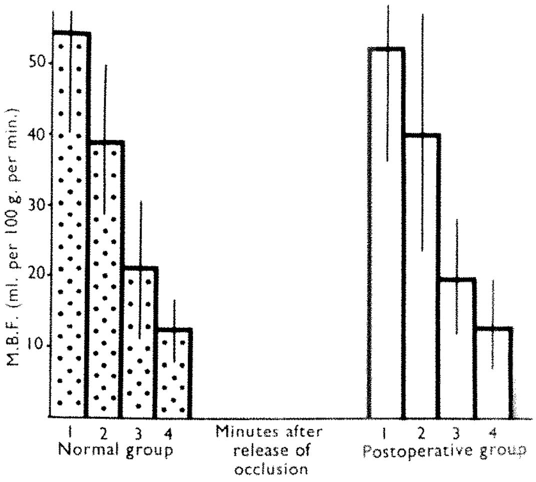

FIG. 2.—Postoperative muscle blood-flow (M.B.F.) in patients with a successful graft (29 limbs) compared with that in normal subjects (68 limbs) (mean ± S.D.).

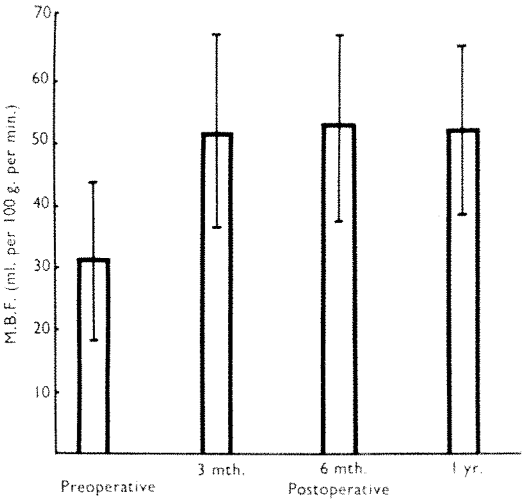

FIG. 3.—Peak muscle blood-flow (M.B.F.) before operation and 3, 6, and 12 months following operation in 17 limbs (mean ± S.D.).

In the third patient the muscle blood-flow following operation remained below the normal range, but there was a dramatic reduction in the time taken to achieve peak blood-flow following ischaemic exercise from a grossly abnormal 3·3 minutes to a normal 0·5 minute. Abolition of this time lag, which is due to slow repressurization of the local vascular bed following removal of the cuff, was accompanied by relief of symptoms. We have had a similar experience following effective thrombo-endarterectomy (Bell and Short, 1971). In the remaining 26 limbs in which the graft functioned well throughout the time under observation the muscle blood-flow remained at approximately normal levels. This supports the view that muscle blood-flow provides objective evidence of the success or failure of the surgical procedure.

In some patients the muscle blood-flow pattern returned to within normal ranges following reconstructive surgery and this is in keeping with the finding of others. Mannick, Jackson, and Coffman (1966), using the local clearance of Na labelled with ^{131}I, found that the clearance after exercise returned to normal following surgery. Snell, Eastcott, and Hamilton (1960), using venous occlusion plethysmography, also found that the pattern of reactive hyperaemia tended towards normal following removal of an arterial occlusion.

In those patients with a patent graft the improvement in muscle blood-flow was well maintained throughout the first postoperative year. Strandness and Bell (1966) have postulated a gradual build-up of muscle blood-flow for several months following surgery. In the present series this was observed in 1 patient. Following operation the peak muscle blood-flow rose from the preoperative level of 20·9 to 32·2, 41·7, and 51·5 ml. per 100 g. per minute at 3, 6, and 12 months respectively. However, in the majority of cases the improvement in muscle blood-flow observed at 3 months was usually well maintained at a constant level throughout the rest of the year. In our previous study (Bell and Short, 1971) it was found that in 50 per cent of cases followed up after thrombo-endarterectomy for femoropopliteal occlusive disease there tended to be a progressive diminution in muscle blood-flow over the first year. This was not found to occur in the present group. This lends support to the view that by-pass vein-grafts functioning satisfactorily will give better long-term results than thrombo-endarterectomy.

THE RESULTS OF 101 OPERATIONS FOR SYMPTOMATIC HIATUS HERNIA

A COMPARISON OF TWO DIFFERENT METHODS

BY C. J. MAGAREY
ROYAL UNITED HOSPITAL, BATH

SUMMARY

The results of all the operations for symptomatic sliding hiatus hernia carried out by 1 surgeon during 5½ years are reviewed. One hundred and six operations were done and 101 patients were available for review after 6 months to 5 years. The earlier patients in the series underwent transthoracic or transabdominal hiatus hernia repair, and the later patients underwent fixation of the lesser gastric curve to the anterior abdominal wall, as described by Boerema (1969). Before operation the two groups were clinically comparable. There were significantly less clinical failures after the Boerema operation, and less radiological recurrences. This simple and rapid operation is, therefore, preferred to the more complicated procedure.

MANY operations have been described for symptomatic sliding hiatus hernia. They have been reviewed recently by Collis (1970) and Mustard (1970). Similar results have been reported in each case by the originator, with a 4–22 per cent clinical failure rate and 0–10 per cent radiological recurrence. However, many of the operations are complicated and difficult, so that different results may be obtained by other operators. There are few reports of large series of patients treated by other operators, and even fewer attempts to compare different methods.

The results obtained in 101 patients in whom a hiatus hernia was repaired by 1 surgeon using three different operations are reviewed after 6 months to 5 years.

MATERIALS AND METHODS

One hundred and six patients undergoing operations by Mr. H. T. John (Consultant Surgeon, Bath Clinical Area) for symptomatic sliding hiatus hernia, confirmed by barium meal or oesophagoscopy, from 1965 to 1970 are reviewed. Three patients died in the immediate postoperative period of pulmonary embolus or myocardial infarction, and 1 patient died 3 months later of cerebral haemorrhage. A further patient has not been traced since her operation, leaving 101 patients followed up for 6 months to 5 years. Until 1968 all the patients underwent hiatus hernia repair by a transthoracic or transabdominal route, depending on the suspicion of other abdominal disorder. After 1968 most patients underwent Boerema's operation, so that there were three groups of patients (*Table I*): 39 transthoracic repairs, 64 thoracic or abdominal repairs (including the 39 transthoracic repairs), and 37 Boerema operations.

The transthoracic repair was carried out through the bed of the seventh or eighth rib. The lower oesophagus and herniated stomach were mobilized. Up to six thread sutures were placed through the wall of the lower oesophagus, the fundus of the stomach, and the under-surface of the diaphragm. They were then tied, fixing the stomach and lower oesophagus below the diaphragm and restoring the gastro-oesophageal angle. Finally, the crura were approximated behind the oesophagus with thread sutures so as to narrow the hiatus.

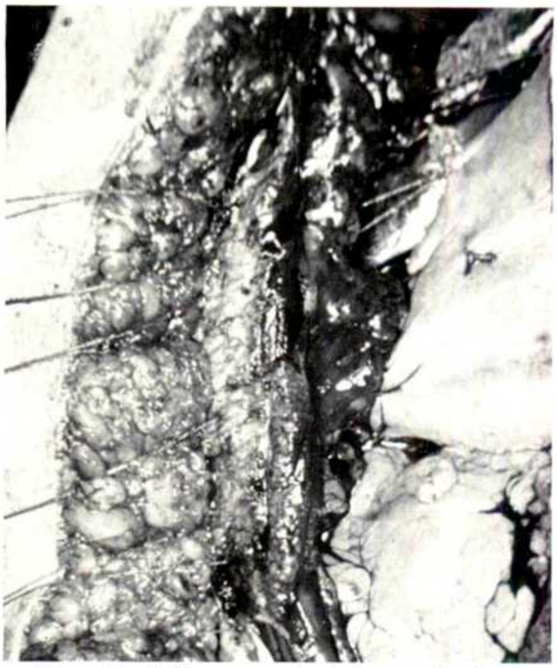

FIG. 1.—For the Boerema operation eight to ten thread sutures are placed in the lesser curve of the stomach and brought out through the rectus 2·5 cm. to the right of the midline incision. The top of this photograph is towards the head of the patient. The stomach is being drawn down from the top right by six sutures (so far) through the rectus sheath which runs down the middle of the picture, beneath the subcutaneous fat and skin on the left of the picture.

Table I.—THE GROUPS OF PATIENTS STUDIED

GROUP	OPERATION	NO. OF PATIENTS				
		1965–7	1968	1969	1970	Total
1. Thoracic	Transthoracic repair of hiatus	24	11	2	2	39
Abdominal	Transabdominal repair of hiatus	14	4	6	1	25
2. Combined	Thoracic or abdominal repair of hiatus	38	15	8	3	64
3. Boerema	Boerema's operation	0	9	6	22	37

The transabdominal repair was carried out through an upper midline incision. The lower oesophagus was mobilized and drawn into the abdomen. The crura were approximated behind the oesophagus to narrow the hiatus, the gastro-oesophageal angle was restored, and the fundus of the stomach was fixed to the diaphragm, all with thread sutures.

The Boerema operation was also carried out through an upper midline abdominal incision. The lower oesophagus was mobilized by digital dissection until at least 5 cm. could be drawn into the abdomen. The crura were usually dissected out and approximated with thread sutures behind the oesophagus to narrow the hiatus, but this step was sometimes omitted and frequently only one or two sutures were used. The subcutaneous fat was cut off the right side of the linea alba, and then eight to ten thread sutures were placed in a row just anterior to the lesser curve of the stomach and each end of each suture was brought out through the abdominal wall 2·5 cm. to the right of the midline (*Fig.* 1). These were tied, so that at least 5 cm. of the lesser curve of the stomach were fixed to the anterior abdominal wall (*Fig.* 2), and the oesophagus was held down into the abdomen under tension. This was the most important step, and Boerema (1969) states: 'The intra-abdominal oesophagus and upper part of the

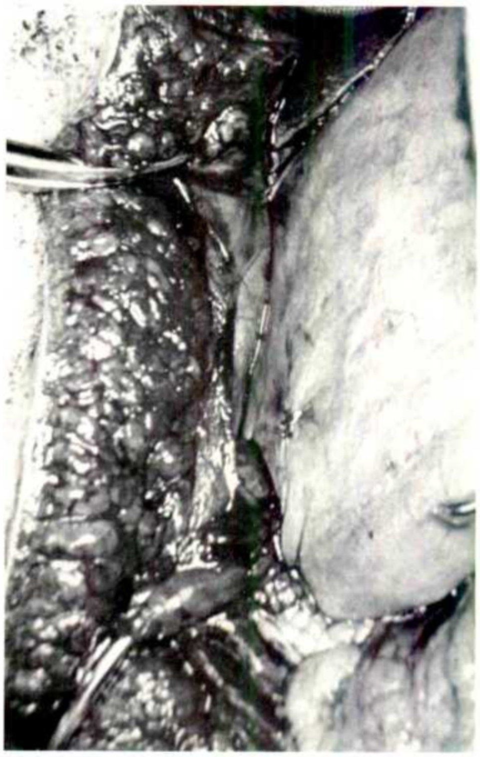

FIG. 2.—The Boerema operation is completed by tying the sutures, thus fixing the lesser curve of the stomach to the anterior abdominal wall. The top of this photograph is towards the head of the patient. The stomach has been drawn over from the right, and is separated from the anterior abdominal wall (on the left) by the peritoneum which is displayed by two artery forceps. A little of the left lobe of the liver is seen at the top of the picture.

lesser curvature must feel like a very tense cord, extending from the hiatus close along the under surface of the liver to the anterior abdominal wall one inch to the right of the median line.' The fundus of the stomach was left free to roll up under the diaphragm, automatically restoring the gastro-oesophageal angle.

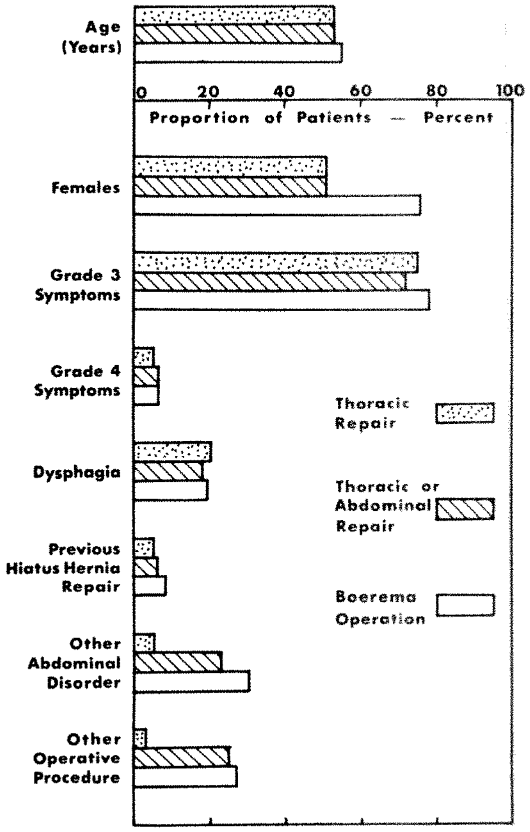

FIG. 3.—Preoperative clinical features of the patients grouped according to *Table I*. The length of each column represents the proportion of patients in each group with each clinical feature, except for the mean age which is shown at the top of the figure.

Preoperative clinical features and any postoperative symptoms at out-patient visits were determined from the hospital notes. The severity of symptoms due to hiatus hernia or resulting from the operation itself was graded retrospectively (*Table II*). For the review all patients were sent questionnaires. They were asked in simple terms to grade the severity of their own symptoms (*Table II*) and to indicate when the symptoms had returned after operation. An unprompted description of the symptoms and any other comments were invited. A patient's general practitioner was approached when any reply was not clear or was not received, and those patients with severe symptoms who had not already been seen were interviewed at the hospital. Satisfactory replies were obtained from 97 of the 101 patients. The results were interpreted by a surgeon (C. J. M.) who had not carried out any of the operations. Only upper gastro-intestinal symptoms or symptoms resulting from the operation itself, such as wound pain or post-vagotomy diarrhoea, were recorded as 'postoperative symptoms'. Dysphagia was usual for up to 6 weeks and therefore was recorded as a symptom only when it lasted for more than 2 months. When a patient with severe recurrent symptoms underwent a further operation for his hiatus hernia it was assumed that his symptoms would have persisted for more than 2 years after the first operation. The results of the second operation were assessed and recorded separately.

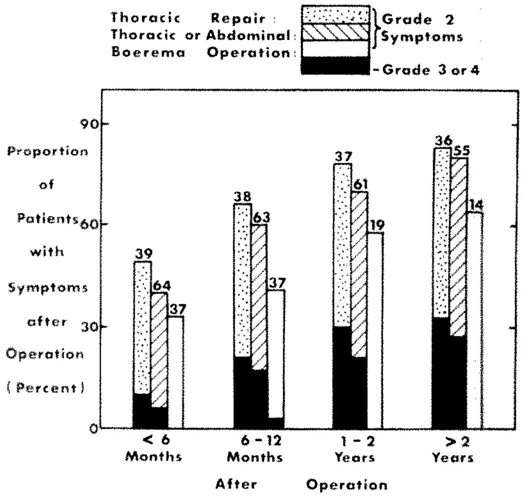

FIG. 4.—Postoperative clinical recurrences in the patients grouped according to *Table I*. The height of each column represents the proportion of patients with recurrent symptoms in each group at each time interval. The number of patients in each group is shown above each column. The severe (grades 3 and 4) symptoms are shown in black, and the mild (grade 2) symptoms are coded according to the group represented.

Table II.—GRADING OF CLINICAL SYMPTOMS*

GRADE	SEVERITY	DESCRIPTION
1	Absent	No symptoms
2	Mild	Symptoms usually relieved by conservative measures
3	Severe	Symptoms resistant to conservative measures
4	Severe	Persistent incapacitating symptoms

* Related to the hiatus hernia or resulting from operation.

All of the patients with severe (grade 3 or 4) recurrent symptoms, many of those with mild (grade 2) symptoms, and all of those who had undergone Boerema operations had postoperative barium-meal studies. A hiatus hernia or gastro-oesophageal reflux in the supine position was considered abnormal, but if it occurred only in the prone position with a bolster under the abdomen it was considered abnormal only when associated with symptoms of reflux. Conversely, when no hiatus hernia or reflux of barium could be demonstrated in patients with severe (grade 3 or 4) symptoms these symptoms were considered not to be due to hiatus hernia or reflux. These symptoms were classed as grade 2 postoperative symptoms for the purpose of analysis to avoid confusion with grade 3 or 4 symptoms due to recurrent hiatus hernia.

RESULTS

The preoperative clinical features of the three groups are compared in *Fig.* 3. There were more females in the Boerema group, but the ages of the patients and the severity of their symptoms were similar. There were less 'other abdominal disorders' discovered in the thoracic group, but as there were more in the abdominal group the incidence in the combined group (7 duodenal ulcers, 5 gall-stones, 2 diverticuloses, and 1 achalasia of the oesophagus out of a total of 64 cases) was similar to that in the Boerema group (4 duodenal ulcers, 5 gall-stones, and 2 diverticuloses out of a total of 37 cases). Likewise, the number of other operative procedures done on the combined group (10 vagotomies, 5 cholecystectomies, and 1 cardiomyotomy out of 64 cases) was similar to that in the Boerema group (3 vagotomies, 5 cholecystectomies, 1 duodenal diverticulectomy, and 1 diagnostic thoracotomy out of 37 cases).

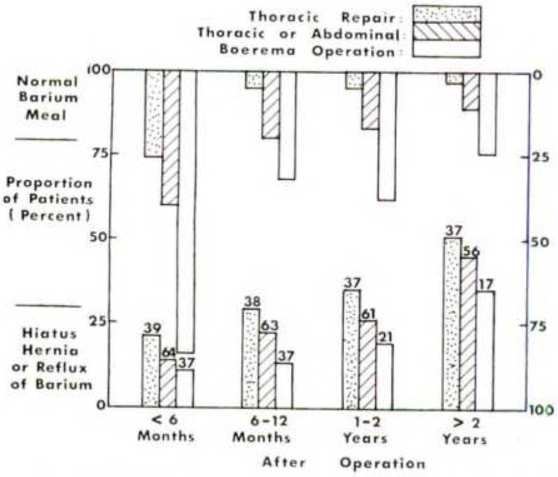

FIG. 5.—Postoperative radiological findings in the patients grouped according to *Table I*. The height of each lower column represents the proportion of patients in each group known to have radiological recurrence. The depth of each upper column represents the proportion known to have normal barium meals. The space between each pair of columns represents the patients who had not had barium-meal studies. The number of patients in each group is shown above each lower column.

The postoperative symptoms of the three groups are compared in *Fig.* 4. Fifty-five of the 64 patients in the combined group were followed up for more than 2 years but most of the clinical recurrences had appeared within a year. In only 6 did symptoms recur after 1 year, 1 of these recurring after 2 years. Ultimately, 15 out of these 55 patients (27 per cent) experienced severe (grade 3 or 4) clinical relapse associated with an abnormal barium meal. At the time of review 14 of the 37 patients in the Boerema group had been followed up for more than 2 years. None of these had severe symptoms associated with an abnormal barium meal, although 1 had grade 3 symptoms (epigastric discomfort, sweating and faintness after meals, and diarrhoea) without radiographic evidence of recurrent hiatus hernia. He had undergone vagotomy and pyloroplasty at the time of his Boerema operation which probably accounts for his symptoms, so they have been classed as grade 2 postoperative symptoms for the purpose of analysis. None of the 5 patients followed up for 1–2 years had severe symptoms, but 1 of the 18 followed up for less than a year had grade 3 symptoms (flatulence, epigastric discomfort after meals, and diarrhoea). She had undergone vagotomy 3 years before her Boerema operation, but she had recurrent hiatus hernia and reflux on barium-meal examination and has been included as a grade 3, severe clinical failure—the only one after a Boerema operation. This clinical failure rate is significantly better than that in the combined group (at 6–12 months, $P < 0{\cdot}05$; at 1–2 years, $P < 0{\cdot}05$; after more than 2 years, $P < 0{\cdot}06$, by the χ^2 test). Only 11 of the 55 (20 per cent) patients in the combined group and 5 of the 14 (36 per cent) in the Boerema group were completely free of symptoms after 2 years, but the rest had only mild symptoms which had been improved by the operation.

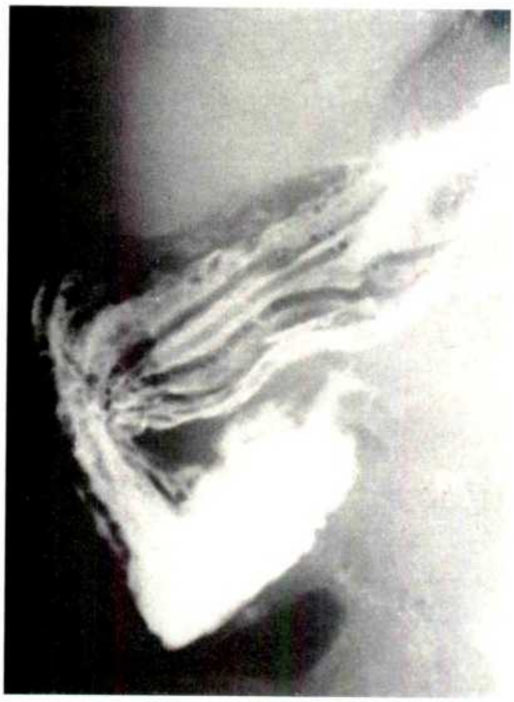

FIG. 6.—Radiological gastric deformity found after the Boerema operation. This is a lateral radiograph of a patient taken during a barium meal more than 2 years after his operation. The top of the picture is towards the head of the patient and his anterior abdominal wall is on the left. The barium within the stomach can be seen extending towards the abdominal wall, showing that the stomach is still fixed there over a length of at least 5 cm.

The barium-meal results are compared in *Fig.* 5. Once recurrent hiatus hernia or abnormal reflux had been demonstrated it was assumed to be present subsequently, so that the results are cumulative. Conversely, when no hiatus hernia or reflux could be shown it was assumed to have been absent since the operation. The results are incomplete because many of the patients with mild or no symptoms did not have a postoperative barium-meal examination, and the investigation of severe symptoms was often delayed. Even so, after 2 years more than half of the patients undergoing thoracic repairs and a third of those undergoing Boerema operations had radiological recurrence; but while many of the former had severe symptoms only 1 in the Boerema group had severe recurrent symptoms. The typical gastric deformity produced by the Boerema operation (*Fig.* 6) persisted for more than 2 years. This seemed to control symptoms, even when reflux of barium could be seen on radiographs.

DISCUSSION

The results of three different operations for sliding hiatus hernia have been compared, but the patients were not randomly allocated so it is important to be certain that other factors did not influence the results. The thoracic and abdominal groups differed clinically because the patients were selected on clinical grounds, and therefore the results of these two approaches cannot be compared. However, it is reasonable to combine these into one group because a similar repair of the hiatus hernia was achieved by each approach. Selection of the patients for the Boerema operation was based on fashion not on clinical grounds so that this group can be compared clinically with the combined group, except for the preponderance of females. The sex of the patients is unlikely to have influenced the results, and comparison of the results obtained in the Boerema group with those in the combined group is valid.

The operations were done to relieve symptoms and therefore the results are best measured by the severity of any postoperative symptoms. This was determined by asking the patients to describe and grade their own symptoms and the replies were interpreted by a surgeon who had not carried out any of the operations. The accuracy was increased by information from general practitioners and by personal interview and radiographic studies of the patients with more severe symptoms. Since the patients in the Boerema group were not followed up for as long as those in the combined group the results have been compared at shorter postoperative periods. At 6–12 months and at 1–2 years there were significantly ($P < 0·05$) less clinical failures in the Boerema group. There were no clinical failures in this group after 2 years, but too few patients had been followed up for this result to reach significance ($P < 0·06$). As the surgeon gained experience with the Boerema operation the results at 6–12 months improved significantly ($P < 0·05$), so that 11 out of the first 16 patients, 5 out of the next 12, and none of the last 9 had postoperative symptoms. Symptoms seldom recurred more than 1 year after thoracic or abdominal repair, and at the time of the review none had appeared more than 1 year after a Boerema operation. It is reasonable to suppose, therefore, that the long-term results of the Boerema operation will improve further as the more recently operated on patients are followed up, and that they will be considerably better than the results obtained in the combined group.

The main value of the radiographic studies was in the diagnosis of symptoms, but all of the patients in the Boerema group had barium meals postoperatively so that a good idea has been obtained of the anatomical result of this operation. Within 6 months only 4 of the 37 had recurrent hiatus hernia and 2 others had recurred when first radiographed after more than 6 months. No hiatus hernia or gastro-oesophageal reflux could be demonstrated in the other 31 patients. This result was not obtained by the insertion of a few stitches in the oesophageal hiatus, because within 6 months there were 9 recurrences in the 29 patients radiographed in the combined group after extensive dissection and repair of the hiatus. The reduction in reflux must, therefore, have been due to the fixation of the stomach to the anterior abdominal wall. It remained fixed for more than 2 years (*Fig.* 6) so that it is likely that the control of reflux will persist. The present 35 per cent (6 out of 17) radiographic recurrence rate after 2 years will improve as more patients are followed up. Seven of the 17 had normal barium meals within 2 years, and the results of the Boerema operation have improved with increased experience. In contrast, the 45 per cent (25 out of 56) known radiographic recurrence rate after 2 years in the combined group is likely to have been worse if the remaining 28 patients had been radiographed. This would confirm, radiologically, the better clinical results of the Boerema operation.

These are the results obtained by one surgeon. Other surgeons may have obtained even better results with another operation, but most other operations described are complicated and require much dissection. Boerema's operation is simple and rapid and is suitable for use even in the elderly and frail (Zeifer, 1968). It achieves all the aims of hiatus hernia repair: closure of the hiatus, infra-diaphragmatic segment of the oesophagus, and acute gastro-oesophageal angle (Collis, 1970; Mustard, 1970), though it seems that the first can be omitted. Boerema's method could be combined with an abdominal repair of the hiatus or another operation (Mustard, 1970), but vagotomy and pyloroplasty did not improve the results in this series. Until another operation has been compared with Boerema's technique in a large group of patients by a surgeon other than the originator of the method, this simple, rapid, and safe operation is preferred.

Acknowledgements.—I thank Mr. H. T. John, Consultant Surgeon, Bath Clinical Area, for allowing me to study his patients, the patients themselves for their co-operation, Dr. S. K. Das for his help in tracing their records, and, in particular, my wife for her patience in typing the many drafts of this paper.

THE MOVEMENTS OF THE ADULT *ASCARIS LUMBRICOIDES*

By MILROY PAUL
COLOMBO, CEYLON

SUMMARY

Deductions made from Makidono's (1956) observations of the movements of ascarids in the small intestine of man and from findings at surgical operations and post-mortem examinations of the positions of ascarids causing clinical disturbances have been used to build a concept of the behaviour of ascarids under normal and abnormal conditions.

THE adult *Ascaris lumbricoides* is the largest nematode parasitic in man, and its movements are easily seen with the naked eye, and yet nothing was known of the modes of movement of this large worm till Makidono (1956) published his *Observations on Ascaris under Fluoroscopy*.

Why were observations under fluoroscopy needed to observe the movements of this large worm? As Makidono observed: 'The ineffectual movements of *Ascaris* in a pan of water are in contrast to the positive progressive locomotion it exhibits in its normal habitat.'

Following the trail created by Fitz (1922), who first visualized ascarids in the gastro-intestinal tract of man during radiographic examinations, Makidono made a series of painstaking and detailed observations on the movements of ascarids in human small intestines. Here for the first time were observations which could not have been made by any other means, because the adult *A. lumbricoides* is formed only in the jejunum of man and can live only in the human body.

Makidono's observations were on ascarids in the small intestine of persons who were unaware of the presence of these worms and who were found on investigation to be harbouring only a few worms each. Makidono's observations relate therefore to ascarids living peacefully and undisturbed in the small intestine of man and which were so few in number that the worms did not impede each other. His observations give a clear picture of the modes of movement of worms living under these conditions. In the present communication Makidono's observations are made the basis for deductions about the mechanics of movements of ascarids in the small intestine.

Much attention has been given in the literature to the clinical disturbances set up by ascarids reaching particular sites. Although the occurrence of ascarids at these sites has been observed at surgical operations or at post-mortem examinations, and descriptions have been published in the literature, these descriptions, accurate though they are, do not give sufficient clues to the chain of events causing the ascarids to take up these positions.

In the present paper the deductions which are made about the mechanics of movements of ascarids living in the small intestine under normal conditions are used to interpret the chain of events leading up to ascarids arriving at unusual sites in the body when conditions are not normal.

MAKIDONO'S OBSERVATIONS

Makidono (1956) made detailed observations on the movement of ascarids in the small intestine in 87 persons, who harboured 588 worms between them. Five of these persons harboured only 1 worm each, three-quarters of the group harboured from 3 to 10 worms each, and only 1 person harboured more than 20 worms.

Ninety-nine per cent of the worms were in the jejunum and ileum, the proportion being 8 : 1 in favour of the jejunum. Ninety-two per cent of these worms were static in the small intestine during the period of observation. These worms were not displaced by intestinal peristalsis, nor could they be dislodged by digital pressures on the abdominal wall made under the guidance of the image on the fluorescent radiographic screen. It was evident that these worms were maintaining their positions in the small intestine by continuous muscular efforts of their own. As Makidono put it: 'The worms resemble fish maintaining their positions in a stream with their heads pointing into the current.'

Makidono observed that in the presence of a large number of worms the mass of worms in the small intestine resembles a bundle of macaroni.

Only 5 per cent of the worms were advancing up the small intestine during the period that they were observed. These worms raised a coil in their bodies as they advanced up the intestine.

Less than 3 per cent of the worms were descending the small intestine during the period that they were observed. Before descending these worms bent backwards upon themselves till their head pointed to the distal end of the intestine, after which they descended the intestine head first.

During earlier examinations Makidono had observed that after an anthelmintic had been administered the bodies of the ascarids became flaccid and that the ascarids were then passively propelled down the small intestines by intestinal peristalsis, their now flaccid bodies being bent into an 'U' with the head and tail ends of the worm pointing to the distal end of the intestine.

SOME DEDUCTIONS ABOUT THE MECHANICS OF MOVEMENTS OF ASCARIDS

Makidono's observation that ascarids which were static in the small intestine directed their head into the current shows that ascarids do not retain their position in the small intestine by attaching themselves by their mouth, which is at the anterior end of the body, to the mucosa of the intestine. On the contrary, he found that the worms maintained themselves in the lumen of the gut pointing their head towards the upper end of the gut.

An *Ascaris* in the small intestine is from time to time being pushed down the small intestine by intestinal peristalsis, and if it is to combat displacement by these peristaltic waves it must make muscular efforts to counteract exactly each wave as it comes along. By directing its head to the proximal end of the gut the *Ascaris* is in a position to counteract each wave of intestinal peristalsis by making movements to advance its body up the intestine.

Makidono observed that ascarids which were advancing up the intestine raised a coil in their bodies as they did so. Why did they do this? To raise a coil in its body the worm would advance the posterior section of its body while keeping the anterior section static. In following this up by advancing the anterior section of its body the worm would thereby have advanced the whole of its body in two phases of movement. By doing this, by advancing half of its body at each phase of its movement up the intestine, the worm is able to use more force in advancing each half section than if it had to advance the whole of its body at one movement.

Movement of a worm up the intestine means advancing against the downward thrusts of the peristaltic waves, and the currents of chyme created by these waves, and the worm would need to make a greater effort to move up the intestine than when it is static and maintaining its position in the intestine.

It is evident from Makidono's observations that no matter whether an ascarid is advancing up the small intestine or whether it is descending the intestine it always moves head first, and that even when it is static and is resisting displacement it combats displacement by making forward movements of its body.

Makidono also observed that regardless of the direction of movement of the *Ascaris* or whether it is static the worm maintains a position in which its body lies extended along the long axis of the small intestine and it curves its body only slightly to conform to the curves of the intestine. By doing this the *Ascaris* presses its body against the walls of the intestine and thus obtains a purchase against which it can make movements to advance its body head first.

The ineffectual movements of ascarids in a pan of water must therefore be due to the worms being unable to secure a purchase on the surface of the pan from which to make their forward movements.

The ridges of the closely set valvulae conniventes of the jejunum would afford an *Ascaris* a better surface to press against and to obtain a purchase from than the smoother walls of the ileum, and this would make the jejunum a more favourable habitat than the ileum. This is confirmed by Makidono's statement that 88 per cent of ascarids observed by him were in the jejunum.

Ascarids in the ileum may therefore be ascarids which were unable to resist effectively being propelled downwards from the jejunum.

ASCARIDS IN THE LARGE INTESTINES

Ascarids passed out in the stools are usually very much alive. Are they ascarids which were living in the colon, or have they passed through the colon enmeshed in the stools?

Ascarids would become more and more enmeshed in the stools towards the distal end of the large intestine where the contents are more and more solid, and worms enmeshed in solid stools would hardly be able to resist being passed out with the stools.

An *Ascaris* in the colon cannot obtain a purchase on the walls of the gut by the expedient of extending its body along the long axis of the gut because of the absence of ridges in the walls of the colon against which the worm could press its body. Moreover the lumen of the colon is so much wider than that of the small intestine that the worm could not get a purchase on its walls efficiently. Thus even in the right colon where the contents of the colon are liquid an *Ascaris* would be unable to make active movements of its own, and it would be swept on with the liquid contents of the right colon.

Surgeons who have dealt with cases of impaction of a mass of ascarids in the ileum by opening the abdominal cavity and massaging the bolus of worms on into the caecum have observed that while the bolus is sometimes expelled in the stools after these operations there are occasions when not a single ascarid is passed out in the stools after such a manœuvre. What could have happened? That it does happen there is no possible doubt.

Cole (1965) relates a case of this kind in which a second operation for intestinal obstruction for adhesions was done 10 days after the first operation. There were no worms in the colon at this second operation. Cole examined the stools passed after operations of this kind and found only ghost worms and fragments of worms' bodies in the stools.

The key to the mystery is to be found in the number of days elapsing after the operation before the stool is passed. If the stool is passed soon after the operation the bolus of worms would be expelled in this stool. If several days elapse before a stool is passed, as might well happen after an abdominal operation, the ascarids in the mass, unable to survive in the colon, perish and their bodies disintegrate so completely that evidence of their presence is to be found only on a microscopic examination of the stools.

It is likely that ascarids perish in the colon because they are unable to nourish themselves on the contents of the colon. Moreover even though they could swallow the liquid contents of the right colon the solid contents of the left colon either could not be swallowed or could be swallowed only with great difficulty.

THE MASSING OF ASCARIDS IN THE SMALL INTESTINE

The number of ascarids which can live in the human small intestine without causing any disturbance from their presence is truly remarkable. Louw (1966) estimated that up to 5000 ascarids can live in the small intestine without causing apparent harm.

The normal content of the small intestine is liquid chyme and the presence of so large a solid object as the body of an adult *A. lumbricoides* could not fail to set up waves of intestinal peristalsis which would be directed to displacing the worm down the intestine.

The fact that up to 5000 ascarids could live in the small intestine without giving a hint of their presence is evidence that the waves of intestinal peristalsis caused by such a large number of worms do not reach the degree of intensity which would result in bouts of acute circumumbilical abdominal colic.

When the number of ascarids in the small intestine is large the fortuitous presence of several ascarids at the same site would excite waves of intestinal peristalsis of a greater intensity than would be the case were these same worms more evenly distributed in the gut. Although these waves of intestinal peristalsis might not be noticed by the host they could be of sufficient intensity to drive ascarids from the more proximal reaches of the intestine down to where a few worms had already aggregated. All the worms would be resisting displacement down the intestine and their bodies would therefore be extended along the long axis of the gut with their heads directed to the proximal end of the gut. This deduction is supported by Makidono's observation: 'in the presence of a large number of worms, X-ray pictures without digital manipulation is sufficient to show that the mass of worms resembles a bundle of macaroni'.

The larger the mass of worms the greater the intensity of the waves of intestinal peristalsis set up from its presence. The mass may become so large that the increased peristalsis is felt by the host as bouts of acute colicky circumumbilical pain. Should the mass of worms be propelled by the peristaltic waves into the caecum the peristalsis and the acute abdominal colic would cease. The worms might then be expelled *en masse* in the stools a day or two later.

The mass of worms may impact in the small intestine as it is being propelled along it, and the mass may then be pushed on again by waves of intestinal peristalsis of an even greater intensity. On the other hand, the mass may impact firmly in the small intestine and remain impacted.

Regardless of whether the impaction of the small intestine is temporary or permanent the complete blockage of the lumen of the intestine by the mass of worms results in a rapid sequence of events which will progress to a fatal termination if the impaction remains.

The firm impaction of a mass of worms in the small intestine may also stretch the walls of the intestine to a degree which results in gangrene of the walls. In the first instance only patches of gangrene occur in the walls. Ascarids emerge through these patches of gangrene into the peritoneal cavity.

THE MIGRATION OF ASCARIDS INTO THE VERMIFORM APPENDIX

The first case to be recorded of the migration of an *Ascaris* into the lumen of the vermiform appendix (Blackadder, 1824) is worth recalling, not only because of its dramatic interest but also because it records the salient features of such a migration with great accuracy.

A man, 41 years of age, was struck down by a bout of excruciating abdominal pain lasting 3½ hours and terminating fatally. At the post-mortem examination an *Ascaris* was found in the lumen of the appendix. The worm had reached the tip of the appendix and only the pointed tail end of the worm projected into the lumen of the caecum.

This case affords clear evidence that the *Ascaris* having entered the appendix had continued advancing into its lumen till it was held up at the tip of the appendix. This appendix was therefore almost as long as the *Ascaris* as only the tip of the worm's tail projected into the caecum. The 3½-hour bout of unrelieved excruciating abdominal pain set up during the migration of the worm into this long appendix caused so much shock that death had resulted from it.

Death from the migration of an *Ascaris* into the lumen of an appendix would be an exceptional event, but in all other respects Blackadder's case records the mode of migration of an *Ascaris* into the appendix and the clinical disturbances resulting from this.

An *Ascaris* propelled into the caecum from the ileum would not be able to make effective movements of its own in the caecum. How then does it come to enter the lumen of the appendix? In Blackadder's case it is recorded that the *Ascaris* had entered the appendix head first. This confirms the deduction which has been made from Makidono's observations that an *Ascaris* can only move with its head forwards. The cases in which an *Ascaris* has entered the lumen of an appendix show that once the head of an *Ascaris* has entered the orifice of an appendix the *Ascaris* continues to advance into the lumen as far as the lumen will permit, which will usually be right up to the tip of the appendix. The deduction that could be made from all this is that the engagement of the head of an *Ascaris* in the orifice of an appendix must be a fortuitous circumstance because of the inability of the worm to make active movements of its own in the caecum, and that once the head of the *Ascaris* has entered the appendix this acts as a stimulus causing the worm to advance through the orifice and to continue advancing into the lumen of the appendix till its advance is held up at the tip or at a constriction in the lumen of the appendix.

The migration of an *Ascaris* into the lumen of an appendix sets up a bout of appendicular colic, and the epigastric or circumumbilical colicky pain from this together with tenderness over the appendix lead to these cases being admitted for operation as acute appendicitis. Examination of such appendices after appendicectomy has been done shows that there is no inflammation of the mucosa of the appendix.

In countries where ascarids are common parasites of man it is not uncommon to find on operating for acute appendicitis an appendix gangrenous at its tip and ascarids in the peritoneal cavity in the neighbourhood of the appendix. In some of these cases an *Ascaris* may be found projecting from the gangrenous tip of the appendix into the peritoneal cavity.

At first sight these findings would suggest that the ascarids had been attracted into the lumen of the appendix by the gangrene at its tip, and that after one *Ascaris* had emerged from the gangrenous tip of the appendix another *Ascaris* in the caecum had been attracted to enter the appendix. Such a view would presuppose that ascarids in the caecum could direct themselves towards the orifice of the appendix. Good reasons have been adduced for rejecting such a view.

A more rational explanation for these findings would be that once an *Ascaris* had entered the lumen of an appendix and had reached the tip of the appendix it would continue to try to move forward against the tip of the appendix. The stretching of the tip of the appendix resulting from this would impair the blood-supply to the tip of the appendix, and this could result in gangrene, an event all the more likely to occur in cases where the blood-supply to the tip of the appendix is poor. Once gangrene of the tip of the appendix occurs the worm continuing to push its head against the soft gangrenous tip of the appendix will push through the tip and emerge from it.

The fact that the worm continues to emerge from the tip of the appendix even after its head has emerged into the peritoneal cavity indicates that the stimulus causing the worm to advance comes not only from the encirclement of the head end of the *Ascaris* by the walls of the appendix, but also from the encirclement of the body of the worm by the walls of the appendix.

Why do other ascarids follow when one worm has emerged into the peritoneal cavity from the gangrenous tip of the appendix? It is likely that the passage of the first worm through the lumen of the appendix by dilating the orifice of the appendix makes the fortuitous engagement of the head of another *Ascaris* in the appendix easy.

The sequence of events postulated for these cases is confirmed by the finding that the mucosa of the appendix in such cases is normal right up to the gangrenous tip of the appendix. There is no pus in the lumen of these appendices.

ASCARIDS IN MECKEL'S DIVERTICULUM

A Meckel's diverticulum could accommodate several ascarids. Viliger (1929) recorded a case in which 64 ascarids had filled a Meckel's diverticulum so tightly that they had stretched its walls to a paper-like thickness.

How does this happen? An *Ascaris* which is ascending or descending the ileum would enter the orifice of a Meckel's diverticulum if this happened to be in its path. As the *Ascaris* could only withdraw its body by bending its anterior end backwards till its head pointed in the reverse direction, an *Ascaris* which had entered a Meckel's diverticulum would be unable to get out of the diverticulum since it would not have sufficient room to bend backwards. It could now only advance up to the tip of the diverticulum and other ascarids entering the diverticulum would have to do the same.

Cases have been recorded of the emergence of ascarids into the peritoneal cavity through the gangrenous tip of a Meckel's diverticulum. The sequence of events would be much the same as in the cases where ascarids emerged from the gangrenous tip of an appendix.

Despite the much wider lumen of a Meckel's diverticulum the escape of ascarids into the peritoneal cavity from its gangrenous tip is not followed by the escape of intestinal fluids into the peritoneal cavity. This must be due to the gangrenous tissue closing on to itself as the *Ascaris* pushes its way out of the diverticulum.

ASCARIDS IN THE BILE- AND PANCREATIC DUCTS

Ascarids in the bile- and pancreatic ducts would have entered these ducts from the duodenum. Makidono's (1956) observations established that the duodenum is not the normal habitat of *A. lumbricoides*. However, ascarids do occasionally reach the duodenum.

They could have been regurgitated into the duodenum from the jejunum during bouts of vomiting caused by the impaction of a mass of worms in the jejunum. Ascarids could also move up into the duodenum and would be likely to do so when the number in the jejunum became large. Louw (1966) stated that the presence of ascarids in the duodenum is strong presumptive evidence of biliary ascariasis. It would be unreasonable to infer from this that ascarids in the duodenum direct their course to the orifice of the duodenal papilla through which they reach the common bile-duct. It is more likely that the presence of ascarids in the duodenum sets the stage for the fortuitous engagement of the head of an *Ascaris* in the orifice of the duodenum papilla, and that should this happen the worm would be stimulated to advance into the ampulla of the bile-duct and from there into either the common bile-duct or the main pancreatic duct.

Observations made on the radiographic fluorescent screen confirm that ascarids enter the common bile-duct or the main pancreatic duct head first. Thus Liang, Wang, Wang, and Liu (1957) observed that an *Ascaris* enters the common bile-duct via the ampulla of the duct and that usually only the *proximal* third of the worm lies in the duct.

Lien (1959) claimed that if one end of the worm is pointed and the other end blunt fixation of the blunt anterior end of the worm at the ampulla of the bile-duct would be evidence that the worm had started to enter the ampulla. He also stated that if the tip of the tail of the worm was left in the duodenum the tail would be seen to move up and down, while the rest of the body of the worm would be fixed.

Ascarids in the Biliary Passages.—From the deductions which have been made about the advance of ascarids into the lumen of an appendix an *Ascaris* which has entered the common bile-duct from the ampulla of the bile-duct would be stimulated to advance up the duct so long as its body is gripped by the orifice of the duodenum papilla, but when the whole body of the worm has passed into the channel of the common bile-duct, that stimulus might cease because of the width of the duct and the worm would remain in the common bile-duct. As was the case with ascarids entering the appendix, once one *Ascaris* has passed through the orifice of the duodenal papilla other worms can follow more easily. Several ascarids may thus enter the common bile-duct, and Wang, Tang, Liu, and Kao (1956) report finding 48 ascarids in a common bile-duct.

Despite its width the common bile-duct could grip the bodies of ascarids sufficiently to stimulate them to advance into the right or the left hepatic duct and from there on into the intrahepatic ducts till they are stopped by the diminishing lumen of the more distal intrahepatic ducts.

Although a normal cystic duct with its spiral valve would not present an easy pathway for an *Ascaris* the dilatation of the cystic duct occurring when the common bile-duct dilates in response to obstruction of the orifice of the duodenal papilla during the passage of an *Ascaris* through it could allow a worm to travel via the cystic duct to the gall-bladder.

Bacteria carried in on the bodies of ascarids could set up suppuration in the biliary tract, and acute inflammation leading to suppuration could occur in the common bile-duct, the intrahepatic bile-duct, and the gall-bladder (Barrera-Ordonez, 1965). A liver abscess from suppuration in the intrahepatic ducts could rupture into the peritoneal, pleural, or pericardial cavity or into viscera within these cavities.

Could ascarids continue to live in the biliary tract? Apparent survival of ascarids for 1 month in the common bile-duct have been reported (Louw, 1966). When an *Ascaris* dies in the biliary tract its body disintegrates. Fragments of its body may form the nuclei for gall-stones (Robinson, 1966). The dead and disintegrating bodies of ascarids in the common bile-duct destroy the ductal mucosa and excite the formation of granulation tissue which becomes firm fibrous tissue stricturing the common bile-duct (Louw, 1966).

Ascarids reaching the intrahepatic ducts disintegrate and disappear, but fertilized ova in the bodies of female worms resist digestion and persist, and these ova stimulate the formation of granulomatous masses in the liver (Anstey, 1966). Segmentation and even embryonation may occur in ova embedded in these granulomatous masses.

Ascarids in the Main Pancreatic Duct.—An *Ascaris* may enter the main pancreatic duct from the ampulla of the bile-duct and should it do so it will move up the duct till it is held by the diminishing calibre of the distal end of the duct. Despite the small diameter of the main pancreatic duct some ascarids have found their way into this duct. Bacteria carried in on the bodies of ascarids and the irritant products from the dead and disintegrating bodies of the worms cause an inflammation of a variable degree of intensity which manifests as acute pancreatitis, subacute pancreatitis, or the formation of a pseudopancreatic cyst.

ASCARIDS IN THE PERITONEAL CAVITY

Deductions have been made as to the events determining the emergence of ascarids from the gangrenous tip of an appendix or a Meckel's diverticulum. Once the ascarids had entered the peritoneal cavity they would be as helpless as ascarids in a pan of water. They would remain close to the place from where they had emerged. Many of these ascarids are found in the pelvis, and it is likely that they were moved there by gravity.

Ascarids may enter the peritoneal cavity through suture lines made at operations on the gastro-intestinal tract as a result of the head of a worm engaging in the suture line. Ascarids may also enter the peritoneal cavity through gangrenous patches in the wall of a small intestine filled to bursting point with ascarids. Ludlow (1927) and Girges (1934) described the emergence of ascarids from the walls of apparently normal small intestine through circular holes a little smaller than the girth of the *Ascaris*. Girges (1934) refers to the suggestion made by Blanchard that these ascarids had nibbled through the mucosa of the small intestine and that this had resulted in a submucous abscess through which the ascarids had pushed their way out. This proposition is not supported by evidence. Moreover the mouth parts of an *Ascaris* are not adapted for biting and as Makidono (1956) observed the worm directs its head into the lumen of the small intestine and away from the mucosa.

Dickson and Cole (1964) provide good evidence for the view that ascarids which emerge from the walls of apparently normal intestine have done so through the softened floors of typhoid ulcers of the ileum.

The emergence of ascarids into the peritoneal cavity from the intestinal tract is not followed by a leak of intestinal content probably because of the closing in of the walls after the worm has passed. Nevertheless the escape of ascarids into the peritoneal cavity is fraught with the danger of peritonitis from bacteria on the bodies of the worms.

An *Ascaris* escaping into the peritoneal cavity could not normally move out of this cavity, but should the head of such a worm engage in the lumen of a tube draining the peritoneal cavity the *Ascaris* would advance along the tube and emerge on to the surface of the abdominal wall. The mechanics of this movement have been deduced from what happens when a worm enters the lumen of an appendix.

An *Ascaris* could not nourish itself in the peritoneal cavity. How long could it survive? Asada (1924) found that adult ascarids could survive for 2 weeks in the peritoneal cavity. When the worm dies in the peritoneal cavity its body disintegrates and disappears, but fertilized ova in the bodies of female worms persist, and if the ova remain together at the site of the worm's body the presence of so many ova in one place excites the formation of a large granulomatous mass. If the worm discharges its ova into the peritoneal cavity these ova became widely dispersed and each ovum becomes encysted in a miliary nodule of granulation tissue resembling the nodules of miliary tuberculosis. Such nodules have been observed and described by Cooray (1951) and de Silva (1957).

SOME OTHER MIGRATIONS OF *A. LUMBRICOIDES*

Many of the other migrations of *A. lumbricoides* can be explained on the basis of the deduction which has been made that if the head of an *Ascaris* engages in an orifice this will act as a powerful stimulus causing the worm to make its way into the orifice and to advance into any channel leading off from it.

Thus, although ascarids carried in the stools to the rectum are usually expelled in the stools, occasionally an *Ascaris* emerges from the anus by active movement of its own. How does this occur? If an *Ascaris* in the rectum chances to get its head engaged in the upper end of the anal canal the worm will be stimulated to advance into and push through the lumen of the closed anal canal till it has emerged from the anus.

The sudden emergence of an *Ascaris* from the nostril by active movements of the worm is the result of the head of an *Ascaris* entering the nostril and thereby being stimulated to emerge from the nostril. This unheralded occurrence shows that ascarids have reached and remained in the nasal passage without giving any hint of their presence there.

The sudden emergence of an *Ascaris* from the orbit medial to the eyeball is a very rare occurrence (Van Rensburg and Kark, 1958). In this case the head of an *Ascaris* in the nasal passages enters the orifice at the lower end of the lacrimal duct and this stimulates the worm to ascend the lacrimal duct and lacrimal sac, from where it emerges by pushing its way out through the softened walls of the lacrimal sac, after these walls have become inflamed by bacteria carried into the sac on the body of the worm.

The emergence of an *Ascaris* from the external auditory meatus is another rare event; the head of an *Ascaris* in the nasopharynx enters the orifice of the auditory tube and this stimulates the *Ascaris* to enter the auditory tube and the middle ear, from where it emerges by perforating the ear-drum, after the ear-drum has become softened by inflammation in the middle ear from bacteria carried in on the bodies of the worms.

These two events occurring suddenly indicate that ascarids reaching the nasal passages and the nasopharynx are not noticed by their host. Oschner, de Bakey, and Dixon (1949) describe cases of sudden suffocation from the impaction of ascarids in the larynx. These ascarids must have remained unnoticed in the laryngopharynx for some time.

Occasionally an *Ascaris* in the laryngopharynx may slip down the larynx and trachea and become impacted in an intrapulmonary bronchus, causing a lung abscess by inflammation from bacteria on the body of the worm.

These events indicate that ascarids in the pharynx or the nasal passages give no hint of their presence. How did they get there? They could have been projected into the laryngopharynx during vomiting. If ascarids in the pharynx and nasal passages are not felt by the host it would follow that ascarids could have ascended from the stomach by muscular efforts of their own, and that the movements of the worms making this ascent would not have been noticed.

Ascarids which had entered the oesophagus would be stimulated to ascend the oesophagus and pharynx from the contact of the walls of the oesophagus and pharynx with the bodies of the worms. The worms would have come from the stomach. There have been no studies on the lines of Makidono of the movements made by ascarids to travel from the jejunum into the duodenum and the stomach; nor have there been studies on the movements of ascarids in the stomach. Although the stomach is not the normal habitat of *A. lumbricoides*, ascarids occasionally live in the stomach, and Girges (1934) records finding large numbers of ascarids there.

Ascarids have been found in the lumen of an acutely inflamed uterine tube (Maxwell, 1924; Sterling and Guay, 1936). Ascarids could reach the uterine tube by emerging from the anus and ascending the vagina and uterus or they could enter the uterine tube through its abdominal orifice from the peritoneal cavity. Both these routes are, however, somewhat improbable.

Ascarids have been found in the urinary bladder of both male and female hosts. It is just possible that an ascarid emerging from the anus could have ascended through the female urethra to the urinary bladder, but this route would not be practicable in the case of a male subject. In the male, ascarids in the bladder have emerged from the external urethral meatus after traversing the male urethra and this would be explicable on the basis of the head of the worm engaging in the internal urethral meatus. Girges (1934) suggests that ascarids reach the urinary bladder through vesico-intestinal fistulae and he states: 'Ascarids may be seen passing through fistulae into the urinary and genital tract.' This would explain how ascarids might reach a uterine tube.

The most remarkable migration of ascarids was that recorded by Boettiger and Werne (1929), who found 2 ascarids at a post-mortem examination. One *Ascaris* was in the right ventricle and the other extended from the right ventricle to the pulmonary artery. These ascarids could have made their way into the inferior vena cava from the liver or from the peritoneal cavity, but there was no evidence of this at the post-mortem examination, and there the matter rests to this day.

Acknowledgement.—I am greatly indebted to Professor S. A. Dissanayake, Professor of Parasitology, University of Ceylon (Colombo), for help and advice in the preparation of this communication.

a
word of comfort
after surgery

UBRETID®
distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.

Full details of UBRETID ampoules and tablets are available upon request.

RADIOTOM 619

for surgical diathermy

The *RADIOTOM 619 is a universal electrosurgical apparatus designed to meet all the clinical requirements of general surgery and the special requirements of neurosurgery.

The RADIOTOM 619 can be placed on a trolley. The small dimensions and the low weight of the unit also make it possible to mount it in a ceiling column, build it into a wall or to use it on a wall bracket or a floor column.

Viaflex. Closest yet to the ideal I.V. solution system.

Lightweight collapsible plastic. Viaflex is all three. That gives easier handling, eliminates accidental breakage, and more important . . . .

No Air. Air venting isn't necessary, so the danger of air embolism is reduced. Where there's no air, there are no airborne contaminants.

Hangs up easily — and doesn't break. It does and it doesn't.

Supplementary medication — Viaflex is the only system with a separate, self-sealing port for supplementary medication. Air is excluded, even when drugs are added.

Clear calibration. With Viaflex, you know what you've given. Clear simple calibration is a vital feature.

AND EASY TO DISPOSE OF. It is.

A safer solution and a safer system. That's Viaflex.

BACTERIAL CONTENT OF THE GASTRIC JUICE

By A. B. MacGREGOR and P. W. ROSS
DEPARTMENTS OF CLINICAL SURGERY AND BACTERIOLOGY, UNIVERSITY OF EDINBURGH MEDICAL SCHOOL

SUMMARY

A survey has been made of the bacteria present in the gastric aspirate obtained from 280 preoperative and postoperative secretion studies. In the preoperative group viable bacteria were isolated from 41 per cent of patients, whereas in the postoperative group they were isolated from 73 per cent. The nature of the bacterial flora also differed in the two groups.

It is suggested that infected stomach contents may cause local sepsis following gastric surgery and that loss of the acid barrier may allow infection by pathogenic bacteria of the gut, producing postoperative diarrhoea.

ALTHOUGH several authors have investigated the bacterial content of gastric juice (Seley and Colp, 1941; Barber and Franklin, 1946; Schwabacher, Salsbury, and Loosemore, 1959; Irvin, Donaldson, and Smith, 1967; Drasar, Shiner, and McLeod, 1969) wide variations have been reported in the proportion of patients who have viable bacteria in the stomach, and little is known of the clinical significance of this. A prospective study conducted in the Department of Clinical Surgery, Edinburgh University, on the acid levels and bacterial content of the stomach in patients with peptic ulceration has been completed and the results are now presented.

MATERIALS AND METHODS

Specimens of gastric juice were taken from all patients who underwent Peptavlon secretion studies. After an overnight fast each patient had a polythene Ryle's tube passed and a specimen of gastric juice aspirated with a sterile syringe. This was sent for bacteriological examination. A second specimen was obtained in a similar fashion at the end of the fast and this was also processed bacteriologically. After neutralization of the specimens two blood-agar and two MacConkey plates were inoculated; one of each was incubated aerobically at 37° C. for 24 hours and the remaining two were incubated anaerobically at 37° C. for 48 hours. All organisms growing on the plates were identified by a Gram-stain, cultural characteristics, and biochemical reactions (Cruickshank, 1965), and the following species were isolated: *Candida* spp., *Escherichia coli*, *Staphylococcus aureus*, *Staphylococcus albus*, alpha-haemolytic streptococci, beta-haemolytic streptococci, *Streptococcus faecalis*, anaerobic streptococci, pneumococci, *Neisseria pharyngis*, *Proteus* spp., diphtheroid bacilli, lactobacilli, *B. anthracoides*, and *Clostridium welchii*.

Results in the postoperative group were obtained at follow-up secretion studies performed at least 2 months after operation.

RESULTS

Two hundred and eighty tests were performed; 181 on preoperative and 99 on postoperative patients. In the preoperative group 143 patients had duodenal ulcers, 5 had gastric ulcers, 2 had gastric carcinomas, and there were 31 miscellaneous diagnoses including hiatus hernia, cholelithiasis, and pyloric stenosis. Eighty-four of the 181 patients (41 per cent) had viable bacteria in the stomach and 108 bacterial growths were obtained. Growths were obtained from 4 of the patients with gastric ulcers, from both patients with gastric carcinomas, from 56 (39 per cent) of the cases of duodenal ulcer, and from 22 (71 per cent) of those with miscellaneous diagnoses.

Table I.—PREOPERATIVE GASTRIC FLORA AND ACID LEVELS FROM 181 PATIENTS

GASTRIC FLORA	ACID LEVELS (mEq./l.)				
	0–10	11–20	21–30	31–50	>50
Total No. of tests	15	32	41	79	14
No growth	1	12	26	47	11
Candida spp.	3	7	5	19	3
Esch. coli	1	1	2	1	1
Staph. aureus	1	1	2	—	—
Staph. albus	2	7	2	2	—
Alpha-haemolytic streptococci	5	4	2	1	—
Beta-haemolytic streptococci	1	—	1	—	—
Strept. faecalis	1	1	—	2	—
Anaerobic streptococci	1	1	1	1	—
Pneumococci	4	2	4	—	—
N. pharyngis	2	2	1	1	—
Proteus spp.	—	—	1	—	—
Diphtheroid bacilli	1	—	1	1	—
Lactobacilli	1	—	—	—	—
B. anthracoides	—	—	—	2	—
Cl. welchii	2	1	—	—	—
Total No. of growths	25	27	22	30	4

Organisms most frequently isolated were those of the *Candida* group, especially from the high acid secretors, whereas in the lower acid ranges organisms such as alpha-haemolytic streptococci, *Staph. albus*, pneumococci, and neisseriae were more common. Fifteen different groups of organisms were isolated (*Table I*). Ten (9 per cent) of the 108 growths were heavy, 34 (31 per cent) moderate, and 64 (59 per cent) scanty.

In the postoperative group, in which the majority of the 99 patients underwent vagotomy with a drainage procedure, there was a marked rise in the proportion of patients from whom bacterial growth was obtained and a considerable change in the proportions of organisms isolated (*Table II*). Whereas in the preoperative group growth of bacteria was obtained from 41 per cent of the patients, growth in the postoperative group was obtained from 73 per cent. Most patients in the latter group had acid levels of 0–10 mEq./l. compared with 30–50 mEq./l. in the preoperative group. The total number of growths from the 72 patients in the postoperative group was 145. The organism most commonly isolated was *Esch. coli*, although *Candida* spp., *Strept. faecalis*, *Staph. albus*, and alpha-haemolytic streptococci were commonly isolated, generally from those patients who had very low acid levels.

Bacteriological studies were conducted on the gastric juice of 46 patients both pre- and postoperatively in order to investigate the effect of surgery on the gastric flora of the same patient. The results are shown in *Table III*, and it can be seen that in terms of growth or no growth 22 of the 46 patients had postoperative findings which differed from the preoperative ones.

Table II.—POSTOPERATIVE GASTRIC FLORA AND ACID LEVELS FROM 99 PATIENTS

GASTRIC FLORA	ACID LEVELS (mEq./l.)				
	0–10	11–20	21–30	31–50	>50
Total No. of tests	66	17	9	5	2
No growth	14	2	4	5	2
Candida spp.	14	7	2	—	—
Esch. coli	28	2	—	—	—
Staph. aureus	6	3	1	—	—
Staph. albus	9	5	—	—	—
Alpha-haemolytic streptococci	10	2	1	—	—
Beta-haemolytic streptococci	3	—	—	—	—
Strept. faecalis	17	3	1	—	—
Anaerobic streptococci	3	1	—	—	—
Pneumococci	7	—	1	—	—
N. pharyngis	2	1	—	—	—
Proteus spp.	6	—	—	—	—
Diphtheroid bacilli	3	—	—	—	—
Lactobacilli	—	3	—	—	—
B. anthracoides	—	—	—	—	—
Cl. welchii	2	2	—	—	—
Total No. of growths	110	29	6	—	—

Table III.—PRE- AND POSTOPERATIVE GROWTH OF ORGANISMS FROM THE GASTRIC JUICE OF 46 PATIENTS

Growth of Organisms	*No. of Patients*
No growth pre- or postoperatively	10
No growth preoperatively but growth postoperatively	21
Growth preoperatively but no growth postoperatively	1
Growth pre- and postoperatively	14
Total	46

The most common difference was that growth was obtained from the postoperative specimens of the gastric juice, no growth having been obtained preoperatively. Furthermore, of the 14 patients whose pre- and postoperative specimens both produced growth, only 2 retained postoperatively the same organisms which had been cultured preoperatively. In 12 patients the flora was different, many coliforms and *Strept. faecalis* organisms being cultured from the postoperative specimens. Also, whereas growth from the preoperative specimens was mostly scanty, growth postoperatively was generally heavier.

DISCUSSION

That a wide variety of bacteria can survive in the stomach has been established by several authors. The proportion of patients with duodenal ulcers in whom this has been reported varies widely, however, though most authors are agreed that there is a very high incidence in patients with gastric ulcers and tumours (Seley and Colp, 1941; Barber and Franklin, 1946; Bach-Nielsen and Amdrup, 1965).

Barber and Franklin (1946) reported that 100 per cent of patients with duodenal ulcers had sterile gastric juice; Högman and Sahlin (1956) found 74 per cent; Seley and Colp (1941) reported 63 per cent; and Bach-Nielsen and Amdrup (1965) recorded only 30 per cent. In the present series 61 per cent of patients with duodenal ulcers had sterile gastric contents. These variations are very wide and are probably related to differing sampling and culture techniques.

It has been shown that there is an association between bacterial growth and various levels of acidity. In the present series this is demonstrated by the wide variety of bacteria grown from those patients with levels of between 0 and 20 mEq./l. compared with the comparatively few grown at levels above 20 mEq./l.

The possibility of local sepsis developing from infected gastric contents at operation was investigated by Bach-Nielsen and Amdrup (1965), but in only 9 out of 176 patients in their series was there any evidence that this had occurred. In the present series this was a possibility in only 1 patient, a 64-year-old man who had a laparotomy performed for abdominal pain and who was found to have a gastric carcinoma. Coliforms, predominantly *Esch. coli*, were grown from his postoperative gastric aspirate and a short period later he developed a wound infection from which similar bacterial species were cultured. His preoperative sample had yielded a light growth of *Esch. coli*. *Staph. aureus* or beta-haemolytic streptococci were isolated from 6 patients preoperatively but none of these developed postoperative sepsis, however.

The second point of interest in these results is the large number of organisms such as *Proteus* spp., *Esch. coli*, and *Strept. faecalis* which was cultured from postoperative samples compared with the small number of those obtained preoperatively. Because postoperative studies were not conducted until at least 2 months after operation this shows that persistence of these organisms in the stomach is not a temporary phenomenon due to regurgitation of intestinal contents during the phase of paralytic ileus, but is a more permanent sequel to upper gastrointestinal surgery. The reason for this is not clear at present, though the small numbers of patients with a high residual acid output did not have the same tendency to harbour coliform organisms as those with a very low acid output and it would appear, therefore, that the level of acid output is more important than regurgitation of small-bowel contents into the stomach.

Diarrhoea following upper gastro-intestinal surgery is probably due to a variety of causes. One of these may be that the loss, or partial loss, of the sterilizing barrier of the hydrochloric acid of the stomach renders this group of patients more susceptible to infection by small doses of pathogenic bacteria which would not be harmful to the normal person. Howie, Duncan, and Mackie (1953) suggested that diarrhoea following upper gastro-intestinal surgery may be bacterial in origin.

CONCLUSIONS

Two main points are made in this paper: first, that infected stomach contents may lead to local sepsis postoperatively and, secondly, that the loss or partial loss of the hydrochloric acid barrier of the stomach may facilitate infection by pathogenic gut bacteria.

A METHOD OF REPAIR OF MYELOMENINGOCELES

BY CARYS M. BANNISTER

DEPARTMENT OF NEUROSURGERY, THE GENERAL INFIRMARY AT LEEDS

SUMMARY

We believe that it is possible in the majority of myelomeningoceles to achieve a satisfactory repair of the lesion. To achieve dural closure the mobilization must be extensive and this can only be done if the anatomy of the myelomeningocele is thoroughly understood. Large skin defects can be closed with primary wound healing provided that the skin is mobilized extensively. To do this it is essential that the subcutaneous layer be retained intact to maintain the blood-supply to the skin. Only exceptionally large lesions require relieving incisions, skin-grafts, or swinging of skin-flaps.

IN recent years increasing interest has been shown in the treatment of myelomeningoceles, and early repair of the lesion is now commonly undertaken in many centres. In general, repair is not easy because it is difficult to identify structures in the grossly abnormal and variable anatomy of the myelomeningocele and because a large skin defect has to be closed. The aims of operating early are to preserve functioning neural tissue and to prevent bacterial invasion of the cerebrospinal axis. To maintain asepsis it is essential that neither the dura nor the skin suture lines should break down; this occurs all too commonly at present, with tragic results for the infant. Although many methods of repair of myelomeningoceles have already been described (Sharrard, Zachary, Lorber, and Bruce, 1963; Ingraham and Matson, 1969; Gurdjian and Thomas, 1970) the purpose of this paper is to report a procedure which permits adequate closure of both the dura and the skin. It is based on experience gained at early operation on 120 infants with myelomeningocele admitted to the Neurosurgical Unit of the General Infirmary at Leeds between October, 1966, and December, 1970.

ANATOMY OF THE MYELOMENINGOCELE

If the lesion is to be operated on successfully it is essential that the surgeon has a thorough understanding of the anatomy of the myelomeningocele, especially of the areas adjacent to normal tissue. It will be recalled that a myelomeningocele may present either as a protruding cyst or as a neuroplaque flush with the surface of the back; in either case the anatomical arrangements of the tissues are the same and there is no difference in the surgical approach.

Deep to the myelomeningocele the vertebral bodies may be normal or, especially at the thoracolumbar junction, wedged to form a kyphus (*Fig.* 1A) (Barson, 1970). The pedicles are rotated outwards to form a shallow gutter of which the lateral dimension is two or three times that of the normal spinal canal.

Dura lines the gutter and the lateral protrusion formed by the pedicles. It also covers part of the dorsal muscles before being reflected posteriorly into the dome of the cyst. At the points of reflection the dura is covered by skin and joins it at a variable distance from the summit of the cyst to form a thin membrane attached to the circumference of the neuroplaque.

The spinal cord, after leaving the spinal canal at the upper limit of the myelomeningocele, passes dorsally and comes to lie immediately beneath the dura. It then flattens out into the disk-shaped neuroplaque whether this lies in the dome of the cyst or flush with the back (*Fig.* 1). Spinal nerves arise from the deep surface of the neuroplaque and cross the underlying cavity which is filled with cerebrospinal fluid (C.S.F.). They then penetrate the dura and leave the spinal gutter through the intervertebral notches.

At the lower limit of the neuroplaque, depending on the spinal level of the lesion, either the spinal cord is re-formed or the nerve-roots arising from it gather together to form the cauda equina (*Fig.* 1).

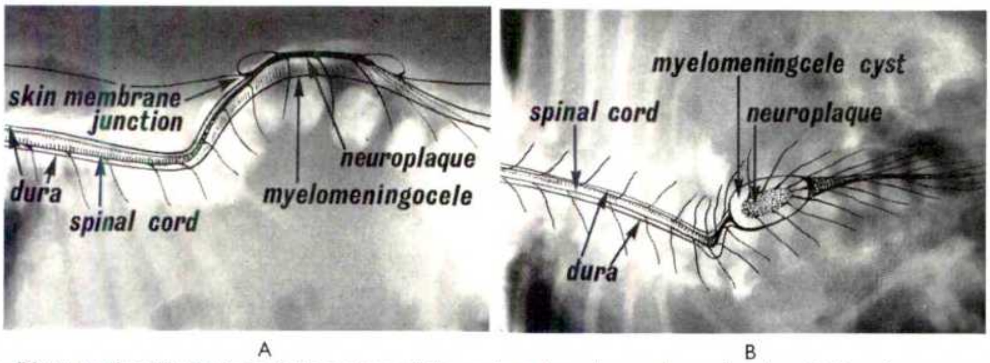
OPERATIVE PROCEDURE

Our aim is to operate on the infants within 8 hours of birth and this is usually achieved.

The umbilical vein is cannulated and any blood shed during the operation is replaced; the usual blood-loss is about 40 ml. We believe transfusion is necessary even in infants in good nutritional status, as wound healing occurs best if the postoperative haemoglobin is maintained at normal levels.

The anaesthetized baby is laid prone on a hot-water blanket. The myelomeningocele and a wide area of surrounding skin are cleaned with a soapy cleansing fluid; chemical antiseptics and alcoholic solutions are avoided because of the risk of damaging functioning neural tissue in the neuroplaque. To prevent mechanical damage to the neuroplaque the cleansing fluid is poured over the myelomeningocele—swabs are never used.

Skin hooks are placed in the skin at the proposed limits of the incision. Tension on the hooks supports the skin while an outline of the incision is scratched with a scalpel. The incision should always be planned to lie vertically because transverse and to a lesser extent oblique incisions are subjected to considerable stress by inevitable movements of the trunk during the healing period. It is stress of this kind which contributes significantly to delayed wound healing and even separation of the edges. At the lateral borders of the myelomeningocele the incision lies as close as possible to the skin–membrane junction but any abnormally thin or thickened skin must be excised because of its poor healing qualities. At the upper and lower limits of the incision triangles of skin are sacrificed to prevent unsightly bunching when the wound is sutured (*Fig.* 2).



A B

FIG. 1.—Diagrammatic representations of the anatomy of the myelomeningocele superimposed on lateral (A) and anteroposterior (B) radiographs of the spine.

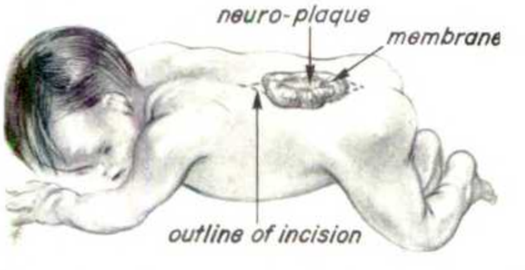


FIG. 2.—The dotted line indicates the position and extent of the skin incision.

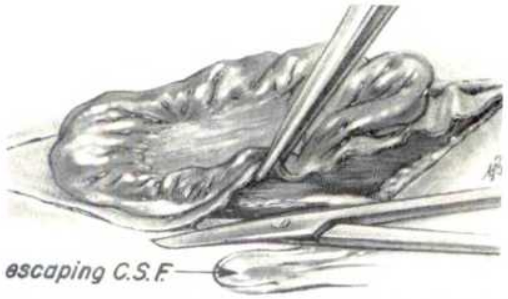

FIG. 3.—The incision at the skin–membrane junction enters the cyst of the myelomeningocele and C.S.F. escapes.

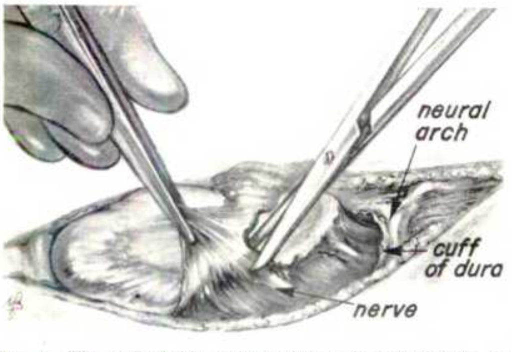

FIG. 4.—The cuff of skin and membranes is excised from the neuroplaque.

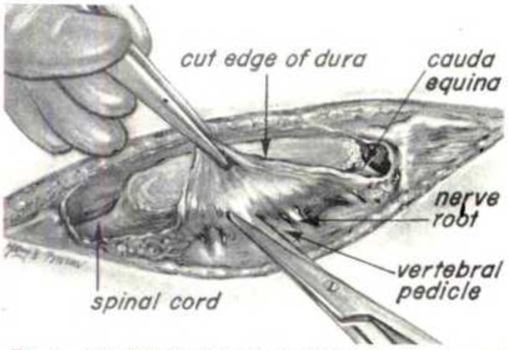

FIG. 5.—The dura has been dissected from the dorsal muscle and medially a band of fibrous tissue attaching the dura to the dorsal surface of the vertebral body is being divided to give adequate medial mobilization of the dura.

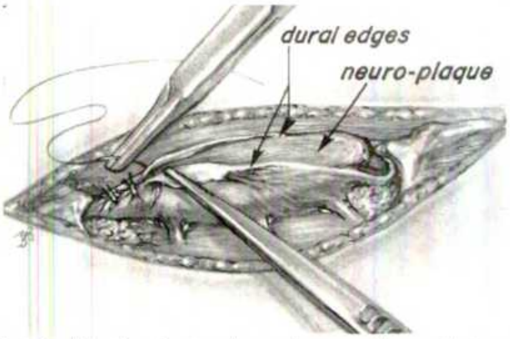

FIG. 6.—The dura is sutured over the neuroplaque with interrupted cat-gut sutures.

The incision is started laterally on each side with a scalpel and completed with scissors (*Fig.* 3) while the skin is pulled taut with hooks. The incision usually passes through the dura and provided that the myelomeningocele cyst has not previously ruptured C.S.F. escapes and the cyst deflates (*Fig.* 3). The skin and dura are divided together on each side until the points are reached where the dura starts to funnel inwards to join the dural sac in the spinal canal above and below the myelomeningocele. Beyond these points the skin and subcutaneous tissues are incised down to the deep fascia covering the dorsal muscles. Then the skin and underlying subcutaneous tissue, starting at the apices of the triangles, are dissected off the deep fascia and reflected towards the skin–membrane junction. As this is approached great care must be taken not to damage the underlying dura and the neural elements. The dura is uncovered as far as the skin–membrane junction and then divided. It is necessary to emphasize the care needed in making these divisions because of the proximity of the underlying neural elements which must not be damaged (*Fig.* 1). When these dural divisions have been made the neuroplaque is free of all surface attachments but it still has attached a cuff of skin and membrane. This cuff is excised from the neuroplaque (*Fig.* 4), but beforehand several filmy vascular adhesions passing from the membrane to the dura covering the dorsal muscles must be coagulated and divided. If the cuff of skin and membrane are left there is a risk that an intrathecal inclusion dermoid may develop in later years (Van Gilder and Schwartz, 1967). After excision of the cuff the neuroplaque is attached to spinal cord elements only and is laid on the dura lining the spinal gutter.

The next step is the mobilization of the dura so that it can be sutured over the neuroplaque to close the dural sac. It is our experience that provided the mobilization is extensive enough there is always sufficient dura to close the sac. The mobilization is started close to the cut edge of skin on each side by making an incision through the dura and the tissues lying superficial to the deep fascia of the dorsal muscles (*Fig.* 5). The line of the incision is kept close to the skin edge until the points are reached where the dura funnels into the spinal canal at the upper and lower ends of the myelomeningocele. The dura and its underlying tissue are dissected off the deep fascia of the dorsal muscles and reflected medially (*Fig.* 5). It is important to reflect the dura covering the muscle together with some underlying tissue because the dura is usually very thin and tears easily; the dura lining the spinal gutter is much thicker and stronger. Within the spinal gutter the dura is attached by several strong fibrous tissue bands to the dorsal surface of the vertebral bodies and these bands must be divided to achieve adequate medial mobilization (*Fig.* 5). The extradural fat lying in the spinal gutter must not be entered as it contains numerous blood-vessels of which large veins especially are easily damaged and bleed profusely. If any bleeding does occur it must be controlled by coagulation without damage to the nerve-roots as they emerge from the dura (*Fig.* 5). The attachment of the upper dural funnel to the laminae of the last complete neural arch is divided, and the dural edges are drawn together and sutured. The lower dural funnel seldom presents a clearly seen attachment for division, and at this end the dural edges are easily brought together.

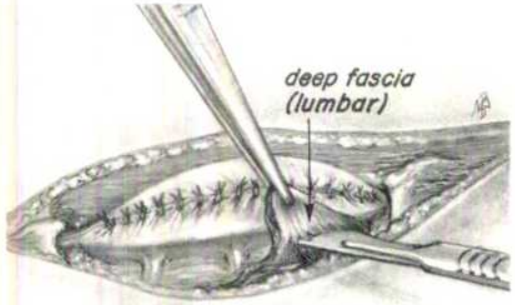

FIG. 7.—A flap of lumbar fascia is dissected from the dorsal muscles.

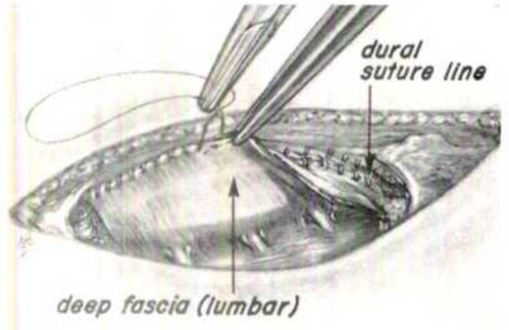

FIG. 8.—The lumbar fascia is sutured over the dural repair.

Interrupted chromic cat-gut sutures are used to evert the edges of the dura (*Fig.* 6). A continuous suture is never used, and unabsorbable suture materials are unsatisfactory because they are often extruded through the wound at a later stage with the risk of wound infection.

If the myelomeningocele lies in the lumbar region a flap of lumbar fascia may be used to give additional protection to the dural suture line. A flap is raised on one side, turned across the midline to cover the dural suture line, and stitched to the lumbar fascia on the opposite side (*Figs*. 7, 8). In the thoracic and sacral areas it is not usually possible to raise a satisfactory flap because the fascia is thin and tenuous.

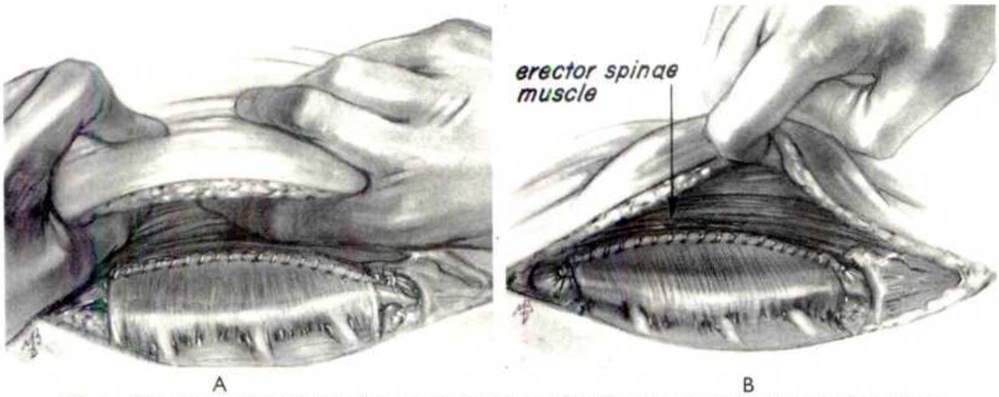

FIG. 9.—The skin together with its subcutaneous layer is mobilized by finger dissection from the deep tissue.

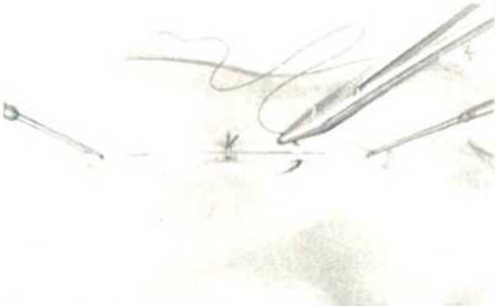

FIG. 10.—The skin incision is pulled taut with skin hooks and sutured with interrupted stitches.

Except in exceptionally large lesions it is always possible to mobilize the skin sufficiently to close the the skin defect, but since it must be mobilized very extensively and sutured under tension it is essential that its blood-supply should be preserved. The blood-supply to the skin arises from a network of vessels lying in the corium fed by arteries from the underlying muscles. When the feeding vessels are divided posteriorly the blood-supply depends on the anterior vessels. It is, therefore, essential that the skin be mobilized with the whole of its subcutaneous layer intact. Sharp dissection with a scalpel or scissors inevitably leads to the plane of dissection lying within the subcutaneous layer; blunt dissection by a finger in the subcutaneous fat strips the skin and the whole of the underlying subcutaneous layer without the use of excessive force (*Fig*. 9 A). On either side the plane between the subcutaneous layer and the deep fascia needs to be entered by sharp dissection, but once entered all further dissection is done with the index finger (*Figs*. 9 A, 9 B). Remarkably little bleeding is produced. Mobilization of the skin is carried out in all directions; only inferiorly do bands of fibrous tissue attaching the skin to the dorsal surface of the lower dural funnel require division. The exact extent of the mobilization should be no more than is necessary to close the defect. To test whether sufficient mobilization has been carried out the skin hooks are placed at the apices of the wound and pulled taut. If the skin edges at the centre of the wound can be brought together without undue tension then mobilization is adequate.

The suturing is started in the centre of the wound (*Fig*. 10). The skin edges are brought together without overlap using interrupted fine silk sutures on an atraumatic needle. The stitches are placed close together near the skin edges to minimize stitch tension.

POSTOPERATIVE MANAGEMENT

After the operation the baby is nursed prone for 10 days. The day after the operation the wound is inspected and any fluid collection under the mobilized skin is aspirated to prevent tension on the suture line. The sutures are removed on the tenth postoperative day.

Acknowledgements.—I wish to thank Mr. R. Myles Gibson for permitting me to operate on these patients and for his constant encouragement. I would also like to express my special thanks to Miss Mary Brown for the drawings used to illustrate this article.

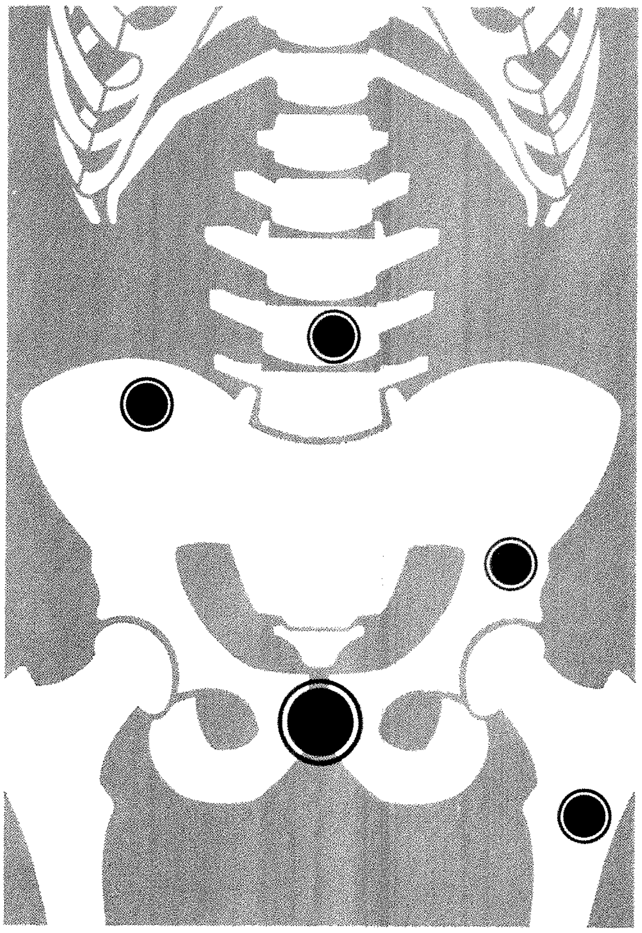
Honvan fosfestrol

Honvan is pharmacologically inert until dephosphorylated. It is selectively activated by tissues rich in acid phosphatase, notably the prostate, where it exerts a local cytotoxic action.

Regression of prostatic tumours and metastases is observed in most patients, including a majority of those unresponsive to standard oestrogen therapy.



a selective cytotoxic action
– in prostatic carcinoma

Response is rapid. **Honvan** is a practical alternative to surgery in acute urinary retention caused by prostatic carcinoma.

Gastric tolerance of **Honvan** is good and side effects comparatively rare.

Honvan is available for both intravenous and oral administration.

WB

morphine without vomiting

CYCLIMORPH* provides the benefits of morphine without the distressing side-effect of vomiting because, in addition to morphine, it contains the rapid-acting anti-emetic cyclizine.
CYCLIMORPH is indicated whenever the benefits of morphine are required, especially where nausea and vomiting would be harmful, as in myocardial infarction, pre-operative medication, post-operative pain and debilitated patients.

Cyclimorph

CYCLIMORPH Injection is subject to the DDA. It is issued in two strengths:
CYCLIMORPH 10 containing Morphine Tartrate (10mg) and Cyclizine Tartrate (50mg);
CYCLIMORPH 15 containing Morphine Tartrate (15mg) and Cyclizine Tartrate (50mg).

PYLORIC FUNCTION AND GALL-STONE DYSPEPSIA*

By A. G. JOHNSON
CHARING CROSS HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

Pyloric function was studied by means of a modified pyloric regurgitation test in which regurgitation was assessed both radiologically and biochemically. Forty-two tests were performed in 40 patients from six clinical groups: those with gall-stones with and without dyspepsia; those after cholecystectomy with and without persistent dyspepsia; and those with normal radiographs with and without dyspepsia. A close correlation was found between a history of flatulent dyspepsia and the detection of pyloric regurgitation in each matched pair of groups and in the series as a whole ($P < 0.001$). The time at which regurgitation occurred appeared to be significant. Regurgitation was not observed in symptomless subjects.

FLATULENT dyspepsia is a well-known symptom complex which has been defined by Rhind and Watson (1968) as follows: 'Epigastric discomfort after meals, a feeling of fullness so that tight clothing is loosened, eructation, with temporary relief and regurgitation of sour fluid to the mouth with heartburn.' Hess (1965) describes it as a sensation of fullness, slight nausea, and tension, especially after particular food, and points out that the discomfort cannot be provoked by palpation.

The relationship between these symptoms and gall-stones has been a subject for discussion for many years and it has been increasingly realized that cholecystectomy fails to relieve the symptoms in a proportion of cases. Maingot (1956) states, 'cholecystectomy has little or no effect in curing the unpleasant symptoms of flatulent dyspepsia'. Rhind and Watson (1968) found that 30 per cent of patients were no better after operation and 70 per cent were either cured or improved. Bodvall (1964) also found that one-third of his patients had persistent postoperative flatulent dyspepsia.

The problem was put into perspective by Price (1963), who found that amongst women between 50 and 70 years of age in an urban general practice there was an equal incidence of these symptoms in those with a normal and those with an abnormal cholecystogram, and he concluded that the relationship between the symptoms and gall-bladder disease was coincidental.

Any theory of the aetiology of flatulent dyspepsia must take all these observations into account. Rains (1964) points out that these symptoms are essentially related to the stomach rather than to the biliary tract and it is, therefore, in disordered gastroduodenal function that the link between these groups of patients is likely to be found. Capper, Butler, Kilby, and Gibson (1967) found a close corrrelation between a history of flatulent dyspepsia and the regurgitation of barium through the pylorus in radiological studies of patients with gall-stones. It was decided, therefore, to test the reproducibility of these findings with reference to patients with gall-stones and to those with a normal cholecystogram and barium meal by using a modified pyloric regurgitation test (P.R.T.).

MATERIALS AND METHODS

Forty-two tests were performed in 40 patients from three clinical groups, each group being matched with equivalent controls. Two patients were tested before and after cholecystectomy.

Group A: Preoperative patients with gall-stones and flatulent dyspepsia; 14 patients (10 female, 4 male); average age of 48 years.

Controls for group A: Preoperative patients with gall-stones and *no* flatulent dyspepsia; 6 patients (5 female, 1 male); average age of 42 years.

Group B: Patients after cholecystectomy with persistent flatulent dyspepsia; 3 patients (all female); average age of 60 years.

Controls for group B: Patients after cholecystectomy with *no* flatulent dyspepsia; 6 patients (4 female, 2 male); average age of 48 years.

Group C: Patients with a normal cholecystogram and barium meal and flatulent dyspepsia ('radiological negative dyspepsia'); 9 patients (4 female, 5 male); average age of 42 years.

Controls for group C: Patients with a normal cholecystogram and barium meal and *no* flatulent dyspepsia; 4 patients (2 female, 2 male); average age of 40 years.

The control patients for group C were under investigation for intermittent mild upper abdominal pain and did not have any of the symptoms under discussion. The stomach, pylorus, and duodenum were macroscopically normal either on barium meal or at subsequent operation in all but 1 patient in whom the pylorus was thought to be 'thickened'. Any patients with active duodenal ulceration or scarring were excluded from the study. (It will be seen that the controls were well matched for sex ratios and average age except in group B where 1 patient of 71 years affected the average.)

Method of Assessment of Symptoms.—A patient was considered to have flatulent dyspepsia if three or more of the following symptoms were present consistently up to the time of testing. They were considered to have no flatulent dyspepsia when none of the symptoms was present. The patients were interviewed and the history, being the more subjective part, was taken before the test started:—

Symptoms.—

Flatulence

1. Repeated belching.
2. Full-feeling after a normal-sized meal.
3. Inability to finish a normal-sized meal.

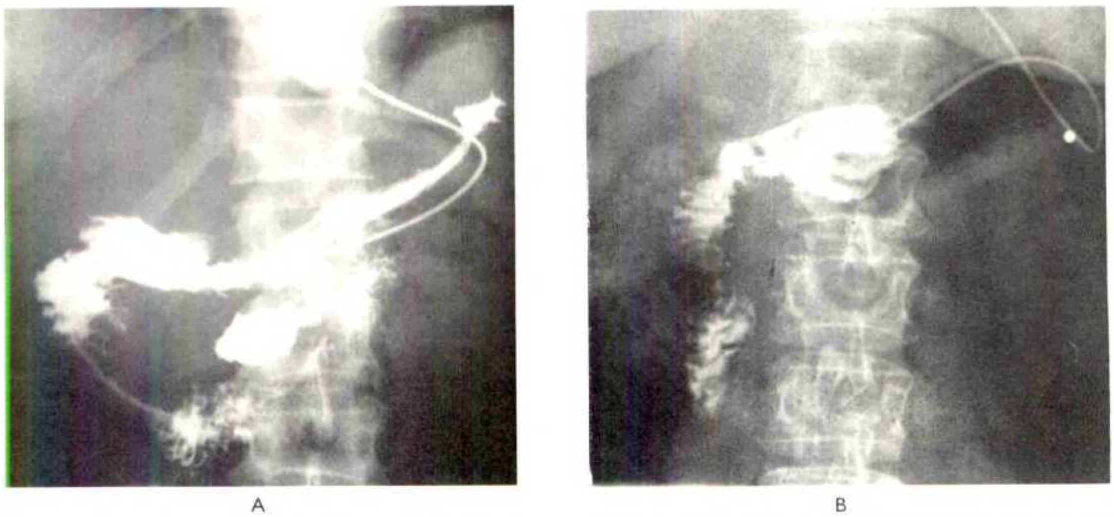
---

* Based on a communication to the Surgical Research Society in January, 1969.

4. Abdomen becomes blown-out so that the clothes have to be loosened.

Dyspepsia after meals

5. Burning discomfort in the epigastrium.
6. Burning discomfort in the chest ('heartburn').
7. Bitter fluid regurgitating into the mouth.



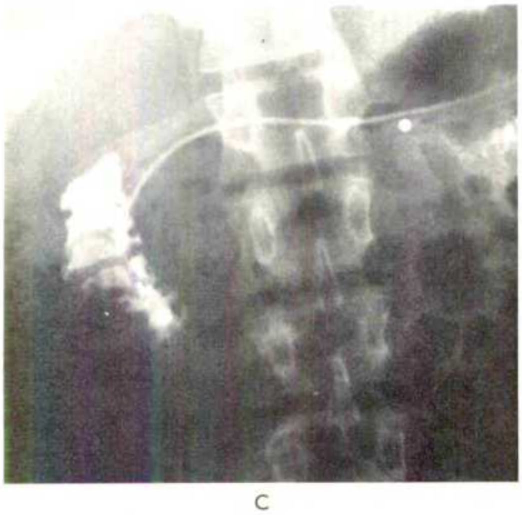


FIG. 1.—Radiographs showing (A) forceful regurgitation of barium into the stomach, (B) moderate regurgitation (note the radio-opaque gall-stones), and (C) no regurgitation.

8. Vomiting (? bile).
9. Nausea.

Some belching is normal. Inability to finish a normal-sized meal implies that the patient is hungry but feels full up soon after starting a meal and this must be distinguished from true anorexia. Heartburn is a symptom of oesophageal regurgitation and for this study it was only considered significant if accompanied by other symptoms. Vomiting is not a common part of the syndrome, but nausea and bloating may end in bilious vomiting.

Technique of the Test.—Capper's technique (Capper, Airth, and Kilby, 1966) was modified in several respects:—

1. A double-lumen plastic tube was used so that samples could be taken simultaneously from the stomach and duodenum, but the external diameter (3 mm.) of the tube passing through the pylorus was only a fraction larger than in Capper's technique.

2. The barium (Micropaque) which was in water was mixed with 0·9 per cent NaCl in the ratio 1 : 2 to produce a more physiological suspension (260 mosmol.). Ten ml. instead of 30 ml. were injected into the duodenum at any one time.

3. As the time that a patient should be screened radiologically is limited to a few minutes, the test was prolonged for $1-1\frac{1}{2}$ hours and evidence of regurgitation was detected biochemically. Duodenal and gastric samples were taken every 10 minutes (the stomach was emptied as completely as possible and 2 ml. of air were used to empty the tube after each sample) and each sample was analysed for *p*H, bilirubin concentration (method of Malloy and Evelyn, 1937), and tryptic activity (qualitatively and, in some patients, quantitatively by the method of Wiggins, 1967).

4. Because in many of these patients the symptoms are initiated or made worse by fatty foods, 7 ml. of arachis oil were put into the duodenum during the test in 25 of the patients.

5. The patient was always in the supine position with the gastric part of the tube in the body or fundus of the stomach, where any regurgitated fluid would collect, and well away from the pylorus. Capper and Airth (1970) found that posture affected the degree of regurgitation in patients with gastric ulcer but not in those with gall-stones.

The patients had not had anything to eat or drink for 4 hours before the test but they had not been starved overnight.

Method of Assessment of Regurgitation during the Test.—Regurgitation on a radiograph was classified as present (forceful, *Fig.* 1 A, or moderate, *Fig.* 1 B) or absent (*Fig.* 1 C), but only after at least four good contractions of the duodenal cap had been observed. The biochemical results were plotted on a graph. There are, therefore, in this test four ways of assessing regurgitation: (1) radiologically, (2) by the presence of barium in the gastric aspirate, or by the presence of (3) bilirubin, or (4) trypsin in the gastric samples (the *absence* of bilirubin or trypsin is only significant if their presence in the duodenal samples has been demonstrated).

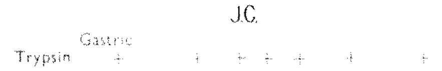

FIG. 2.—Graph of type-1 regurgitation. Note the presence of trypsin in the stomach throughout the test. Histograms represent the volume of the samples.

RESULTS

Positive evidence of regurgitation was of two types:—

Type 1: Where there was radiological (P.R.T. + ve) and biochemical evidence of pyloric regurgitation intermittently or continuously throughout the test; *Fig.* 2 shows the results of such a test in graph form. Trypsin is present in the gastric juice throughout.

Type 2: Where there was no radiological evidence of regurgitation (P.R.T. – ve), but regurgitation did occur after the duodenal bilirubin concentration had risen spontaneously (*Fig.* 3) or after arachis oil (*Fig.* 4).

Table I gives the results of the tests in each group of patients and shows the close correlation between a history of flatulent dyspepsia and the observation of pyloric regurgitation. When each group and its control are combined there is a highly significant statistical correlation ($P < 0{\cdot}001$). It should be noted that 2 patients with gall-stones (group A) and one with normal radiographs (group C) did not show any regurgitation despite a history of flatulent dyspepsia.

Table II shows each group subdivided by the type of regurgitation response observed and whether or not arachis oil was used. It could be argued that those who showed no regurgitation without the use of arachis oil might have shown regurgitation if it had been used. Even if it is assumed that all 7 subjects would have shown regurgitation the correlation between symptoms and regurgitation is still highly significant ($P < 0{\cdot}01$). When arachis oil was given to those already showing regurgitation (Type I) there was either an increase in the bilirubin concentration in the gastric juice (3 patients) or little change (6 patients).

Relationship between Pyloric Regurgitation and Flatulent Dyspepsia.—It is one thing to find a relationship between a *history* of flatulent dyspepsia and pyloric regurgitation in a test situation and quite another to say that the regurgitation causes the symptoms. However, of the 23 patients who showed regurgitation, 13 actually complained of their symptoms during the test at the time when regurgitation occurred. They said their symptoms were the same as those they had after meals and included sudden onset of belching as well as a bloated feeling, nausea, or burning epigastric discomfort. (These symptoms are included in the term 'nausea' in *Figs.* 3 and 4.) The first appearance of bile in the stomach just preceded the symptoms and in all cases they were immediately relieved by aspirating the gastric contents. Two out of 3 patients in whom a small quantity (5–10 ml.) of juice was aspirated from the

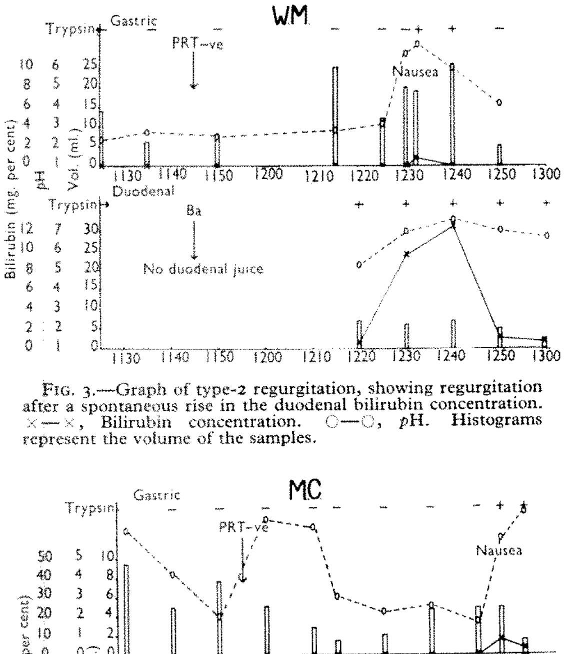

FIG. 3.—Graph of type-2 regurgitation, showing regurgitation after a spontaneous rise in the duodenal bilirubin concentration. ×—×, Bilirubin concentration. ○—○, *p*H. Histograms represent the volume of the samples.

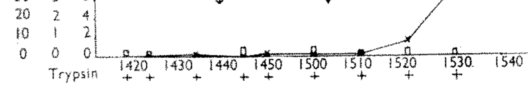

FIG. 4.—Graph of type-2 response, showing regurgitation after a rise in the duodenal bilirubin concentration following arachis oil.

duodenal tube and put down the gastric tube experienced their symptoms at this time. A similar observation was made by Toye and Williams (1965) in a patient with post-gastrectomy bilious vomiting.

A difference was observed in the rise of intragastric *p*H produced by the regurgitation between those who experienced their symptoms during the test and those who did not; 10 out of 13 in the first group showed a *p*H rise greater than 2, whereas only 2 out of 10 in the second group showed such a rise. (The initial *p*H levels did not differ significantly, but, *p*H being a logarithmic scale, the distributions were too far from normal for standard statistical tests to be applied.) This suggests that symptoms were produced by regurgitating duodenal juice if it was of sufficient quantity to change the gastric *p*H significantly, especially if this occurred suddenly.

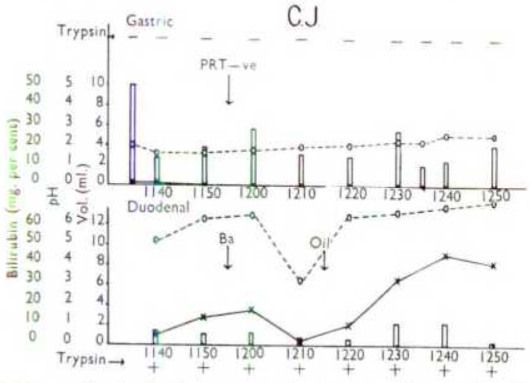

FIG. 5.—Graph showing no regurgitation even after arachis oil.

Table I.—CORRELATION BETWEEN A HISTORY OF FLATULENT DYSPEPSIA AND EVIDENCE OF PYLORIC REGURGITATION

GROUP	REGURGITATION OBSERVED	REGURGITATION NOT OBSERVED
A. Patients before cholecystectomy:—		
History of flatulent dyspepsia	12	2
No history of flatulent dyspepsia (controls)	0	6
B. Patients after cholecystectomy:—		
History of flatulent dyspepsia	3	0
No history of flatulent dyspepsia (controls)	0	6
C. Patients with normal radiographs:—		
History of flatulent dyspepsia	8	1
No history of flatulent dyspepsia (controls)	0	4
All patients:—		
History of flatulent dyspepsia	23	3
No history of flatulent dyspepsia (controls)	0	16

$\chi^2 = 33{\cdot}1$; $P < 0{\cdot}001$.

DISCUSSION

The Problem of 'Normal' Controls.—The selection of controls for a study such as this presents difficulties: to be sure that the control patient is 'normal' a cholecystogram and barium meal would have to be performed, as symptomless gall-stones and duodenal ulcers are not uncommon in this age-group. This is ethically unjustified in a symptomless person. The control patient, therefore, becomes one who is symptomless (*see Fig.* 5). It is for this reason that each group was compared with controls as similar as possible but without the symptoms under consideration. Capper and others (1966) found no regurgitation in 15 volunteer patients without any gastro-intestinal symptoms. Flint and Grech (1970) found regurgitation in 1 of 12 symptomless volunteers. We have studied 9 healthy young volunteers by the present technique (arachis oil being given in 3) and found slight radiological evidence of regurgitation in 1.

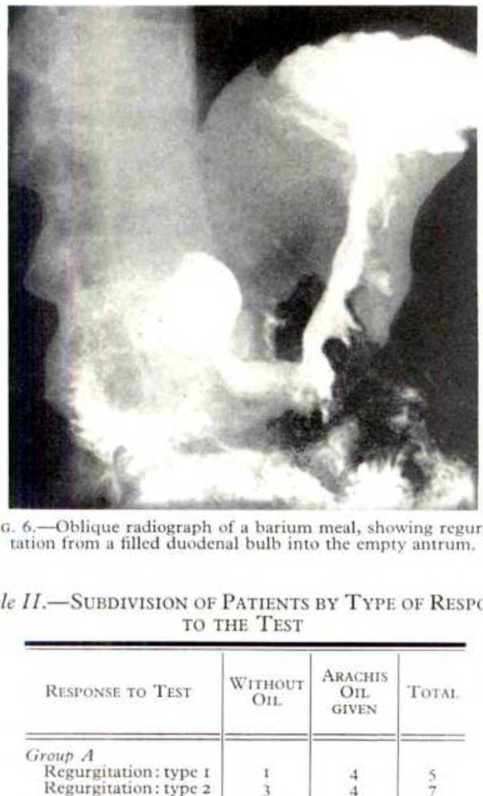

FIG. 6.—Oblique radiograph of a barium meal, showing regurgitation from a filled duodenal bulb into the empty antrum.

Table II.—SUBDIVISION OF PATIENTS BY TYPE OF RESPONSE TO THE TEST

RESPONSE TO TEST	WITHOUT OIL	ARACHIS OIL GIVEN	TOTAL
Group A			
Regurgitation: type 1	1	4	5
Regurgitation: type 2	3	4	7
No regurgitation	2	6	8
Group B			
Regurgitation: type 1	0	1	1
Regurgitation: type 2	0	2	2
No regurgitation	3	3	6
Group C			
Regurgitation: type 1	3	4	7
Regurgitation: type 2	0	1	1
No regurgitation	2	3	5

Criticism of the Test.—The obvious criticism of the technique of the test described in this paper is that the presence of the tube through the pylorus is itself responsible for the regurgitation. There are four answers to this criticism:—

1. Regurgitation did not occur in 19 out of the 42 patients tested, despite a tube being through the pylorus.

2. Regurgitation can be seen in about 50 per cent of routine barium meals if a careful technique is used (MacLean, 1969—*see Fig.* 6). This does not,

however, imply that regurgitation is a normal phenomenon as all the patients referred for barium meals have some gastric symptoms.

3. The duodenum can be filled with barium and then the tube carefully withdrawn into the stomach. This was done in 2 patients and subsequent regurgitation occurred in 1 and not in the other.

4. Regurgitation can be seen in some patients when the duodenum is filled via the common bile-duct at T-tube cholangiography (*Fig.* 7). This observation has recently been used as an argument that regurgitation is a physiological phenomenon as it was observed in one-third of 36 patients tested 10–14 days postoperatively (Beneventano and Schein, 1970). However, this is not a physiological situation and the present studies suggest that a proportion of patients will continue to show regurgitation after biliary operations. It is mentioned here to show that regurgitation does not occur only when a tube is across the pylorus.

The Timing of Pyloric Regurgitation.—Of particular interest are the patients who only show regurgitation after the duodenal bilirubin concentration rises (type 2), usually when the gall-bladder bile first appears in the duodenum but sometimes when there is an increase in bile-flow with a radiologically non-functioning gall-bladder or after cholecystectomy. Thomas and Baldwin (1969) found that duodenal motility is greatly affected by small quantities of bile or bile-salts in contact with the mucosa. Adlercreutz, Pettersson, Adlercreutz, Gribbe, and Wegelius (1960), while studying the effect of cholecystokinin on the duodenum, found an increase in tone and markedly accelerated contractions coinciding with the entrance of bile into the duodenum which failed to occur after cholecystectomy. These findings may provide a clue to the cause of duodenal juice regurgitation of type 2 and of those patients whose symptoms are cured by cholecystectomy. The effect of bile in the duodenum is not merely a result of an increase in volume, as the injection of a similar volume of barium saline is not accompanied by regurgitation. The regurgitation is also not solely due to inhibition of gastric motility by the arachis oil, as it occurs 25–30 minutes after the oil is given (*see Fig.* 4), whereas inhibition is complete within 4 minutes (Quigley, Werle, Ligon, Read, Radzow, and Meschan, 1941). The only clinical difference found between patients showing a type-1 and those showing a type-2 response was that type-1 patients tended to experience their symptoms at varying times after a meal whereas all except 1 of those with a type-2 response experienced their symptoms about half an hour after the meal. This is the time of maximum bile-flow and is the time after giving arachis oil that regurgitation occurred during the test (*Figs.* 3, 4).

Effects of Duodenal Juice in the Stomach.—If bile in the stomach is an aetiological factor in gastric ulceration, as has been suggested (Capper, 1967; Rhodes, Barnardo, Phillips, Rovelstad, and Hofman, 1969), then many of these patients with flatulent dyspepsia would be expected, sooner or later, to develop a gastric ulcer. It would need a long-term follow-up to demonstrate whether or not this occurs but other factors may be involved. For example, the length of time that the duodenal juice is in contact with the gastric mucosa may be important and a delay in gastric emptying may also be necessary for ulceration to occur.

CONCLUSIONS

1. There is a close correlation between a history of flatulent dyspepsia and radiological and biochemical evidence of regurgitation of duodenal juice into the stomach. This is true for patients before and after cholecystectomy and for those with a normal gall-bladder.

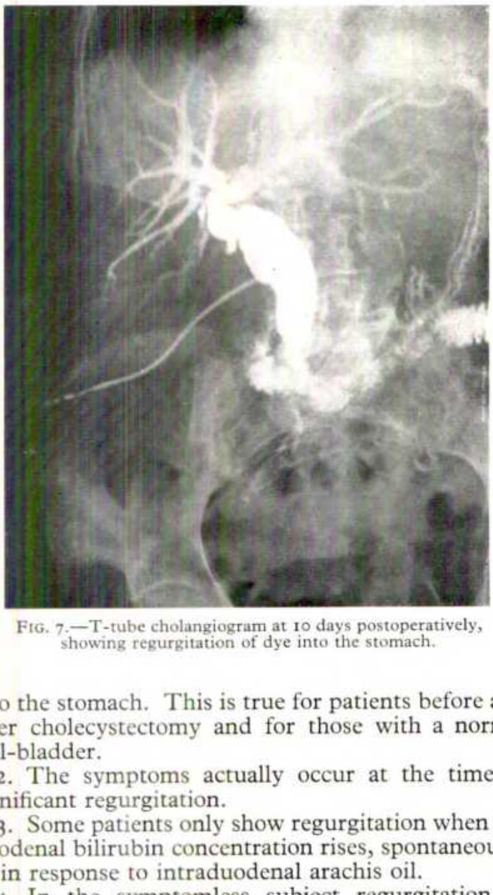

FIG. 7.—T-tube cholangiogram at 10 days postoperatively, showing regurgitation of dye into the stomach.

2. The symptoms actually occur at the time of significant regurgitation.

3. Some patients only show regurgitation when the duodenal bilirubin concentration rises, spontaneously or in response to intraduodenal arachis oil.

4. In the symptomless subject regurgitation of duodenal juice does not occur in the test situation.

The theory that regurgitation of duodenal juice is a significant factor in the production of the symptoms of flatulent dyspepsia provides a satisfactory explanation of the clinical findings. It explains why the same symptoms may occur in patients with a normal gall-bladder and in those with an abnormal gall-bladder, and why some patients have no symptoms of flatulent dyspepsia despite the presence of gall-stones. Those with a severely malfunctioning pylorus have symptoms which are little altered by cholecystectomy, but it is those whose pyloric malfunction is in some way related to their gall-stones who will be relieved by cholecystectomy; the mechanism of this relationship is the subject of further study.

Acknowledgements.—I am very grateful to Professor A. J. Harding Rains and Mr. H. L. Cochrane for allowing me to study patients under their care, and to Mr. R. C. Fuller for *Fig.* 7. I am also indebted to Dr. D. MacPherson and Miss

D. Monkton for allowing me to use screening facilities, and to Mr. C. J. C. Kirk, Miss V. J. Ranson, and Miss C. March for technical assistance.

The Photographic Department of Charing Cross Hospital provided the illustrations.

The work was supported by a Charing Cross Hospital Governors' Research Fellowship and forms part of the requirements for the M.Chir. degree of Cambridge University.

A MODIFICATION OF THE FINNEY PYLOROPLASTY

BY C. WASTELL

WESTMINSTER MEDICAL SCHOOL, LONDON

MANY different techniques have been used for the production of a pyloroplasty since Finney's original description in 1902. The one to be described here has been used in a personal series of 50 cases and is both simple and quick to perform. In none of the cases thus operated on has there been any complications attributable to the pyloroplasty.

THE TECHNIQUE

The second part of the duodenum is mobilized by dividing the peritoneum along its lateral border—the so-called 'Kocher manœuvre'. This results in exposure of the inferior vena cava and is not complete until the second part of the duodenum can be lifted forwards and to the left towards the midline.

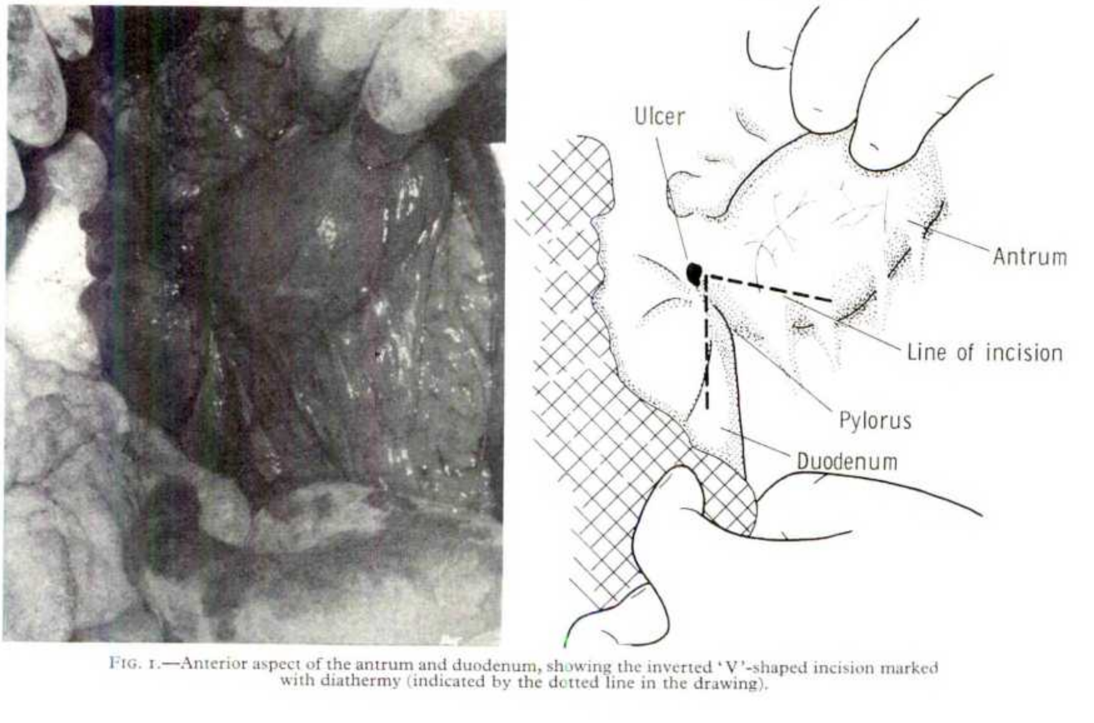

FIG. 1.—Anterior aspect of the antrum and duodenum, showing the inverted 'V'-shaped incision marked with diathermy (indicated by the dotted line in the drawing).

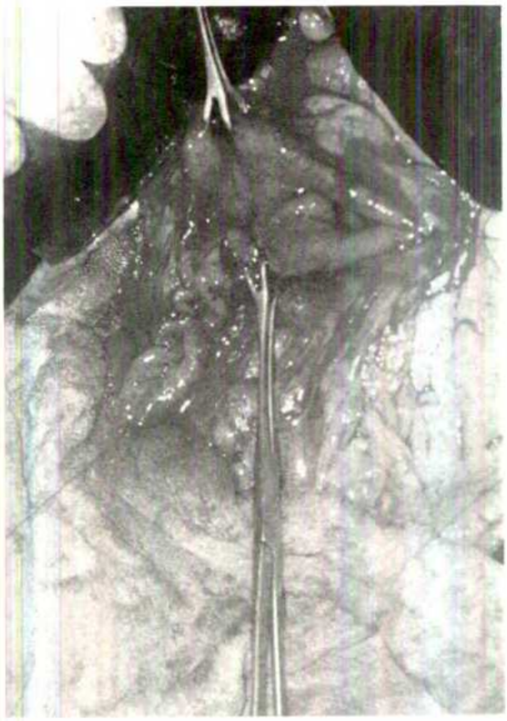
Fig. 1 shows the inverted 'V'-shaped incision, the apex being centred on the pylorus. Each limb of the 'V' is 5 cm. long, making the total length of the incision 10 cm. It has been found an advantage to measure this distance accurately with a ruler and a pair of callipers. The incision itself is made using the diathermy, and 00 chromic stay sutures are placed at either end. *Fig.* 2 shows the completed incision, the pyloric ring being marked by two Babcock forceps.



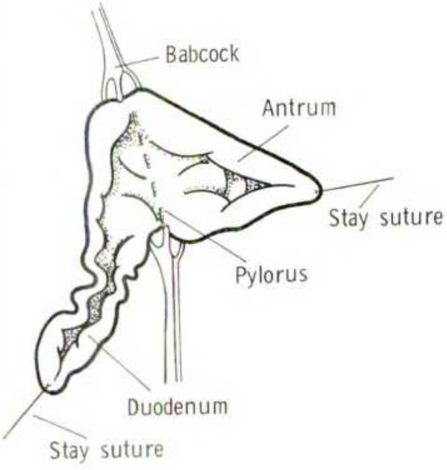


FIG. 2.—The incision has been made in the antrum, pylorus, and duodenum. The ends of the incision are being held apart by means of stay sutures and the pylorus by the two Babcock forceps.

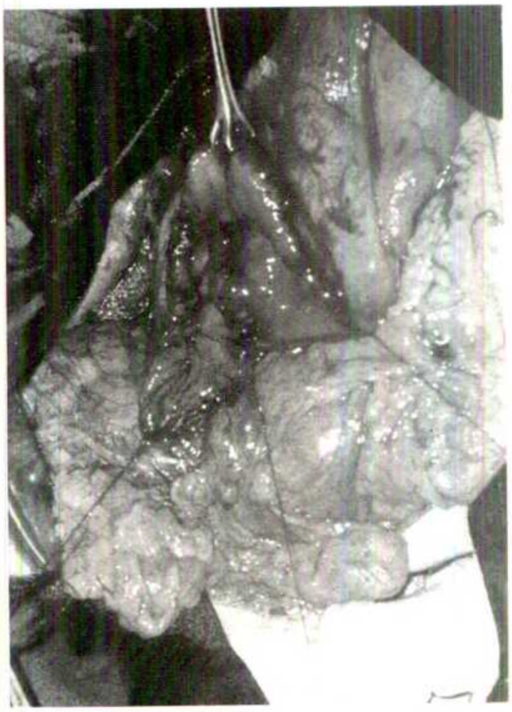

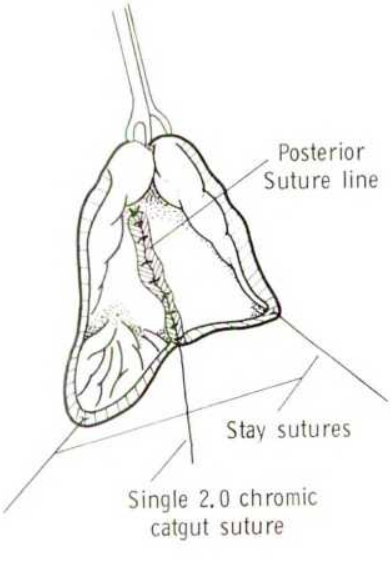

FIG. 3.—The posterior suture line is half completed.

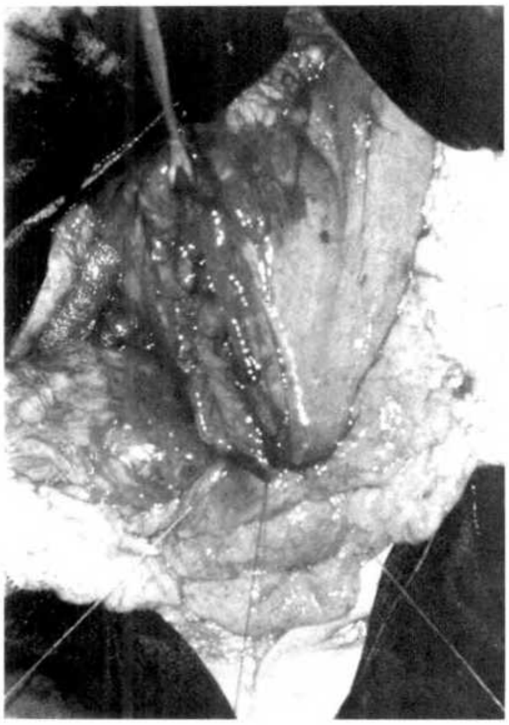
The suture line for the pyloroplasty consists of one layer of 00 chromic catgut using a 30-mm. half-circle atraumatic needle. The suture line commences at the pylorus, at the point that it is being gripped by the lower Babcock forceps in *Fig.* 2. A simple all-coats stitch is used and the half-completed posterior wall of the pyloroplasty is illustrated in *Fig.* 3. *Fig.* 4 shows the nearly completed posterior line; the two stay sutures have almost been brought together. When the two stay sutures meet they are tied



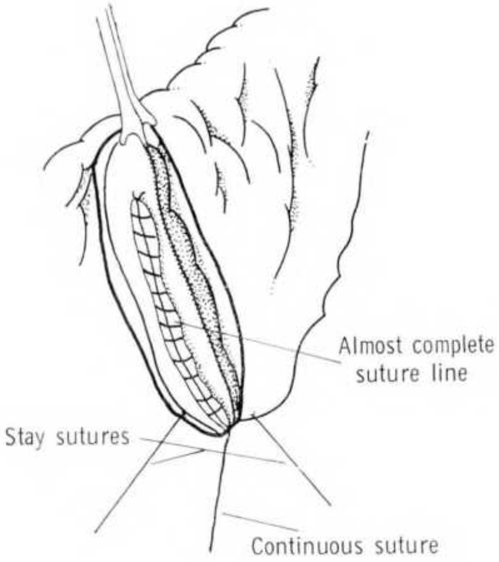


FIG. 4.—The posterior line is now nearly completed. The two stay sutures at either end of the incision are almost approximated.

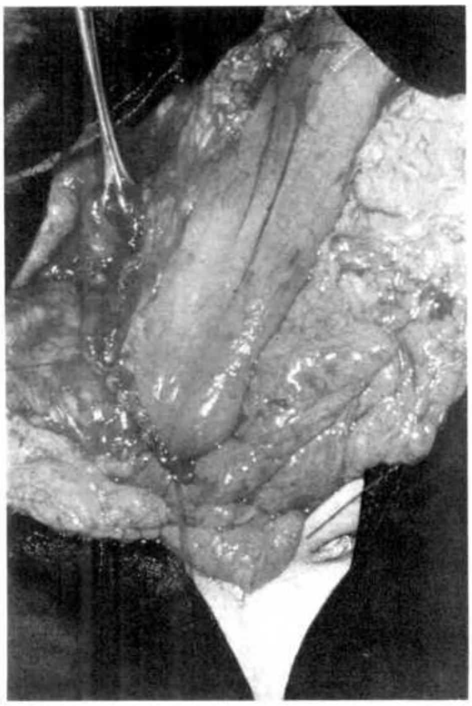

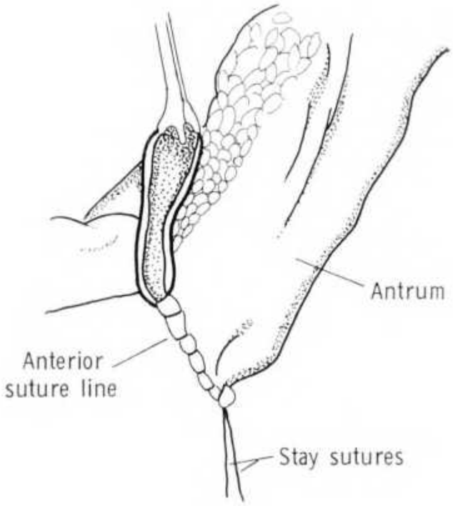

FIG. 5.—The stay sutures have been tied and the anterior suture line is half completed.

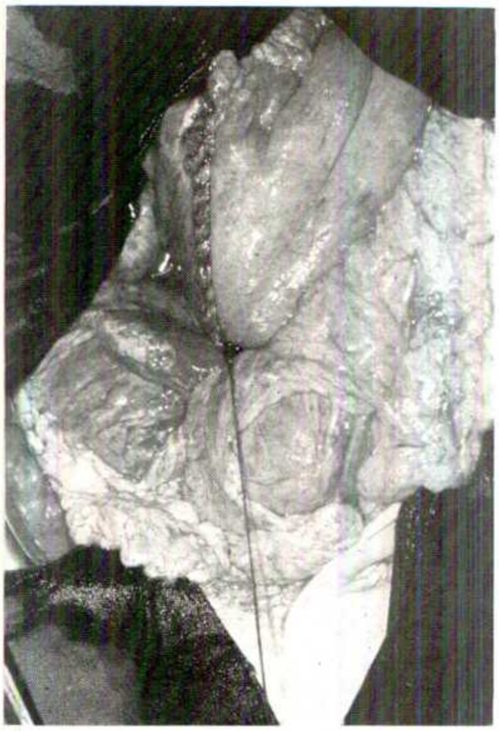
together and this point forms the inferior part of the pyloroplasty.

The continuous suture is now carried upwards on the anterior aspect, again using the simple over-and-over stitch, and *Fig.* 5 shows this anterior suture line half completed. The completed suture line is shown in *Fig.* 6.



The stoma between the antrum and the duodenum is the width of the tips of three fingers and is not seriously compromised by the inverted posterior suture line. The operation is completed by covering the anterior suture line with a layer of omentum lightly sutured in place.

DISCUSSION

The main feature of this modified Finney pyloroplasty is the closure of the incision with a single 00 chromic catgut suture. The advantage of this is twofold. First, a minimum of tissue is inverted and the reduction in the lumen is, therefore, slight. Secondly, it is quick to perform.

The strength of a suture line performed with a single suture is bound to be questioned. However, in the 50 cases operated on no leak has occurred in spite of the fact that no postoperative intragastric tube of any description was employed and patients were allowed 15 ml. of water per hour as soon as they had recovered from the anaesthetic. Naturally, if after the anastomosis has been finished it does not look satisfactory, then extra interrupted catgut sutures are introduced before the completed suture line is covered with omentum. Similarly, if in the first few postoperative days there is evidence of gastric retention, a nasogastric tube is introduced although none of the 50 cases reported here has required intubation.

We prefer to use catgut for these anastomoses because of the tendency of non-absorbable sutures to work their way into the lumen of the stomach and duodenum. Several cases in which non-absorbable sutures were used originally have been re-operated on and a piece of silk or thread has been found projecting from the suture line creating a 'foreign-body' anastomotic ulcer.

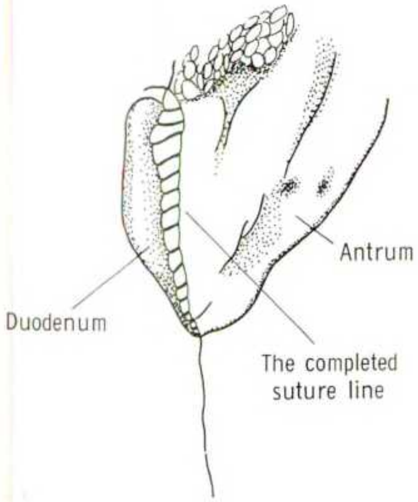


FIG. 6.—The completed anterior suture line.

The most common type of pyloroplasty used in this country is the Heineke–Mikulicz which suffers from two disadvantages. The first of these is that the centre of the suture line tends to be under some tension and the sutures may tear away from the duodenum. The second is that the stoma is not quite so large as that which results from a Finney pyloroplasty.

This modified Finney pyloroplasty can be used when there is considerable scarring of the first part of the duodenum. It therefore has the advantages of speed, reliability, and general applicability.

Acknowledgements.—My thanks are due to Dr. P. Hansell, Mr. D. Gibbons, and the Department of Medical Illustration for the line drawings and photographs, and also to Professor H. Ellis, Mr. D. Harland, Mr. R. Fidian, and Mr. E. Harper for referring some of the 50 cases.

AORTO-ENTERIC FISTULAE: AN UNCOMMON COMPLICATION OF ABDOMINAL AORTIC ANEURYSMS

By J. P. D. RECKLESS, I. McCOLL, AND G. W. TAYLOR

PROFESSORIAL SURGICAL UNIT, ST. BARTHOLOMEW'S HOSPITAL, LONDON

SUMMARY

Three cases of aorto-enteric fistula which have been treated successfully by resection of the aortic aneurysm are described. Only 5 other successful cases have been reported. One hundred and thirty-one cases are reviewed and analysed, and though more than half of these survived for 24 hours or longer after the first gastro-intestinal haemorrhage, no untreated long-term survival has been recorded. We feel that urgent assessment and early corrective surgery is the only treatment which offers a reasonable chance of survival.

ABDOMINAL aortic aneurysms may remain asymptomatic for many years, but eventual intraperitoneal or retroperitoneal rupture is usual. Rupture into other structures is much less common. Rupture into the gastro-intestinal tract has been reported in 128 cases, 15 of which have been treated surgically with 5 survivors. Three cases have been seen at St. Bartholomew's Hospital since 1968 and have been successfully treated. These are described here and the condition is reviewed.

CASE REPORTS

Case 1.—T. B., a 63-year-old man, was transferred from his local hospital on 23 March, 1968, with a history of rectal bleeding and severe back and left loin pain for 1 day. Two and a quarter years previously an abdominal aortic aneurysm had been wrapped with three separate 1·2-cm. Teflon bands. Three hospital admissions for abdominal pain had subsequently been necessary, and a left superficial femoral artery occlusion had occurred 2 years after the operation.

Blood-pressure was 130/85 and pulse 84 per minute. A large expansile mass was palpable at the left costal margin and loin. The rectum contained dark blood.

At laparotomy a 12-cm. atheromatous infrarenal aneurysm was found to have become adherent to the small intestine between the Teflon bands and a 1-cm. aortojejunal fistula was present 30 cm. distal to the duodenojejunal junction. The aneurysm had also ruptured posteriorly into the left psoas muscle and the pelvis. The aneurysm was resected and replaced by a 19 × 9·5-mm. knitted Dacron bifurcation graft, while the jejunum was closed with 00 chromic catgut in two layers. Bilateral lumbar sympathectomy was performed, and following this the external iliac blood-flow was greater than 800 ml. per minute on each side. Reperitonealization of the graft was not possible.

Postoperative progress was satisfactory and the patient was well 4 years later.

Case 2.—G. Y., a 73-year-old woman, had been hypertensive for 10 years and an aortic aneurysm had been diagnosed at laparotomy 3 years earlier. On 4 Oct., 1968, she passed blood per rectum and was admitted to hospital. A similar massive bleed 1 month previously and haematemesis and melaena 3 months previously had been treated conservatively.

The patient was in moderate circulatory failure with a relatively low blood-pressure of 125/80. A moderate-sized abdominal mass was present, but there was no bruit. Haemoglobin was 7·1 g. per 100 ml., and P.C.V. was 22 per cent. A retrograde aortogram showed a saccular aortic aneurysm 3 cm. below the renal arteries, and a diagnosis of aorto-enteric fistula was made.

At laparotomy the duodenum was adherent to an atheromatous aneurysm and a 2·5-cm. defect was present in the anterior wall of the aneurysm with a 2-mm. fistula into the third part of the duodenum. In view of the potentially infected field a Dacron prosthesis was not used and an aortic aneurysmorrhaphy was performed. The aortic tube was reconstituted by an overlapping technique using two layers of 000 Mersilene and the duodenum was closed directly. Duodenal hold-up occurred for 2 weeks before adequate gastro-intestinal motility returned.

The patient was well 3½ years later and peripheral pulses were all present. She experiences occasional attacks of colicky abdominal pain.

Case 3.—F. S., a 60-year-old man, complained of 3 months' back pain. He was anxious and rather depressed with signs of chronic bronchitis. Radiographs of the chest and lumbar spine, routine blood chemistry, urine examination, and a pyelogram were all normal.

The pain persisted and the patient was admitted 2 months later on 17 May, 1969, when barium studies, a cholangiogram, a lymphangiogram, a bone-marrow biopsy, an inguinal lymph-node biopsy, and a lumbar puncture were unhelpful. There was no evidence of multiple myelomatosis or porphyria, and the Wassermann reaction was negative.

On 17 June haematemesis occurred, followed by the passage per rectum of about 700 ml. of bright-red blood. Laparotomy revealed a 7-cm. atheromatous aneurysm of the infrarenal aorta which had formed a 1-cm. fistula into the third part of a greatly distended and pulsating duodenum. The resected aneurysm was replaced by a 19 × 9·5-mm. knitted Dacron bifurcation graft, and the duodenal defect was closed with interrupted 00 chromic catgut sutures in two layers. Omentum mobilized on a gastro-epiploic pedicle was interposed between the graft and the duodenum.

The postoperative course was prolonged and stormy. The patient was ventilated and a tracheostomy was required on 21 June. Gram-negative septicaemia and peritonitis on 27 June necessitated a second laparotomy, and extensive ischaemic necrosis of the colonic wall with perforation of the sigmoid was found and was treated with a Hartmann's resection and colostomy.

Cephaloridine and streptomycin were changed to cephaloridine and chloramphenicol. Right-lung collapse occurred on two occasions, leading to cardiac arrest and requiring bronchoscopy and further intermittent positive-pressure ventilation until 16 July. Further chest infections with *Pseudomonas* and *Proteus* organisms, another lung collapse and consolidation, and two more cardiorespiratory arrests delayed progress. Progressive anaemia required repeated transfusion, and a period of acute renal failure followed a major transfusion reaction. Drainage of a pneumothorax was necessary following an attempt to tap a subphrenic abscess. Polymyxin parenterally and by inhalation was followed by gentamicin, and infection was finally controlled.

Three months after operation and after 8 weeks' ventilation the patient was discharged, his weight having increased from 40·6 to 53·6 kg. At 24 months' follow-up the patient was well, with a functioning colostomy, and the alimentary, respiratory, and peripheral vascular systems were otherwise normal. Closure of the colostomy has been postponed on account of his chronic bronchitis.

Table I.—AETIOLOGY, SEX, AND AGE AT PRESENTATION IN 118 PATIENTS WITH PRIMARY AORTO-ENTERIC FISTULA*

AETIOLOGY	NO. OF CASES		AVERAGE AGE			PERCENTAGE OF TOTAL CASES		
	Male	Female	Male	Female	Both	Male	Female	Both
Atherosclerosis	54	18	67	66	67	59	67	61
Syphilis	8	1	42	32	41	9	4	8
Tuberculosis	8	2	57	58	57	9	7	8
Mycotic	6	1	46	20	42	7	4	6
Unknown	15	5	53	56	54	16	18	17
Total	91	27	60	60	60			

* Insufficient information was available in a further 13 reported cases.

Table II.—PRESENTING SYMPTOMS IN 118 PATIENTS WITH PRIMARY AORTO-ENTERIC FISTULA*

Presenting Symptom	*Percentage of Patients*
Haematemesis	40
Melaena	40
Abdominal pain	48
Lumbar or back pain	22
Previously known abdominal mass (diagnosed or probable aneurysm)	20

* Insufficient information was available in 13 other patients.

DISCUSSION AND REVIEW OF LITERATURE

Sir Astley Cooper first described a case of aorto-enteric fistula in 1829 (7),* and the condition was mentioned by Chamel and Dalmas in 1833 (5). Successful surgical treatment was reported in 1961 by Maclean and Couves (31), the patient being well 30 months afterwards. One hundred and twenty-eight cases have been found in the literature (1–4, 6, 8, 10–26, 28–45), to which we have added 3 cases, making 131 in all. Sex, age, and aetiology are summarized in *Table I*. Seventy-seven per cent of the cases occurred in males and the average age for both sexes was 60 years. Atherosclerosis was the commonest cause, being reported in 61 per cent of the cases. The average age of these patients was 67 years. Intra-abdominal sepsis complicated 3 cases in the atherosclerotic group. Twenty-two per cent of cases were syphilitic, tuberculous, or mycotic and these tended to occur in younger patients.

The commonest presenting symptoms were gastro-intestinal bleeding and abdominal and back pain (*Table II*). Sixty-five per cent of the patients had haematemesis and 54 per cent melaena, but bleeding was not manifest until after admission in some patients. In 56 per cent of the patients an abdominal mass was felt on admission, three-quarters of these being pulsatile. In only 20 per cent had a mass been known to be present beforehand.

The most common site for the fistula was the third part of the duodenum (72 out of 125 fistulae) and this is probably due to the relative fixity of the duodenum compared with the rest of the bowel, and the close relationship of the third part of the duodenum to the aorta. Aorto-enteric fistulae have, however, been reported affecting all parts of the gut from the stomach to the rectum (*Table III*).

Table III.—SITES OF RUPTURE INTO THE BOWEL IN 123 PATIENTS WITH PRIMARY AORTO-ENTERIC FISTULA*

Site	*Number*	*Percentage*
Stomach	6	4·8
Duodenum		
First part	1	0·8
Second part	5	4·0
Third part	72	57·6
Fourth part	6	4·8
Unspecified	18	14·4
Total	102	81·6
Small bowel		
Jejunum	7	5·6
Ileum	2	1·6
Unspecified	1	0·8
Total	10	8·0
Large bowel		
Caecum	1	0·8
Ascending colon	1	0·8
Sigmoid colon	4	3·2
Rectum	1	0·8
Total	7	5·6

* Insufficient information was available in 8 other patients.

Two cases ruptured into two sites, and both sites are included. Two cases with fistulation into the bowel ruptured in addition into the vena cava and into the left ureter.

Table IV.—LENGTH OF TIME FROM FIRST GASTRO-INTESTINAL HAEMORRHAGE TO DEATH OR SURGICAL INTERVENTION IN 115 PATIENTS WITH PRIMARY AORTO-ENTERIC FISTULA*

Length of Time	*No. of Patients*
Less than 6 hours	30
From 6 to 24 hours	17
From 1 to 7 days	31
More than 1 week	37

* Insufficient information was available in 16 other patients.

The interval between the first gastro-intestinal bleed and diagnosis is of importance in allowing time for treatment (*Table IV*). Some patients have had several episodes of bleeding extending over several months, and 68 of 115 patients for whom information is available survived for 24 hours or longer after the first haemorrhage. Adequate time is therefore available for surgery to be attempted in the majority of cases.

SURGICAL TREATMENT

Details are given in the literature of 15 patients who were treated surgically (2, 6, 10–13, 17–19, 30, 31, 33, 44), of whom 5 (33 per cent) survived. The

---

* Throughout figures in parentheses relate to the reference numbers.

3 cases reported in this paper all recovered and bring the survival to 8 out of 18 cases (44 per cent). All of the known surviving cases had ruptured into the small intestine (7 into the duodenum). Seven of the 8 survivors were treated with prosthetic grafts, the exception being *Case* 2 in the present series in whom aortic aneurysmorrhaphy was possible.

Of the 18 patients who were treated surgically, 10 had serious postoperative complications and only 1 of these survived (*Case* 3 in the present series). Septicaemia or intra-abdominal sepsis occurred in 7, with ischaemic colitis and peritonitis requiring partial colonic resection in 2. In 5 patients there was graft leakage, with further gastro-intestinal haemorrhage in 3, while 3 patients developed renal failure.

Although the mortality following surgery is formidable (56 per cent in the cases reviewed here), we have not found any reports of survival for more than a few months in patients with an untreated aorto-enteric fistula. Early surgery holds the only hope of long-term survival for these patients. Our experience of survival in all of 3 patients suggests that prompt diagnosis and operation may lead to improvement in the present overall figures. The diagnosis should be considered in all patients with gastro-intestinal bleeding and an abdominal mass, especially if it is pulsatile. An increased incidence of peptic ulceration, however, is associated with abdominal aortic aneurysms in a necropsy population (27). In 44 per cent of patients no abdominal mass was reported. In such cases the diagnosis is likely to be made at laparotomy for persistent gastro-intestinal haemorrhage, and the outcome then depends largely on the facilities and skills available to the surgeon. Once surgery has been performed and the patient has recovered, it seems likely that the prognosis will be similar to that following resection of aortic aneurysms which have not developed fistulae. DeBakey, Crawford, Cooley, Morris, Royster, and Abbott (9) have shown that long-term survival after resection of aortic aneurysms is only slightly less than that for a normal population matched for age and sex, unless hypertension or ischaemic heart disease was present before surgery.

KEEPING THE STERILE FIELD STERILE

—that is the objective of patient drapes in theatre

BARRIER* Theatre Drapes — unlike absorbent cotton drapes — are treated to resist strike-through of fluids — thus reducing the risk of bacterial transfer to the open wound.

BARRIER* Theatre Drapes also provide a number of other advantages:—

* Drapes are folded, cuffed and marked for convenient, aseptic handling.

* A full range of both composite and single item drape sets are available for the majority procedures.

* Presented in both sterile form and for inclusion in hospital prepared packs.

* Complemented by an advanced and unique drape system of absorbent/repellent adhesive towels.

* Completely disposable, reducing the work load in service departments and eliminating associated laundry problems.

A handbook of information about thrombolytic therapy with Kabikinase will be sent on request.

AORTO-CAVAL FISTULAE: AN UNCOMMON COMPLICATION OF ABDOMINAL AORTIC ANEURYSMS

By J. P. D. RECKLESS, I. McCOLL, and G. W. TAYLOR
PROFESSORIAL SURGICAL UNIT, ST. BARTHOLOMEW'S HOSPITAL, LONDON

SUMMARY

Two cases of successfully treated aorto-caval fistula are described, bringing the total number of reported cases to 71. Forty-one cases which were treated surgically are reviewed. The aetiology of the leg oedema is discussed.

THE natural history of abdominal aortic aneurysms is usually of enlargement and eventual rupture. This is commonly intra- or retroperitoneal, but may occur into other structures such as the gut (26)* or the inferior vena cava.

Three cases of aorto-caval fistula have been seen at St. Bartholomew's Hospital and have been successfully treated. One of these has been reported elsewhere (28), and the other 2 are described below. The literature is briefly reviewed.

CASE REPORTS

Case 1.—A. H., a 59-year-old man, was admitted on 9 Aug., 1968, complaining of backache, nausea, vomiting, and malaise of 2 months' duration. Six weeks before admission considerable oedema of the legs and scrotum had suddenly developed and had been treated with digitalis and diuretics.

There was mild dyspnoea at rest and bilateral basal crepitations, and the jugular venous pressure was raised 8 cm. The pulse was 72 per minute and collapsing, the blood-pressure was 160/40, and a Corrigan sign was present. The liver was palpable 5 cm. below the costal margin, and a large pulsatile epigastric mass with a harsh continuous bruit was present. An abdominal radiograph showed calcification in an aortic aneurysm. The Wassermann reaction was positive, but was thought to be nonspecific as full serology was otherwise negative. The cardiac failure was thought to be due to an aorto-caval fistula.

On 14 Aug. an aneurysm, 22 × 15 cm., was excised and a 3·5-cm. defect in the inferior vena cava was closed with 000 Mersilene. Aorto-femoral continuity was restored by a 22 × 11-mm. knitted Dacron bifurcation graft across which omentum was sutured. The central venous pressure dropped from 27 cm. to 10 cm. as the fistula was controlled, and a marked diuresis and a 10-kg. weight-loss were noted in the next 10 days.

Histology showed atheromatous change without evidence of luetic aortitis. Hypertension (260/125) was controlled by methyldopa, and the patient was symptom free and had all the pedal pulses present 3½ years postoperatively.

Case 2.—H. B., a 62-year-old man, was admitted on 23 Feb., 1970. Over 24 hours, following sudden pain in the left iliac fossa and groin, marked left leg oedema had developed. The patient had been obese and hypertensive for some years, and was taking guanethidine and a diuretic.

The blood-pressure was 105/50 and the pulse was 70 per minute and collapsing. There was a hyperdynamic cardiac impulse and an aortic systolic ejection murmur, but no evidence of left or right heart failure. In the left iliac fossa an expansile mass was present with a thrill and a machinery murmur. The left leg was markedly oedematous, blue, and with dilated pulsating veins draining upwards over the lower abdomen. The circumference of the thigh was 3 cm. greater on the left side, and that of the calf was 8·5 cm. greater.

A diagnosis of an aorto-iliac aneurysm with a left iliac arteriovenous fistula led to laparotomy on the same day. An aortic aneurysm, 8 × 12 cm., extended into a left common iliac artery aneurysm, 10 × 10 cm. Arterial pulsation was present in the inferior vena cava. The aorta and iliac vessels were controlled and the iliac aneurysm was opened. Venous bleeding was stopped by clamping the external and common iliac veins and by occluding the internal iliac vein lumen through the 2·5-cm. fistula by using a Fogarty embolectomy catheter balloon. The defect was closed and the aneurysm resected, leaving the posterior wall of the aortic aneurysm in situ. A 22 × 11-mm. knitted Dacron bifurcation graft was used to restore aorto-iliac continuity.

Apart from a deep venous thrombosis of the left leg and a possible pulmonary embolus, progress was uneventful. Follow-up at 24 months was satisfactory.

DISCUSSION

Arteriovenous fistulae of the large intra-abdominal vessels are known to be a possible complication of surgery to the intervertebral disks, but the cases reported here and a number of others in the literature occurred as primary events of ruptured abdominal aneurysms. The first such case of aorto-caval fistula was reported in 1831 by Syme (34) in a 22-year-old man in whom the aetiology was probably syphilitic. Slow deterioration occurred till death 3½ months later.

Twenty-six cases were found by Boffi (2) in 1955, and 28 further cases were reviewed in 1968 by Nennhaus and Javid (25). The present review (3, 13, 15, 17, 20–22, 27, 30, 32, 33, 37, 38) brings the total number of reported cases to 71. Forty-one cases have been surgically treated (1, 3, 7, 8, 18, 19, 21, 25, 27–33, 35–38). The average age of these cases was 61 years, and all except 3 were male. The aetiology was atherosclerotic in the majority of the cases, but 2 were syphilitic (18, 33), 1 was probably mycotic (25), 1 was due to Ehlers-Danlos syndrome (20), and a further patient had Marfan's syndrome (12).

Abdominal or back pain, a palpable aneurysm, and a continuous abdominal bruit were each present in over four-fifths of the patients, while a high output cardiac state and a widened pulse pressure were present in over half (*Table I*).

While cardiac failure is common, the abdominal and lower limb oedema is partly the result of venous hypertension and partly due to inferior vena cava compression by the aneurysm. *Case* 2 had a high output cardiac state without failure, and the gross oedema on the side of the fistula only confirms the importance of these local factors. Venous hypertension may be the cause of haematuria and rectal bleeding in some patients, and may contribute to the incidence of anorexia, nausea, and vomiting. Renal function is also impaired in some patients where a raised urea is reported.

---

* Throughout figures in parentheses relate to the reference numbers.

Table I.—Symptoms and Signs in 41 Surgically Treated Patients presenting with Primary Aorto-caval Fistula

Symptoms and Signs	*Occurrence* (per cent)
Abdominal or back pain	88
Palpable aneurysm	90
Abdominal bruit	83
High output cardiac state	54
Congestive cardiac failure	37
Wide pulse pressure and reduced diastolic pressure	61
Lower-limb oedema	56
Haematuria	17
Rectal bleeding	5
Anorexia, nausea, and vomiting	24
Lethargy, impaired cerebration	20

Surgery was undertaken at about 16 days after fistulation (range, 6 hours to 2 months). Not until surgical control of the fistula is achieved does the patient's condition usually improve, with the central venous pressure falling from 20–30 cm. to normal.

Thirty of the 41 patients survived surgery, but 4 are known to have died of later complications. Three developed secondary aorto-enteric fistulae (9, 10, 35), whilst the fourth, in whom a post-mortem examination was not performed, suffered a terminal haematemesis (25). Such secondary fistulae are well recognized and occur more frequently than the primary fistulae discussed in this article. They occur early after surgery (accompanied by infection, or by graft and suture-line disruption with false aneurysm formation), or late (with graft and suture material failure, or with adherence of the bowel to the prosthesis). Care in the choice of the graft and suture material, and separation of the prosthesis and bowel by peritoneum or omentum will reduce these complications.

NON-GANGRENOUS ISCHAEMIC COLITIS

A REVIEW OF 17 CASES

By ALASTAIR R. BROWN
DEPARTMENT OF SURGERY, SYDNEY HOSPITAL, SYDNEY

SUMMARY

Ischaemic lesions of the colon can be divided into gangrenous and non-gangrenous groups.

In this paper 17 patients with non-gangrenous ischaemic colitis are reported; 16 of these occurred spontaneously and 1 followed an anterior resection of the rectum.

The clinical and radiological findings are described.

The lesions varied in extent and severity from a short segment of transient mucosal damage to a long permanent stricture.

An early barium-enema examination is essential for the initial diagnosis. Repeat barium enemas are necessary to ascertain the final outcome. The radiological changes are at least partially reversible and even extensive strictures may show a marked improvement over a period of months.

In this group five lesions were resected but none of the resections was performed during the acute phase. It is concluded that non-gangrenous lesions can usually be managed conservatively. The indications for surgical intervention are discussed.

ISCHAEMIC colitis is a non-specific inflammatory disease of the colon. It has been reported as a complication of abdominal aortic surgery (Birnbaum, Rudy, and Wylie, 1964), as a terminal event in patients with cardiac disease (McGovern and Goulston, 1965), and as a spontaneous occurrence in otherwise well patients (Marston, Pheils, Thomas, and Morson, 1966).

Marston and others (1966) classified the lesions according to the severity of the damage into (1) gangrenous, (2) stricturing, and (3) transient groups. However, experience with the present cases and with other reported cases (Boley, Schwartz, Lash, and Sternhill, 1963; de Dombal, Fletcher, and Harris, 1969) suggests that the most useful classification distinguishes only gangrenous and non-gangrenous lesions.

Gangrenous ischaemic colitis is often fatal and usually follows aortic surgery (Barnes, Ellis, Kirklin, and Edwards, 1958; Young, Britton, de Wolfe, and Humphries, 1962; Miller and Knox, 1966; Bicks, Bale, Howard, and McBurney, 1968). Spontaneously occurring gangrenous lesions are rare (Demos, 1963).

More than 120 cases of non-gangrenous ischaemic colitis have been reported. A few of these have followed aortic surgery (Movius, 1955; Bernatz, 1960; Smith and Szilagyi, 1960; Birnbaum and others, 1964; Goodman, 1964; Bicks and others, 1968; Miller and Bennet, 1968), but most have occurred spontaneously (Boley, Schwartz, Kreiger, Schultz, Siew, and Allen, 1965; Irwin, 1965; Marshak, Maklansky, and Calem, 1965; Payan, Levine, Bronstein, and King, 1965; Roberts, 1965; Shippey and Acker, 1965; Varga and Currie, 1965; Dunbar, 1966; Farman, 1966; Marston and others, 1966; Bentlif and Eichhorn, 1967; Coligado and Fleshler, 1967; Shea, 1967; Byrd, Sawyers, Bomar, and Klatte, 1968; Calem, Gaudiano-Ruiz, Pochaczevsky, and Papadakis, 1968; Dickson, 1968; Kilpatrick, Farman, Yesner, and Spiro, 1968; Sturdy, 1968; Thomas, 1968; Bentlif, 1969; de Dombal and others, 1969; Gross, 1969, Pheils, 1969; Rowe-Jones, 1969; Williams, Bosniak, Wittenberg, Manuel, Grimes, and Byrne, 1969; Balslev, Jensen, Norgaard, and Poll, 1970).

CLINICAL MATERIAL AND OBSERVATIONS

Seventeen patients suffering from non-gangrenous ischaemic colitis are reported. Sixteen of the lesions occurred spontaneously, and 1 followed an anterior resection of the rectum.

The group comprises 10 women and 7 men. Their ages ranged from 36 to 88 years with a median age of 64 years (*Table I*).

Clinical Features.—One patient (*Case* 4) had had a single episode of painless rectal bleeding 6 months earlier. None of the other patients had had a previous bowel disorder.

Fourteen patients presented with rapidly developing and usually continuous pain in the left or lower abdomen. Eleven of them required urgent admission to hospital. The pain was accompanied by vomiting in 7 patients.

Three patients had no pain, *Cases* 9 and 12 presented with recurrent episodes of blood-stained diarrhoea, and *Case* 14 had no symptoms attributable to the ischaemia.

Sixteen patients had diarrhoea, sometimes preceded by tenesmus.

Thirteen patients had rectal bleeding. This occurred either as blood-stained diarrhoea or as frank rectal bleeding after an initial bout of diarrhoea. In some cases the bleeding persisted for several days, but it was never sufficient to require transfusion. Two other patients (*Cases* 4 and 17) were found to have occult blood in their stools, and both became anaemic.

In contrast to the severity of the symptoms the physical signs were usually mild. Localized abdominal tenderness was noted in 8 patients. A diagnosis of intestinal obstruction was made in 3 patients (*Cases* 5, 6, and 7), and some abdominal distension was noted in others. *Case* 2 developed a pyrexia and a tachycardia with abdominal distension and tenderness and was diagnosed as having acute ulcerative

colitis. Four other patients (*Cases* 3, 5, 6, and 17) were noted to have a mild pyrexia and in *Case* 17 this persisted for 4 weeks.

Sigmoidoscopy.—Thirteen patients had a sigmoidoscopy when first seen. Although several of them had blood in the rectum, only 3 (*Cases* 2, 11, and 12) had mucosal changes. In these 3 patients the rectal mucosa was normal, but the mucosa of the rectosigmoid was oedematous. In *Case* 2 it was possible to manipulate the sigmoidoscope into the sigmoid colon; the mucosa here was reddened and superficial ulcers with areas of submucosal haemorrhage were noted. A biopsy from this region showed infarcted mucosa. A repeat examination a few days later revealed several shallow granulating ulcers with areas of normal mucosa between.

Radiology.—Plain radiographs of the abdomen were taken of all the patients who were seen during their acute illness. These showed dilated loops of small intestine with fluid levels in the 3 patients who were diagnosed as having intestinal obstruction.

All of the patients had one or more barium enemas performed. In those patients in whom the first examination was performed early the demonstration of 'thumb printing' and tubular narrowing was considered to be diagnostic (*Figs.* 2 A, 4 A, 5 A, and 7 A). *Cases* 2, 12, and 17 were thought to have stricturing from ulcerative colitis or Crohn's disease

pro- haemor- at same	Radiological changes and clinical course	(*Fig.* 8 B)  8 months	Normal bowel function for 8 months	Diagnosis of Crohn's disease favoured initially because of pyrexia, but subsequent clinical course and radiological changes favour ischaemic colitis

(*Figs.* 1 and 8 A). *Cases* 1 and 4, with short segments of colon involved, were each thought to have a carcinoma (*Fig.* 3 A).

Nine patients had a repeat barium enema later. In 3 there was permanent colonic damage in the form of stricturing, sometimes with 'sacculation' of the colonic wall (*Figs.* 2 B, 5 B, and 8 B). In the other 6 the colon had returned to normal (*Figs.* 4 B and 7 B).

Management.—Twelve patients were in hospital during their acute illness, but in some of the patients the correct diagnosis was not made until later. *Cases* 5 and 6 both had an emergency laparotomy performed for suspected intestinal obstruction, and *Case* 7 had a femoral hernia explored for the same reason. *Case* 2 was treated as acute ulcerative colitis with systemic and local steroids. *Case* 17 was given ampicillin for an intercurrent infection. The treatment of the other patients was symptomatic: several were given intravenous fluids, and some required narcotic analgesics. All of the patients except *Cases* 2 and 17 were symptom-free within 5 days.

Five lesions were resected. In *Cases* 1 and 4 the radiological appearances were suggestive of carcinoma, and a resection was performed because of the uncertain nature of the lesion found. *Case* 12 required a resection because of complications arising in coexistent diverticular disease. Only 2 patients (*Cases* 2 and 14) required resections because of the extent of the colonic damage (*Figs.* 2 and 6). All of the resections were done after the acute episode had subsided.

Operative Findings.—In the patients who had an emergency laparotomy the affected segments of the colon were pale and contracted. In both cases the colonic wall felt thickened and oedematous and became plum-coloured with handling. The transition to normal colon was abrupt at both ends of the affected segments. The nature of the lesion was not appreciated at the time, and the state of the mesenteric circulation was not noted in either case. The lesions were not resected.

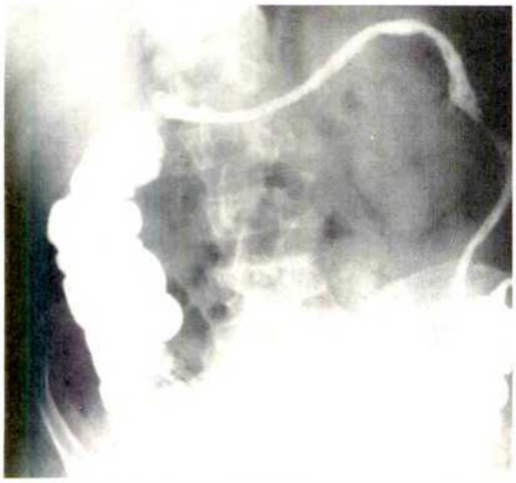

FIG. 1.—*Case* 2. Long ischaemic stricture involving the transverse and descending colon. Demonstrated 3 weeks after onset of symptoms.

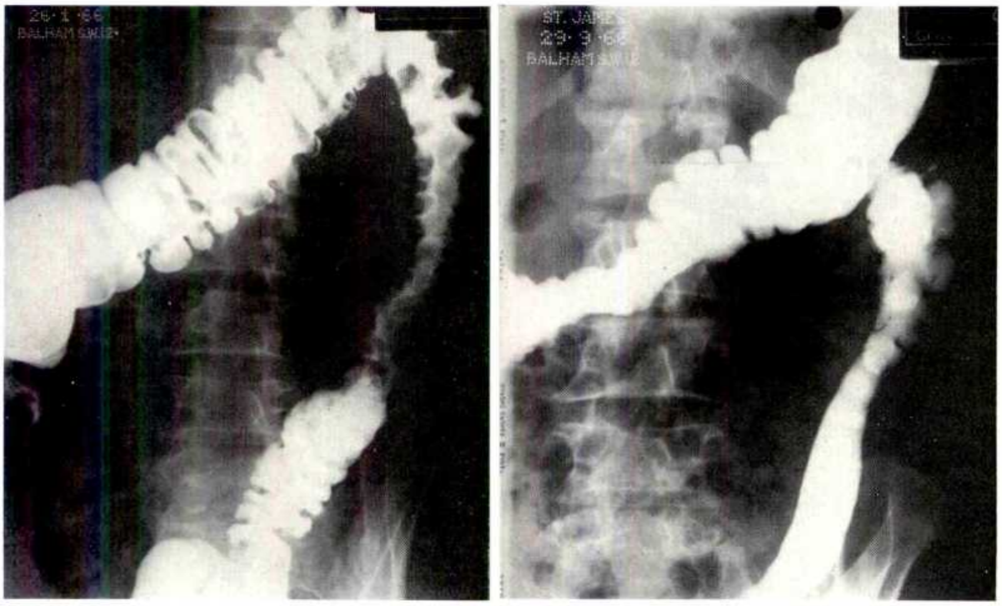


A B

FIG. 2.—*Case* 3. A, Tubular narrowing and 'thumb printing' involving the splenic flexure and the descending colon. Demonstrated 5 days after onset of symptoms. B, Permanent stricturing with 'sacculation' of the antimesenteric side of the descending colon. Demonstrated 8 months later.

In the patients who had resections the appearances of the lesions at operation were similar, but they felt fibrotic rather than oedematous and small dilated veins were evident on the serosal surfaces. Omental and peritoneal adhesions were noted. The condition of their mesenteric vessels was not recorded.

Pathology.—All of the resected specimens had similar macroscopic appearances: superficial mucosal ulceration with narrowing of the lumen and rigid thickening of the colonic wall mainly due to widening of the submucosal layer (*Fig.* 3 B).

Microscopically the submucosal layer, and to a lesser extent the subserosal layer, were infiltrated with fibrous tissue containing inflammatory cells. A few haemosiderin-containing macrophages were noted after staining of the sections with Prussian blue. In two specimens some endarteritis was noted in the intramural arteries and arterioles. There were no granulomas visible in the sections. No colonies of *Clostridium welchii* were seen.

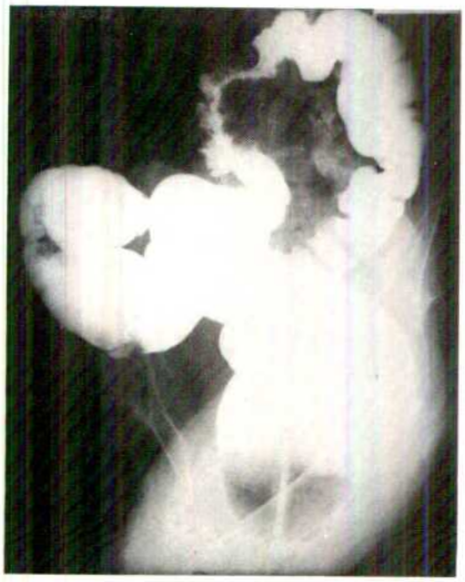
Progress.—None of these patients has had a recurrence of the ischaemia. At least 3 patients have permanent colonic damage, but they have remained well, with normal bowel function, for up to 3 years.

DISCUSSION

Non-gangrenous ischaemic colitis is diagnosed on the basis of both clinical and radiological findings. Histological confirmation is obtained only when the lesion can be reached sigmoidoscopically for biopsy, or a resection becomes necessary. In the present group such cases constituted a minority.

Clinically the most notable features are (1) the acute onset; (2) the severity of the abdominal pain; (3) diarrhoea, which may be preceded by tenesmus and which commences soon after the onset of the pain; (4) the passage of blood per rectum; (5) the mild systemic disturbance; (6) the paucity of physical signs; and (7) the self-limiting nature of the condition. A few patients have signs of intestinal obstruction during the acute illness, and a few develop incomplete large-bowel obstruction later if severe stricturing occurs. Occasionally a patient presents an atypical picture with little or no pain and with a chronic rather than an acute illness. Such a presentation is still compatible with reversible changes in the colon. When the local and systemic signs are pronounced the possibility of a gangrenous lesion must be considered.

The differentiation of this condition from, for example, acute ulcerative colitis, Crohn's disease, diverticular disease, carcinoma, or intussusception of a polyp is made radiologically. The most notable radiological features are (1) the presence of 'thumb printing' in the acute stage (Boley and others, 1963); (2) tubular narrowing of the affected segment, which is usually clearly demarcated but which sometimes has 'funnelled' ends (Thomas, 1968); (3) the quite



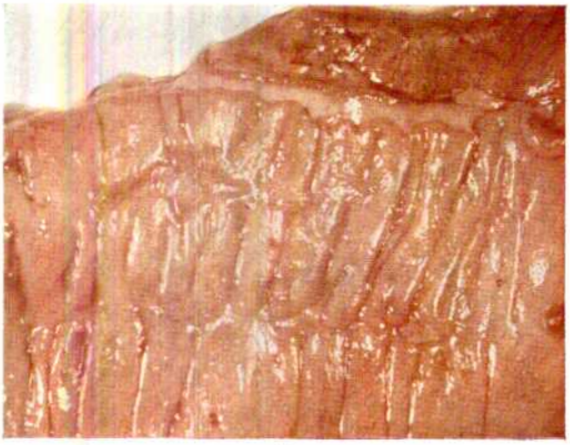


FIG. 3.—*Case* 4. A, Ischaemic lesion in the transverse colon mistaken for carcinoma. Demonstrated 6 days after onset of symptoms. B, Specimen showing marked widening of the submucosal layer, granulating ulcers, and normal mucosa. Resected 2 weeks after onset of symptoms.

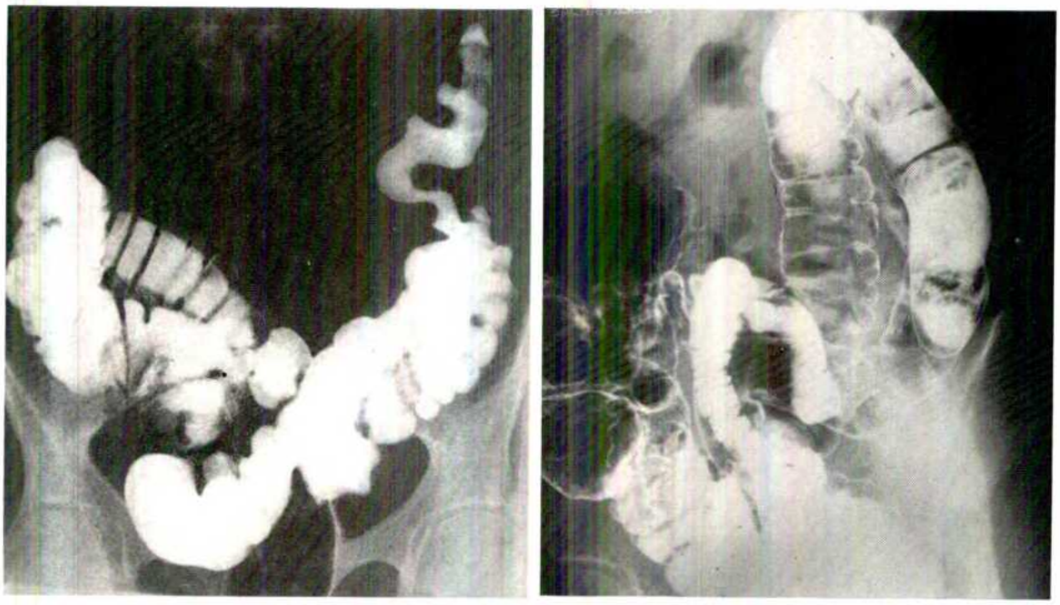

FIG. 4.—*Case* 10. A, Tubular narrowing with 'thumb printing' in the splenic flexure region. Demonstrated 2 days after onset of symptoms. B, The colon has returned to normal. Demonstrated 5 months later.

rapid changes in appearance resulting either in a return to normal or in segmental stricturing, sometimes with 'sacculation' of the wall (Marston and others, 1966); (4) the tendency for the affected segment of colon to shorten, even after stricturing has occurred; and (5) the tendency for the lesions to occur in the splenic flexure region (Marston and others, 1966). However, these features are non-specific and other conditions may have similar appearances. For example, polyposis, pseudopolyposis, lipomatosis, pneumatosis, and some malignant tumours can produce appearances similar to 'thumb printing'. Crohn's disease, ulcerative colitis, tuberculosis, and linitis plastica of the colon can produce similar segmental stricturing. Nevertheless, when the radiographic findings are considered in conjunction with the clinical picture the distinction between these lesions and ischaemic lesions usually can be made.

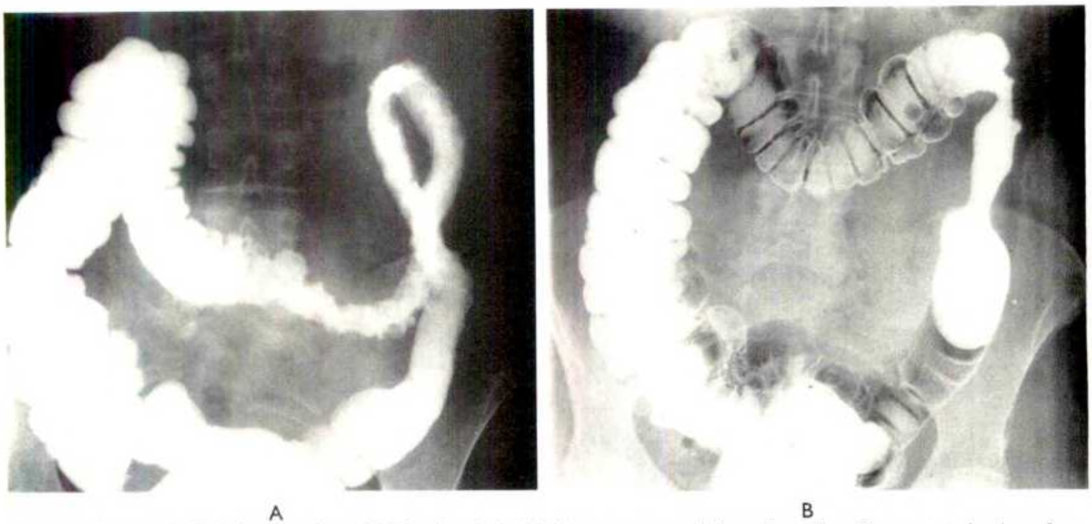

FIG. 5.—*Case* 13. A, Tubular narrowing with 'thumb printing' in the transverse and descending colon. Demonstrated 4 days after onset of symptoms. B, Permanent long stricture with 'funnelling' of ends. Demonstrated 2 months later.

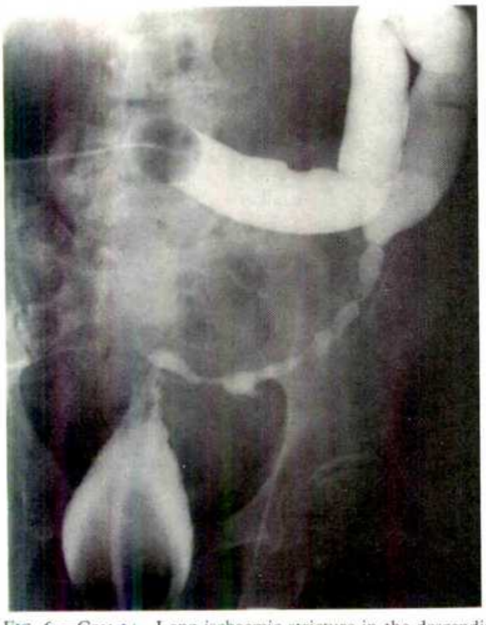

FIG. 6.—*Case* 14. Long ischaemic stricture in the descending colon after anterior resection of rectum (barium introduced per rectum and via the colostomy).

It is notable that the severity of the symptoms often bears no relation to the severity or the extent of the colonic damage as shown on the radiographs. For example, a patient with quite severe symptoms may sustain transient damage (*Fig*. 7), while a patient with relatively mild symptoms may have extensive permanent damage (*Fig*. 5).

The tendency for the radiological changes to be reversible emphasizes the need for an early barium enema when an ischaemic lesion is suspected, and the examination can be performed while symptoms are still present.

When diagnostic doubt exists after the first barium enema, serial barium enemas should be performed to demonstrate the evolutional changes which distinguish ischaemic lesions from other lesions. Serial barium studies also make it possible to determine whether the colonic damage is permanent and how extensive it is. In some patients the initial colonic involvement proves to be largely permanent (*Fig*. 2), while in others even the presence of marked stricturing (*Fig*. 8 A) does not prevent considerable recovery (*Fig*. 8 B). It is probable that such shortening of the strictured area is not entirely the result of recovery, for contracture of the affected segment may also contribute to it (Rowe Jones, 1969; Brown, 1972).

In the acute stage the duration of the symptoms is more useful than the severity of the symptoms as a guide to the extent of the colonic damage. *Cases* 2 and 17 each had an acute illness lasting longer than 5 days and both sustained extensive damage with marked stricturing (*Figs*. 1 and 8 A), yet *Case* 2 had severe symptoms, while *Case* 17 had relatively mild ones.

Thus in some patients the changes in the colon are temporary while in others they are permanent, although their modes of presentation are similar. At the time of their acute illness it is not possible clinically, or radiologically, to determine which patients have sustained permanent colonic damage and which have not. This unpredictable variation in the end-result of the ischaemic episode restricts the applicability of the classification of ischaemic lesions proposed by Marston and others (1966). The distinction between 'stricturing' and 'transient' lesions can only be made several weeks after the acute illness, and it is better therefore to regard non-gangrenous ischaemic colitis as a condition with lesions ranging in severity from extensive permanent stricturing at one extreme to transient ischaemic damage at the other.

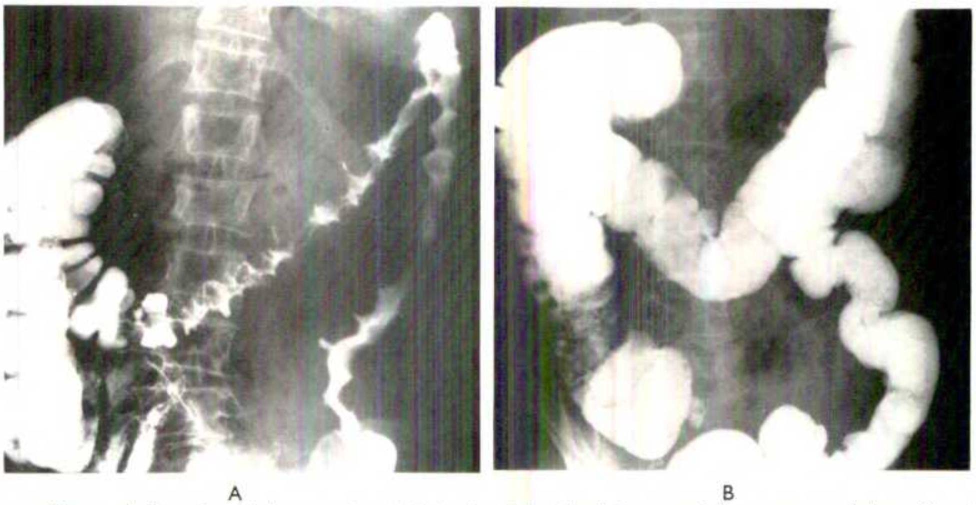

FIG. 7.—*Case* 15. A, Extensive tubular narrowing with 'thumb printing' involving most of the transverse and descending colon. Demonstrated 2 days after onset of symptoms. B, The colon has returned to normal. Demonstrated 7 weeks later.

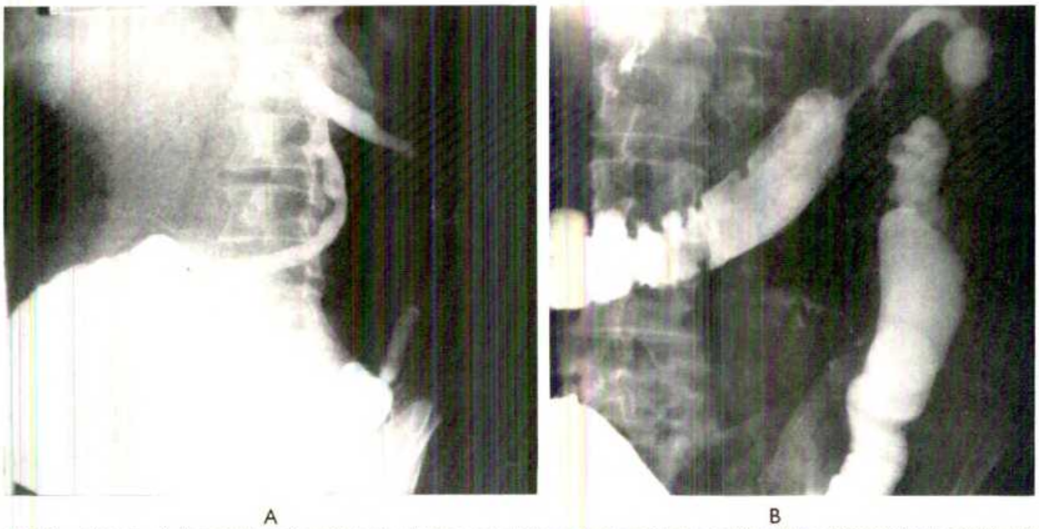

FIG. 8.—*Case* 17. A, Long ischaemic stricture involving most of the transverse and descending colon. Demonstrated 2 weeks after onset of symptoms. B, Marked reduction in the length of the stricture with the appearance of 'sacculation' of the colonic wall. Demonstrated 8 months later.

Management.—The management of ischaemic colitis in the acute phase is determined by the presence or absence of colonic gangrene. Clinically, the paucity of physical signs, the mild systemic disturbance, and the self-limiting course of the non-gangrenous condition are sufficient to distinguish it from the highly lethal gangrenous one, in which signs of peritonitis with shock predominate.

With spontaneously occurring lesions progression from a non-gangrenous to a gangrenous state is unlikely (Marston, 1968), and if there are signs of intestinal obstruction they will resolve with conservative management. Operation should be reserved for those patients in whom there is doubt about the viability of the colon.

After abdominal aortic surgery the development of gangrene may be insidious (Miller and Knox, 1966) and more caution seems necessary, but vigilance during the original procedure should reduce the chances of intestinal ischaemia developing (Rob and Snyder, 1966).

Established lesions sometimes require operation because there is doubt about the diagnosis, but resection is necessary only when there is partial obstruction due to severe segmental stricturing. Marston (1969) advocates resection of all permanently strictured lesions, but several of the patients described here have maintained normal bowel function in the presence of quite marked stricturing. This is a benign condition mainly affecting older patients, and it is desirable therefore to avoid a colonic resection when possible. There is no evidence that the lesions subsequently extend, and a symptomless benign stricture can be retained without hazard.

When an established lesion is resected the extent of involvement is usually well defined and is less than had appeared in the acute phase. Provided the viability of the remaining colon is not in doubt a one-stage resection is then a safe procedure.

In the present group, although no specific therapy was given either for the ischaemia or for the colonic damage, the persistence of ischaemic damage in some of the patients emphasizes the need for non-operative therapeutic measures.

Experimental studies have shown a number of measures to be beneficial in the management of ischaemic bowel. However, the natural tendency for the colon to recover makes the efficacy of such measures difficult to assess, and clinical experience of them is small.

Low-molecular-weight dextran to prevent sludging of the blood has proved useful experimentally (D'Angelo, Ameriso, and Tredway, 1963) and would be safer than anticoagulation since the lesions are usually haemorrhagic.

Adrenergic alpha-receptors which are prominently represented in the arterioles of the bowel (Green and Kepschar, 1959) may be significant in the production of non-occlusive ischaemia. Williams, Anastasia, Hasiotis, Bosniak, and Byrne (1968) have shown that phenoxybenzamine (an alpha-receptor-blocking agent) prevents necrosis of the intestine in experimental non-occlusive ischaemia, but the place of this substance in clinical practice has yet to be defined.

A fuller understanding of the pathogenesis of the colonic lesions should lead to more effective measures to minimize the permanent damage. Marston (1967) has described these lesions as infected infarcts because bacterial invasion of the colonic wall is to be expected following damage to the mucosa, but what part bacteria play in the pathogenesis of the resulting lesions is uncertain. Experimentally, antibiotics reduce the severity of ischaemic damage to the bowel (Cohn and Atik, 1961). Prophylactic non-absorbable antibiotics are sometimes used routinely in aortic surgery, but ischaemic lesions of the colon still occur (Bicks and others, 1968). Nevertheless, a combination of systemic broad-spectrum antibiotics and non-absorbable intestinal antibiotics could be beneficial in the management of lesions that occur spontaneously.

Acknowledgements.—I wish to thank Mr. Norman Tanner, Mr. A. M. Desmond, and Mr. J. Burke, of St. James's Hospital, London, and Mr. M. Killingback, of Sydney Hospital, for permission to publish these cases. I also wish to thank Dr. B. C. Morson, of St. Mark's Hospital, London, for reviewing the histological sections.

AN ASSESSMENT OF THE VALUE OF MEASURING UNCOLLECTED GASTRIC SECRETION DURING ROUTINE SECRETION STUDIES IN MAN*

BY C. W. VENABLES

DEPARTMENT OF SURGERY, UNIVERSITY OF NEWCASTLE UPON TYNE

SUMMARY

A simple 'wash-out' collection technique employing phenol red as a marker has been used during routine gastric secretion studies and its value has been assessed. Studies repeated on a single individual showed good reproducibility. When measured this way loss was not affected greatly by the volume secreted.

With this technique the repeatability of pentagastrin tests has been assessed at intervals of 6 weeks. This demonstrated that both acid and pepsin outputs could vary considerably, with a mean variation in acid of over 26 per cent.

The effects of histamine, pentagastrin, and insulin upon loss have been studied.

Loss has been found to vary considerably from one study to another and from one patient to another and may on occasions be considerable, particularly after previous surgery.

These findings suggest that a method of measuring loss should be adopted by any centre which wishes to use secretion studies to analyse the effects of treatment.

THE value of secretion studies in clinical practice depends upon the accuracy with which they are performed. One possible source of inaccuracy is the failure to collect all the secretion produced, giving a falsely low calculated secretion. Surprisingly few workers have attempted to measure such losses so that the value of estimating the amount of secretion escaping collection has not been assessed fully.

The present study was designed to establish a simple method of collection. Sophisticated techniques (such as the use of a radioactive marker) have been avoided and the method described relies upon changes in the concentration of phenol red (a non-absorbable marker) between the time of instillation and withdrawal from the stomach.

MATERIALS AND METHODS

Technique.—Prior to a test all medications were withheld for 24 hours and the subject was fasted for 12 hours.

A double-lumen tube of special construction was used (*Fig.* 1). One lumen ended 15 cm. proximal to the other and had two holes drilled near its end to produce a fine spray when phenol red was infused through it. Infusion was controlled by a peristaltic pump (Watson-Marlowe) at a rate between 10 and 15 ml. per minute. Phenol red was made up before a test by adding 20 ml. of stock solution (1·5 g. per litre) to 2 litres of distilled water. The second lumen was connected to suction (5 mm. Hg) via a three-way tap that allowed air to be injected if the tube became blocked.

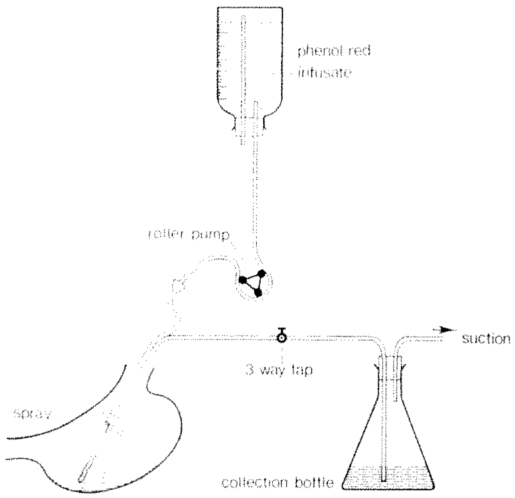

FIG. 1.—Diagrammatic representation of the collection technique.

Tests were performed by passing the tube into the stomach and adjusting its position until phenol red injected down the infusion limb was recovered easily up the other limb. This technique proved as good as radiographic screening, confirming the findings of Hassan and Hobsley (1970). After positioning 'wash-out' was commenced. It was found necessary to have a preliminary period of 'wash-out' to remove residual overnight secretion and to allow equilibration of phenol red to occur otherwise the concentration of phenol red recovered was low, giving a false measurement of loss of secretion. Usually 15 minutes were sufficient unless gastric retention was present, when preliminary 'wash-out' was continued until the recovered fluid was clear.

---

* Based on a paper delivered to the Surgical Research Society in January, 1969.

Basal secretion was collected for 15 minutes and pentagastrin (6·0 µg. per kg. i.m.) or histamine (40 µg. per kg. s.c.) was given and the stimulated secretion was collected over the next 60 minutes. In some studies insulin (0·2 U. per kg.) was given intravenously at the end of this period and secretion was collected for a further 75 minutes.

Measurements.—The volume of each collection was recorded and samples were analysed for acid, pepsin, and phenol red.

Acid.—Total titratable acidity was measured to *p*H 7 using an automatic titrimeter.

Pepsin.—This was measured as total peptic activity at *p*H 2·1 using a modified Hunt (1948) technique. The modification was the use of bovine serum albumin (fraction) as substrate; this gave a similar activity curve for gastric juice and purified pepsin (Sigma 1 : 60,000). Results are expressed as equivalent to the amount of Sigma pepsin having the same activity (1 Hunt unit = 4·2 µg.).

Table I.—RESULTS OF FOUR PENTAGASTRIN AND FOUR HISTAMINE TESTS PERFORMED ON A SINGLE HEALTHY MALE OVER A 12-MONTH PERIOD IN ORDER TO TEST REPRODUCIBILITY

TEST	BASAL HOUR				STIMULATED HOUR						LOSS	
	Acid (mEq. per hr.)		*Pepsin* (mg. per hr.)		*Acid* (mEq. per hr.)		*Pepsin* (mg. per hr.)		*Volume* (ml. per hr.)			
	Mean ± S.E.	Coefficient of Variation (per cent)	Mean ± S.E.	Coefficient of Variation (per cent)	Mean ± S.E.	Coefficient of Variation (per cent)	Mean ± S.E.	Coefficient of Variation (per cent)	Mean ± S.E.	Coefficient of Variation (per cent)	Mean ± S.E.	Coefficient of Variation (per cent)
Histamine	1·4 ± 0·4	32	60·1 ± 25·9	43	18·7 ± 2·3	12	210·5 ± 11·8	6	302·0 ± 23·0	7	22·1 ± 6·7	30
Pentagastrin	1·4 ± 0·7	50	59·8 ± 34·8	58	16·6 ± 2·7	16	163·6 ± 30·6	19	302·0 ± 30·9	10	12·7 ± 4·1	33

Phenol Red.—After filtration 5 ml. of the collected secretion were added to 10 ml. of sodium phosphate solution (2·75 g. per 100 ml.) and the optical density (O.D.) was read at 545 mµ using a blank of 5 ml. of distilled water in phosphate solution. Biliary contamination could produce erroneous results; to correct this each sample was re-read at 670 mµ against a blank of the original infusate in phosphate solution. If a reading was obtained this was subtracted from that at 545 mµ to give the corrected optical density. The validity for this correction was established in *in vitro* studies.

Calculation of Loss.—This was calculated from the following formulae:—

$$\text{Total volume } (T)\ (\text{secretion} + \text{phenol red}) = \frac{\text{O.D. infusate}}{\text{O.D. sample}} \times \text{volume infused } (V_1),$$

$$\text{Secretion volume} = T - V_1,$$

$$\text{Loss } (L) = T - \text{volume recovered},$$

$$\text{Percentage loss} = (L/T) \times 100.$$

Plan of Investigations.—Three hundred and fifty-four patients and volunteers were investigated. Most were patients with suspected peptic ulcer disease and all had the procedure explained and their co-operation was obtained. The studies performed were as follows:—

1. *Reproducibility.*—Four pentagastrin and four histamine tests were performed upon a single healthy male subject over a 12-month period.

2. *Effect of 'Wash-out' upon Pentagastrin-stimulated Secretion.*—

a. 'Wash-out' versus 'non-wash-out': Twelve patients had a 'wash-out' and a 'non-wash-out' pentagastrin test at intervals from a few days to 3 months.

b. 'Wash-out' versus 'wash-out': Twenty-one duodenal ulcer patients had repeat 'wash-out' pentagastrin studies performed at 6-week intervals.

3. *Effect of Volume secreted upon Loss.*—This was assessed by comparing the percentage losses during pentagastrin studies in 150 patients who had not been subjected to surgery. These were drawn at random from over 1000 studies performed with this collection technique over a 3-year period. The patients were divided into five groups depending upon the volume secreted in the hour after stimulation, the first 30 patients drawn in each group being used for the comparison.

4. *Effect of Different Stimuli upon Loss.*—

a. Histamine versus pentagastrin: Twelve patients had a pentagastrin and histamine test performed using the 'wash-out' collection technique. The tests were all performed within a few days of one another.

b. Pentagastrin versus insulin: Fifty-nine duodenal ulcer patients had a combined pentagastrin/insulin test prior to surgery.

5. *Effects of Different Surgical Procedures upon Loss.*—

a. Vagotomy and pyloroplasty: Fifty-nine patients had pentagastrin/insulin tests before and 6 weeks after this operation.

b. Various gastric operations: Losses in the hour following pentagastrin were compared in the following groups of patients studied more than 18 months after surgery: Billroth-I gastrectomy (15); Polya gastrectomy (21); vagotomy and gastro-enterostomy (28); vagotomy and pyloroplasty (34).

RESULTS

1. Reproducibility (*Table I*).—Basal secretion showed marked variation from one study to another, but the mean outputs of acid and pepsin during the

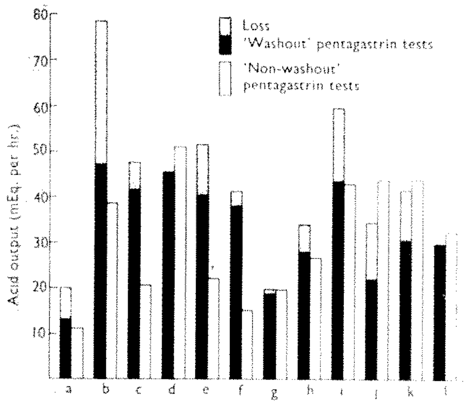

FIG. 2.—Individual acid outputs in response to pentagastrin stimulation in 12 patients studied by 'wash-out' and 'non-wash-out' collection techniques. (Recovery was complete during the 'wash-out' studies on d and l.)

Table II.—COMPARISON OF MEAN ACID OUTPUTS WITH AND WITHOUT CORRECTION FOR LOSS DURING 'WASH-OUT' AND 'NON-WASH-OUT' STUDIES ON 12 SUBJECTS

TEST	ACID OUTPUT (mEq per hr.)			
	Basal Secretion		*Pentagastrin-stimulated Secretion*	
	Corrected for Loss	Uncorrected for Loss	Corrected for Loss	Uncorrected for Loss
'Wash-out'	27·9 ± 14·0	16·1 ± 15·6	42·0 ± 16·7	33·2 ± 11·2
'Non-wash-out'	—	7·0 ± 4·3	—	30·6 ± 13·3

Table III.—COMPARISON OF THE LOSSES FOUND AND VARIATION IN ACID, PEPSIN, AND UNCOLLECTED SECRETION IN REPEAT 'WASH-OUT' STUDIES ON 22 DUODENAL ULCER PATIENTS

	LOSS (per cent)		VARIATION BETWEEN TWO TESTS (per cent)		
	Test 1	Test 2	Acid	Pepsin	Loss
Corrected for loss	23·5 ± 17·0	21·3 ± 19·1	26·7 ± 18·9	33·9 ± 23·0	16·9 ± 16·1
Uncorrected for loss	— —	— —	25·1 ± 20·7	30·3 ± 23·2	— —

histamine and pentagastrin studies were remarkably similar. Following stimulation the coefficient of variation was lower after histamine (acid 12 per cent; pepsin, 6 per cent) than after pentagastrin (acid, 16 per cent; pepsin, 19 per cent), but both were lower than the variation in loss, suggesting that had this not been measured the variability would have been larger. Pepsin output following pentagastrin was significantly lower than after histamine ($P < 0·05$) but acid output was not.

2. Effect of 'Wash-out' upon Pentagastrin-stimulated Secretion (*Table II*).—

a. 'Wash-out' versus 'Non-wash-out'.—Basal secretion was significantly higher during the 'wash-out' studies than during the 'non-wash-out' tests even when no allowance for loss was made ($P < 0·05$). On the other hand, 'wash-out' did not affect the response to pentagastrin, as the mean acid output was not significantly different ($P > 0·30$) when loss was not measured. An interesting finding was that 5 patients showed considerable differences (*Fig.* 2) in their acid outputs on the two occasions and the mean difference between the response obtained on the two occasions was 26·1 per cent (S.D. ± 22·6).

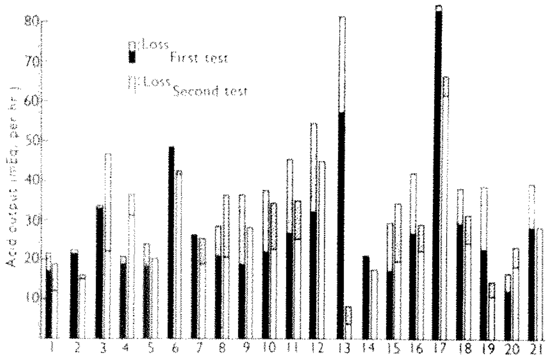

FIG. 3.—Acid outputs in 21 patients studied by 'wash-out' on two occasions.

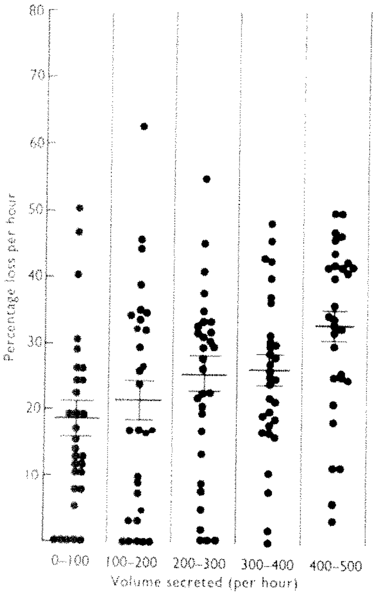

FIG. 4.—Measured percentage loss during pentagastrin studies on 150 patients secreting at various rates.

b. 'Wash-out' versus 'Wash-out'.—There was no difference in the mean acid and pepsin outputs in the two studies but, as in (*a*), individual patients showed considerable differences in the responses obtained (*Fig.* 3). Four had acid outputs and 9 had pepsin outputs that differed between the two studies by more than 30 per cent. These differences could not be attributed to errors in measuring loss as they still occurred when this was not calculated, and the variation in loss between the two studies (16·9 ± 16·1 per cent) was less than the variation in either acid or pepsin outputs (*Table III*).

3. Effect of the Volume secreted upon Loss.—Hobsley and Silen (1969) noted that the measured loss in their studies varied with the rate of secretion, being largest when the volume secreted was small. The present study differed from theirs in the use of a high flow-rate (10–15 ml. per minute compared with 0·05 ml. per minute) and it was necessary to investigate whether similar results would be obtained with this technique. *Fig.* 4 illustrates the percentage losses found in 150 patients investigated before surgery in whom the volume secreted after pentagastrin varied from less than 100 ml. per hour to 500 ml. per hour. It was found that the lowest losses occurred when the volume secreted was small and highest when the volume secreted was large, although the mean losses in each group were not significantly different from one another until the volume secreted was greater than 400 ml. per hour.

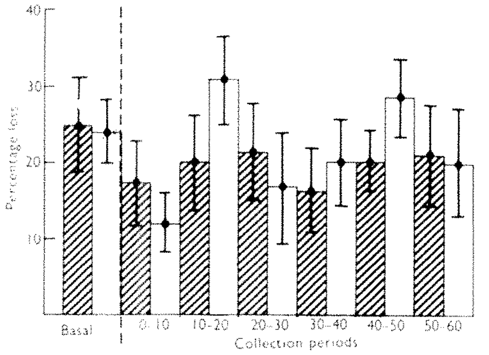

FIG. 5.—Mean percentage losses in individual collection periods following histamine and pentagastrin stimulation in 12 individuals.

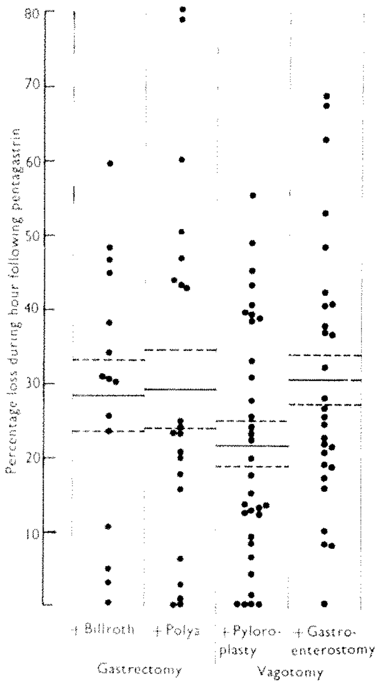

FIG. 7.—Measured losses during the hour after pentagastrin stimulation in 98 patients studied more than 18 months after various gastric operations.

4. Effect of Different Stimuli upon Loss.—

a. Histamine versus Pentagastrin (*Fig.* 5).—For these studies secretion was collected at 10-minute intervals and loss was calculated both for each collection period and for the hour after stimulation. There was no difference in the mean loss for the whole hour after histamine (19·9 ± 19·0 per cent) or after pentagastrin (20·4 ± 16·1 per cent), but during individual collection periods differences were seen. Histamine was associated with an almost constant loss of around 20 per cent, whilst pentagastrin produced two peak periods of loss during the 10–20-minute and 40–50-minute periods. The first peak was associated with the peak in acid secretion.

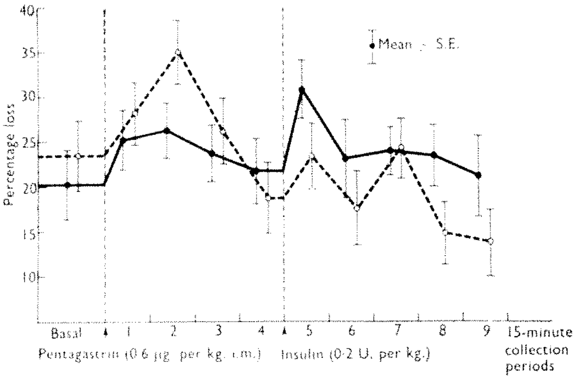

FIG. 6.—The effects of vagotomy and pyloroplasty upon the percentage loss during comparable collection periods in repeat pentagastrin/insulin studies before (——) and 6 weeks (– – –) after operation.

b. Pentagastrin versus Insulin (*Fig.* 6).—These were compared by assessing loss during the peak periods of secretion (15–45 minutes after pentagastrin and 30–60 minutes after insulin) following each substance. The stimuli were given consecutively in a combined test prior to surgery. Loss did not differ significantly following pentagastrin and insulin when investigated in this way, the mean loss after pentagastrin being 24·9 per cent (S.D. ± 22·9) and that after insulin being 23·7 per cent (S.D. ± 23·6) before surgery.

5. Effects of Different Surgical Procedures upon Loss.—

a. Vagotomy and Pyloroplasty.—During repeat pentagastrin/insulin tests performed before and 6 weeks after surgery loss was calculated for each collection period (*Fig.* 6). It was found that after operation there was an increase in loss during the basal period and the first three collection periods after pentagastrin, but thereafter loss was less in the postoperative study. The only periods when these differences achieved statistical significance were the 15–30-minute period after pentagastrin and the 0–15-minute and 45–60-minute periods after insulin.

b. Various Gastric Operations.—The effect of different gastric operations upon loss was assessed by calculating the amount of uncollected secretion during pentagastrin studies performed more than 18 months after operation. There was a considerable variation (*Fig.* 7) in the amount lost in different patients, the largest occurring when the stomach had been anastomosed to the jejunum. The vagotomy and pyloroplasty group had a lower mean loss (21·9 per cent) than any of the other groups (Billroth-I, 28·4 per cent; Polya, 29·2 per cent; vagotomy and gastro-enterostomy, 30·7 per cent), but this difference was only significant when compared with the vagotomy and gastro-enterostomy group ($P < 0.05$).

DISCUSSION

Royle and Catchpole (1967) showed that significant losses could occur during gastric secretion tests, and Hobsley and Silen (1969) confirmed their findings. The importance of such losses during routine studies has not been investigated in detail. A collection technique was required that would be readily applicable to any investigation and would give an estimate of loss. Stephens and Kyle (1963) tried to prevent losses by means of a 'blocker' in the pylorus but this technique is too difficult for routine studies. Phenol red was chosen for the present investigation because it is not absorbed by the stomach (Hollander, Penner, and Saltzman, 1937; Hunt, 1949) and it appears to be a good 'marker' in recovery studies in the dog (Bloom, Jacobson, and Grossman, 1967). Other workers have used phenol red but most have instilled and withdrawn it over a fixed time interval (Brooks, Erskine, Gephart, Swaim, and Moore, 1950; Hunt and Spurrell, 1951; Sen and Roy, 1963; Aylett and Tonkin, 1964), which is unsuitable for following the pattern of a response. In the present studies the marker was infused continuously throughout the test, a technique similar to that described by Scobie and Rovelstad (1965) using phenolphthalein and by Hobsley and Silen (1966). The major difference in the present study was in the use of a high flow-rate. This made the collection of secretion easier as the volume infused was nearly always greater than the volume secreted, thus producing a physical 'wash-out' effect. This overcame the increased loss at low secretion rates noted by Hobsley and Silen (1969) when a low flow-rate was used. The method proved to be simple to perform, requiring little additional equipment. Most of the studies reported in this paper were performed by a trained nurse with minimal medical supervision. Reproducibility was found to be acceptable and appeared to be improved compared with studies where loss was not measured. The only disadvantages were that basal secretion was increased and that the calculation of acid concentrations could be inaccurate when the volume secreted was small. This latter disadvantage only became important if Hollander's (1951) criteria for incomplete vagotomy were used during insulin studies. Why was basal secretion increased (a finding reported by others using marker techniques)? The most likely explanation is that dilution of gastric juice prior to its entering the duodenum removed some of its inhibitory effects.

Having established the method it was then used to investigate several aspects of loss. The first was whether its use would improve the repeatability of secretion studies, and this did not occur. It was interesting to find how much the response to pentagastrin could vary from one study to another, whether loss was measured or not. This appeared to be a true variation in response and has not been reported before, presumably because most repeat studies have been performed within a day or so and not at 6-week intervals as was done here. It is obviously important to recognize that this can occur as repeat studies may be used to assess treatment.

Investigation of the effect of various standard stimuli (histamine, pentagastrin, and insulin) upon loss was examined. Insulin and pentagastrin were found to be similar in their effects, producing fluctuations in loss with peak losses during the period of peak gastric secretory activity. This suggests that these agents may have an effect upon motility as well as upon secretion. Histamine, on the other hand, did not appear to affect emptying directly.

The amount lost during pentagastrin stimulation was increased by vagotomy and pyloroplasty. The greatest loss occurred at the time of peak acid secretion, so that if this is not measured a falsely high reduction in acid output would be calculated. Other operative procedures were associated with considerable losses in some individuals, particularly where the stomach had been anastomosed to the jejunum.

TWO UNUSUAL LEG ULCERS

BY A. N. FAWCETT AND D. A. HARRISON
DEPARTMENTS OF SURGERY AND PATHOLOGY, THE ROYAL INFIRMARY, SHEFFIELD

SUMMARY

Two unusual leg 'ulcers' are reported. The first represents an uncommon site for a basal-cell epithelioma, the atypicality of which is emphasized by its lymph-borne metastasis. The second, a fibrosarcoma, is an example of a rare type of malignant transformation occurring in a long-standing varicose ulcer.

ULCERATION of the leg is commonly associated with varicose veins or is a sequel of deep-vein thrombosis. Other causes are burns, syphilis, lupus vulgaris, scrofuloderma, and pyoderma gangrenosum. In this paper two unusual ulcers of the leg are described.

CASE REPORT

Case 1.—Mrs. F. G. was first seen in 1965 at the age of 73 years. For 8 years she had noticed a progressively enlarging ulcer below and medial to the left knee. In 1961 she had attended another hospital where the lesion had been excised and the defect covered with a skin-graft. Histology had shown the lesion to be a basal-cell epithelioma. Satisfactory healing had occurred, but by 1964 the ulcer had recurred and the patient had been given a course of radiotherapy (5000 rad over 7 days). This had failed to produce any regression of the tumour and she was admitted in August, 1965, for further surgery. At that time the ulcer measured 6·5 × 5 cm. and the proximal edge, which was 7·5 cm. distal to the knee-joint, had indurated edges and a raw, bleeding base. Inguinal lymph-nodes were not palpable. A biopsy confirmed the diagnosis of basal-cell epithelioma and a further excision was performed, including part of the periosteum over the tibia, and the defect was covered satisfactorily with a skin-graft.

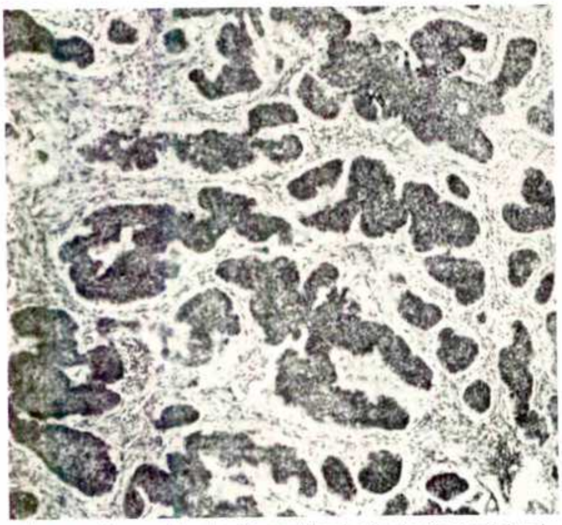

FIG. 1.—*Case* 1. Islands of typical basal cells showing peripheral palisading. H. and E. (× 32.)

By April, 1966, the tumour had recurred and was again excised. Histology again showed the lesion to be a basal-cell epithelioma and suggested that excision had been incomplete. By October, 1967, a nodule 1·5 cm. in diameter was present in the scar and this was excised, giving a 2-cm. clearance around the nodule, but again histological examination suggested that the excision was incomplete. Subsequent traumatic ulceration of the grafted area was successfully treated by bed-rest, and in April, 1968, a wide excision of the upper part of the grafted area was performed in an attempt to eradicate any remaining tumour, but malignant cells were not seen in the excised specimen.

In June, 1969, the patient was found to have developed an enlarged lymph-node in the left groin with some tethering to the overlying skin, but this appeared to progress only slowly until September, 1970, when she developed a small ulcer in the groin. Biopsy of this ulcer showed the presence of basal-cell epithelioma and she was given a course of irradiation to the inguinal gland fields (4500 rad in 17 treatments over 25 days). This produced a slight improvement in the ulcer but failed to heal it.

HISTOLOGY.—The histological features of the four positive biopsy specimens taken between 1965 and 1968 were essentially similar and were typically those of a basal-cell epithelioma. The tissue forming the ulcer base consisted of irregular islands of pale basal cells which extended deeply into the underlying dermis (*Fig.* 1). There was a moderate degree of nuclear pleomorphism and mitotic figures were fairly frequent. In addition, several small foci containing parakeratotic cells and horn cysts were seen, particularly in the first specimen (*Fig.* 2). In all the specimens peripheral palisading was present in some degree, but deeper areas of the sections revealed a tendency for the basal-cell islands to break up and disperse widely as narrow strands through the fibrotic stroma. In the most attenuated areas these were represented by columns of single cells which often anastomosed with neighbouring strands (*Fig.* 3). Tumour tissue extended up to the resection margins in all three biopsies taken before the grafted area was widely excised in 1968,

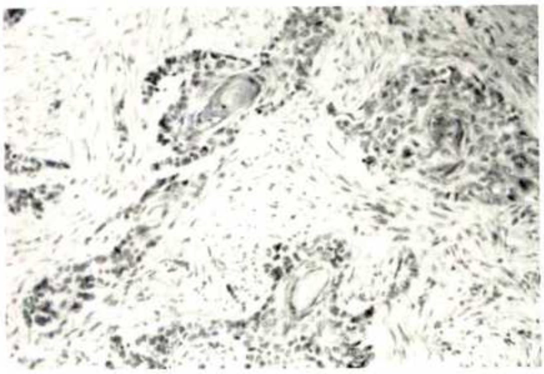

FIG. 2.—*Case* 1. Foci of keratinization with basal-cell nests. H. and E. (× 57.)

and infiltration of the subcutaneous fat was noted. Although in none of the sections was there any evidence of lymphatic invasion the biopsy in 1966 showed a small dermal blood-vessel partially surrounded by tumour cells, with a breach of continuity of the wall in one area (*Fig.* 4). The histological pattern of the tumour seen in the biopsy of the inguinal gland was similar to that of the original ulcer, except that the foci of parakeratosis with horn cysts were absent.

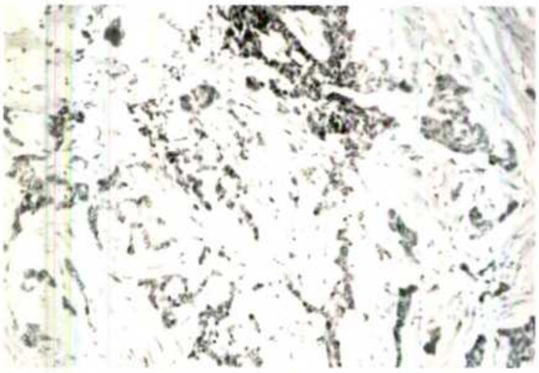

FIG. 3.—*Case* 1. Strands and columns of basal cells showing infiltrating characteristics with stromal fibrosis. H. and E. (× 57.)

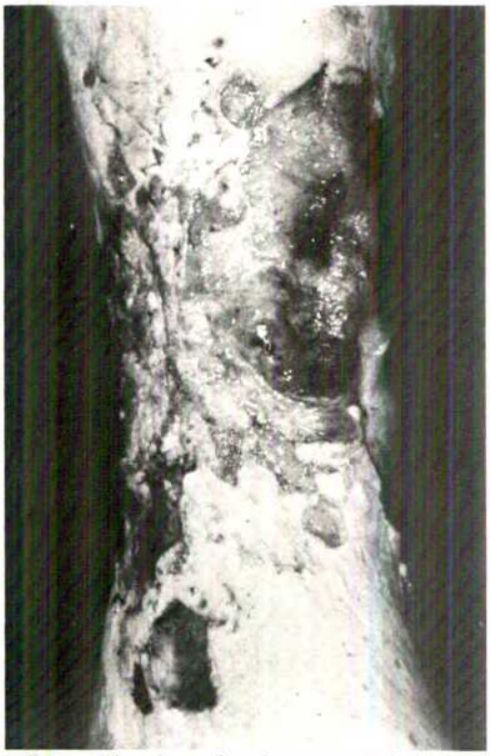

FIG. 5.—The primary ulcerating tumour on the left leg.

Lattes and Kessler (1951) laid down four criteria for accepting the diagnosis of metastasizing basal-cell epithelioma: first, that the primary tumour or metastasis is not of squamous-cell type; secondly, that the metastasis is not a new primary tumour or a direct extension of the primary; thirdly, that the primary tumour arises from the skin; and fourthly, that the histological appearance is typical of basal-cell epithelioma. If these criteria are adhered to, proven

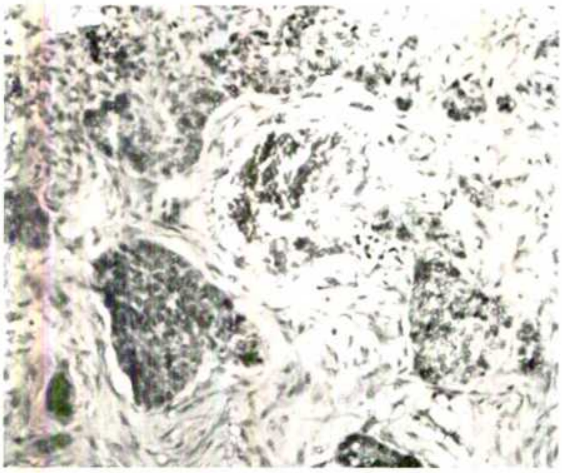

FIG. 4.—*Case* 1. Small arteriole surrounded by basal-cell epithelioma and showing a breach in the continuity of the wall below and to the right. H. and E. (× 75.)

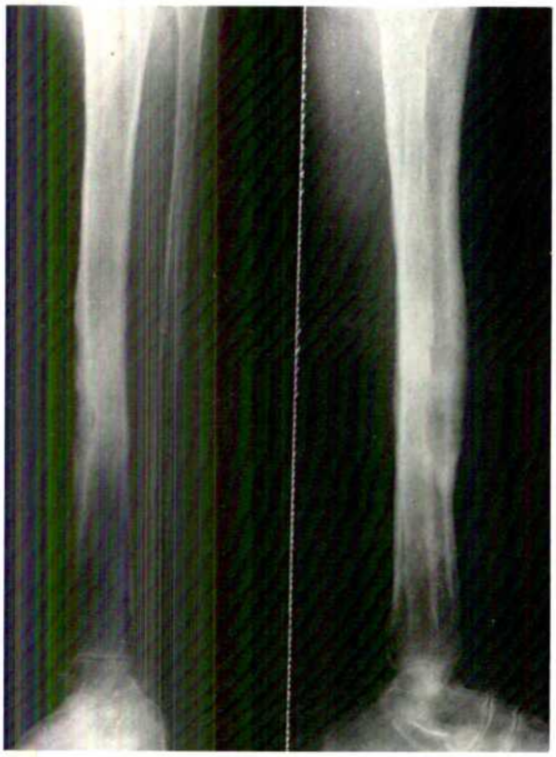

FIG. 6.—Radiograph of the left lower limb, showing marked periosteal reaction.

cases of metastasizing basal-cell epithelioma are uncommon. Cotran (1961) reviewing 9050 cases of basal-cell tumour could find only 9 with definite evidence of metastasis, an incidence of 0·1 per cent. Earlier, Cade (1940) described 1 such case in 183 epitheliomas, an incidence of 0·54 per cent. The site of the primary tumour in the present case is also unusual. Only 1 of Cotran's (1961) cases had a primary tumour not on the face or scalp, this being on the back, as was the single case reported by Urbach and Alkek (1969). Coletta, Haentze, and Thomas (1968) reported a case of basal-cell epithelioma of the left leg with multiple metastases, including involvement of the inguinal lymph-nodes. The sites of the primary tumour in other case reports include the scapular region (Binkley and Rauschkolb, 1962), the scalp (Crawford and Joslin, 1964), the face (Singer, 1944; Pickren and Katz, 1958), and the forehead (DeNavasquez, 1941). In many of the cases referred to metastases were widespread and included not only the regional lymph-nodes but also the lungs (the most frequent site of extension beyond the regional nodes), bone-marrow, and the viscera. Both vascular and lymphatic routes of spread are quoted and DeNavasquez (1941), Cotran (1961), and Crawford and Joslin (1964) report blood-vessel invasion in their material. Although vascular invasion was noticed in our case in 1966 there is, to date, no clinical evidence of widespread metastasis.

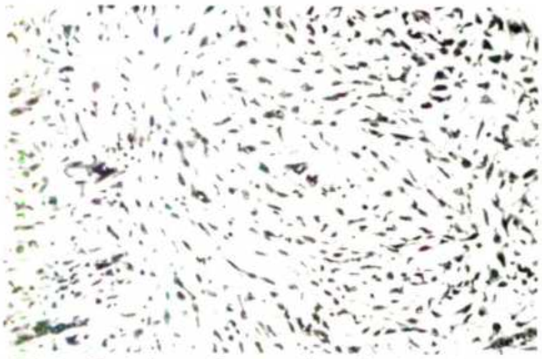

FIG. 7.—Typical area of tumour, illustrating both plump and spindle-cell elements of fibrosarcoma. H. and E. (× 57.)

In 2 of the cases with lung involvement (Pickren and Katz, 1958) widespread metastasis developed as a direct result of invasion of the oral mucosa by an ulcerating basal-cell epithelioma of the face and the aspiration of viable tumour cells.

The interval of 10 years between the appearance of the primary and secondary tumours gives a good indication of the usual time sequence, 7–43 years being quoted by Cotran (1961), and contrasts strongly with a 3-year period for most metastasizing squamous-cell carcinomas (Katz, Urbach, and Lilienfield, 1957). In spite of this a mortality rate of 50 per cent has been calculated (Binkley and Rauschkolb, 1962).

Attempts have been made to correlate the histological appearances with metastatic tendencies, and whilst Cotran (1961) could find no consistent differential features, 4 of his cases showed central foci of keratinization in typical basal-cell masses. Two other cases showed a tendency to form central cell whorls. The areas of keratinization do not resemble those seen in well-differentiated squamous-cell carcinoma since there is absence of an evolution through the prickle-cell phase. These features, seen in our case, were also commented upon by DeNavasquez (1941), Binkley and Rauschkolb (1962), and Crawford and Joslin (1964). Lever (1967), however, considers that these features are frequently seen in typical non-metastasizing basal-cell epitheliomas. Urbach and Alkek (1969) suggested that basal-cell epitheliomas with so-called basi-squamous or metatypical features are more likely to metastasize. These include prominent pleomorphism, malignant dyskeratosis, and abnormal mitotic figures, all of which were seen in the present case. Not seen, however, were the larger, acidophilic cells with loss of peripheral palisading described in the case of Thomas (1968).

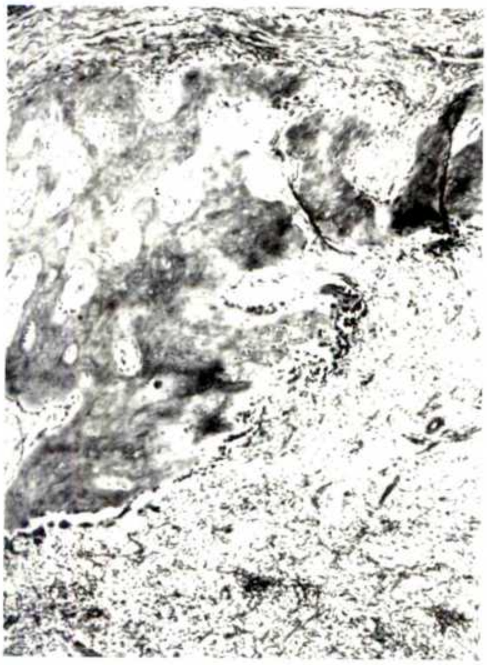

FIG. 8.—Bone trabeculae infiltrated by fibrosarcoma. H. and E. (× 30.)

Case 2.—Mrs. F. M., aged 68 years, reattended at the Out-patients' Clinic in January, 1971. She had previously been seen in 1961 and at that time she had given a 38-year history of varicose veins and a 25-year history of recurrent ulceration of the left lower leg to which skin-grafts had been applied on 6 occasions. At that time the lower two-thirds of the left leg had been grossly indurated and multiple ulcers had been present. The patient had been markedly overweight (88·3 kg., 164 cm.). She had therefore been advised to lose weight and in 1 year she had lost 25 kg. and the ulcers had healed completely. She had been admitted to hospital in November, 1962, and a Trendelenburg operation had been performed on the left leg and the long saphenous vein stripped out. The wounds in the lower leg had healed rather slowly and the patient had been lost to follow-up in July, 1963. When she attended in January, 1971, the patient maintained that her ulcers had remained completely healed for several years until she had knocked her leg 6 weeks before her out-patient visit. Two weeks later she had noticed a lump in the area and this had rapidly been followed by ulceration (*Fig.* 5). In addition a large node was palpable in the left groin.

A chest radiograph was normal, but a radiograph of the left lower leg showed extensive periosteal reaction extending down the shafts of the lower halves of both the tibia and fibula (*Fig.* 6). A small area of bone rarefaction was noted and the appearances were thought to be due to a chronic inflammatory condition rather than neoplastic invasion. The lesion was biopsied on two occasions and a left Gritti-Strokes amputation was subsequently performed.

HISTOLOGY.—A number of sections were prepared from the original biopsy material and later from the operative specimen. In addition to routine haematoxylin and eosin preparations special stains used included Beilschowsky-Maresch's stain for reticulin, periodic acid-Schiff, and Masson's trichrome.

The epithelium at the ulcer margins showed a marked downward prolongation of the stratum Malpighii but no evidence of either pseudo-epitheliomatous hyperplasia or overt carcinomatous change. The main tumour mass consisted of interlacing bundles of both plump and spindle-celled elements with much metachromatic mucopolysaccharide material in the less compact areas (*Fig.* 7). In the ulcer floor there were large areas of pale, eosinophilic, necrotic tissue with many thin-walled capillaries and a dense, acute inflammatory cell infiltrate which in places resembled active granulation tissue. Towards the periosteum the inflammatory infiltrate was less obvious and the vascular component diminished. In addition to considerable nuclear pleomorphism mitotic figures were frequent and in many cases abnormal. Throughout the tumour there was an absence of well-marked intercellular collagen bundles and taken together with the other features a diagnosis of fibrosarcoma was made. Sections made to include periosteum and bone showed evidence of wide infiltration by tumour tissue which in areas occupied the interstices of the marrow cavity (*Fig.* 8). Although a careful search of the serial sections failed to reveal unequivocal lymphatic or blood-vessel involvement, the invasive characteristics of the tumour make this virtually certain.

In any area of long-standing skin ulceration abnormalities in the adjacent tissues may become evident. Most commonly these are reactive changes in the epidermis bordering the ulcer and are seen as downward prolongations of the prickle-cell layer. This was clearly seen in one area in the present case. A slightly more alarming picture is presented by the changes of pseudo-epitheliomatous hyperplasia which nevertheless is benign. A malignant change occurring in chronically ulcerated skin is usually carcinomatous in type and the development of sarcoma is uncommon. Glasser (1939) could find reports of only 2 cases of sarcoma arising in varicose ulcers. More recently, Cruickshank, McConnell, and Miller (1963), reviewing 44 cases of malignancy occurring in scars, chronic ulcers, and sinuses, described 3 sarcomas, 2 arising in a varicose ulcer. The average duration of varicose ulceration before the development of a carcinoma was 21 years, whilst the single sarcoma developed in an ulcer of less than 5 years' duration with a fatal outcome 6 months later. This relatively short time interval contrasts with the present case in which ulceration had been present for 35 years. Difficulties in the histological diagnosis occur in cases of epidermoid epitheliomas simulating sarcoma, and this has been reported particularly in connexion with chronic radiodermatitis (Sims and Kirsch, 1948). The absence of prickle-cells or keratin is a point against an epitheliomatous origin. Although the features of the present case are typically fibrosarcomatous, other sarcomas reported have been myxomatous growths with so many blood-vessels that their appearance strongly suggested granulation tissue (Cruickshank and others, 1963). The single case of Dawson and McIntosh (1970) contained a malignant haemangiomatous element sufficient to warrant a diagnosis of 'granulation tissue sarcoma'.

As in all cases of malignant transformation the question of pathogenesis has been discussed at length. Menkin (1960) suggested that a growth-promotion factor, which he believed to be present in inflammatory exudate, acts in conjunction with scar tissue to produce excessive growth and finally the features of malignancy. In this respect a varicose ulcer lies midway between a healed scar and an osteomyelitic sinus in malignant potential. Peterkin (1955) also discussed an additional factor in the erythema ab igne commonly seen in women.

Acknowledgements.—Our thanks are due to Mr. D. H. Randall for allowing us to publish details of these 2 patients who were under his care, and to Mrs. Marion Row, Department of Pathology, University of Sheffield, for the preparation of the photomicrographs.

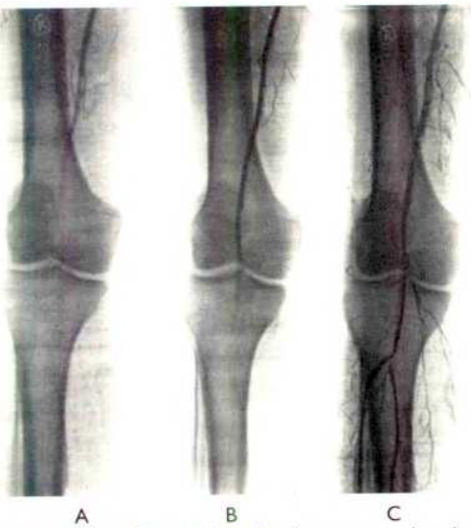
ROUTINE OPERATIVE ARTERIOGRAPHY IN ARTERIAL EMBOLECTOMY

BY G. E. MAVOR, M. G. WALKER, AND D. P. DHALL
ABERDEEN ROYAL INFIRMARY

THE results of surgical treatment of peripheral arterial embolism have been greatly improved by the use of balloon catheters, which were first introduced for this purpose by Fogarty, Cranley, Krause, Strasser, and Hafner (1963). It is now recognized that surgery is the treatment of choice in peripheral embolism in both the upper and lower limbs and is probably contra-indicated only in the presence of established limb gangrene or, when following myocardial ischaemia and failure, embolism is a near terminal event.

The aim of treatment is no longer mere limb survival but the restoration of patency of the affected arterial tree in its whole length. Only by arteriography can complete arterial patency be guaranteed. Our experience with embolectomy under routine operative arteriographic control confirms that clearance of the arterial tree in its whole length is greatly facilitated and results thereby improved.



A B C

FIG. 1.—Operative arteriography shows progressive clearing of the popliteal artery (A, B). In the final arteriogram (C) some thrombus may remain at the popliteal bifurcation area.

MATERIALS AND METHODS

The present series covers the last 71 arterial embolectomies carried out at the Aberdeen Royal Infirmary. Sixty of the embolectomies were performed on the lower limb (*Table I*). In all instances embolectomy was carried out from the common femoral artery for the lower limb and from the axillary artery for the upper limb. In all instances except 9 operative arteriography was used. After routine passage of the balloon catheter distally, either once or twice with removal of thrombus, operative arteriography was undertaken. The technique consisted of the passage of a 30-cm. Portex nylon intravenous cannula via the arteriotomy distally into the femoral or brachial arteries. About 10 ml. of Angiografin 3 per cent were injected distally and an arteriogram was taken, attention being directed particularly to the popliteal and brachial bifurcation areas. Occasionally two or three arteriograms were required before adequate clearance was demonstrated. When operative arteriography was satisfactory results were good (*Table II*). In 13 cases arteriography was unsatisfactory in so far as proper visualization of the popliteal or brachial bifurcation and the distal arterial tree was not obtained, owing mainly to technical inexperience or difficulty. All the cases with peripheral arterial embolism were subjected to embolectomy except when gangrene was established. In some,

delay was considerable (*Table III*). There were 14 early deaths in the series (*Table IV*).

CASE REPORTS

Case 1.—A man aged 61 years presented complaining of the sudden onset of coldness pallor in both legs. A left femoroprofunda embolus had been removed 3 years previously. The common femoral arteries were exposed and bilateral embolectomies were carried out under operative arteriographic control. On the right side two operative arteriograms showed that clearance was inadequate despite removal of much thrombus (*Fig.* 1 A, B). Further passage of the balloon catheter to the ankle and the removal of more thrombus were then followed by a third and finally adequate operative arteriogram (*Fig.* 1 C). On the left side operative arteriography showed that clearance of the posterior tibial artery was initially inadequate (*Fig.* 2 A). Postoperative recovery on both sides was satisfactory (*Fig.* 2 A, B).

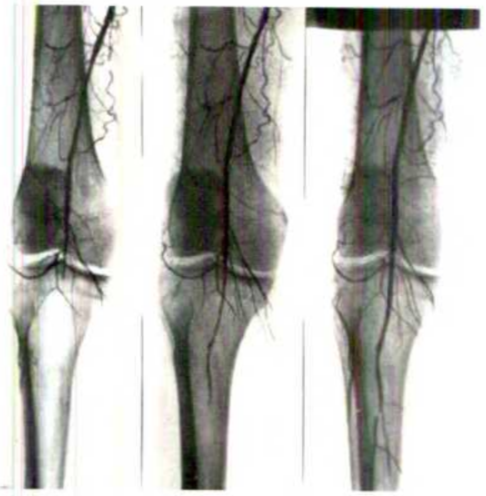

FIG. 3.—The first operative arteriogram (A) shows persistent distal popliteal occlusion. Progressive clearance is demonstrated in (B) and (C).

Table II.—RESULTS OF ARTERIAL EMBOLECTOMY

	ARTERIOGRAPHY SATISFACTORY	ARTERIOGRAPHY UNSATISFACTORY (13)/NOT DONE (9)
No. of embolectomies	49	22
Patent arterial tree and normal leg (clinically)	47	13
Persistent ischaemia	2*	8†
No. of deaths	4	10

* One case was due to persistent posterior tibial occlusion and the other to peroneal artery damage and arteriovenous fistula formation. There was 1 amputation in this group.

† There were 5 amputations in this group.

Table III.—TIME BETWEEN ONSET OF OCCLUSION AND SURGERY

Time	*No. of Embolectomies*
0–6 hours	21
6–12 hours	13
12–24 hours	4
72 hours	11
No information	22
Total	71

Case 2.—A woman aged 52 years was admitted with an obvious arterial embolus lodged in the right common femoral artery. She had had a myocardial infarction about 1 year previously, and was in atrial fibrillation when seen at the present time. The right common femoral artery was exposed and considerable thrombus was removed from the distal arterial tree, the balloon catheter being passed easily to the ankle twice. A subsequent operative arteriogram centred on the distal popliteal area showed that distal popliteal occlusion persisted (*Fig.* 3 A). More thrombus was removed, and although the operative arteriogram showed improvement it was not yet satisfactory (*Fig.* 3 B). Further thrombus was removed and further arteriography revealed adequate clearance (*Fig.* 3 C). The postoperative result was satisfactory.

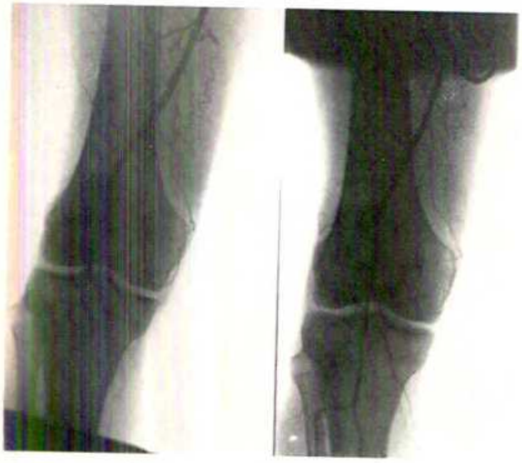

FIG. 4.—The first operative arteriogram (A) shows persistent distal popliteal occlusion despite previous removal of much thrombus. The final film (B) is satisfactory.

Table IV.—CAUSES OF DEATHS OCCURRING WITHIN 7 DAYS AFTER EMBOLECTOMY

Cause of Death	*No. of Deaths*
Myocardial infarction/failure	6
Cerebral embolism	2
Mesenteric embolism	1
Carcinoma	1
Amputation	2
Unknown	2
Total	14

Case 3.—A woman aged 42 years complained of coldness and numbness of the right foot 10 hours after undergoing mitral valvotomy for rheumatic heart disease. A diagnosis of right common femoral embolism was made, and at operation a femoroprofunda embolus was removed, the balloon catheter being passed easily to the ankle. Routine operative arteriography then showed that the distal popliteal artery was still occluded (*Fig.* 4 A). The balloon catheter was passed to the ankle, further thrombus was removed, and a second arteriogram visualized the distal popliteal and anterior and posterior tibial arteries (*Fig.* 4 B). The patient's subsequent postoperative course was satisfactory.

DISCUSSION

The improved results in arterial embolectomy with the Fogarty balloon catheter are largely due to the feasibility of treating the whole length of the arterial tree, removing both the embolus and its fragments and any propagated thrombus. The operation is carried out from the common femoral artery for the lower limb and from the axillary artery for the upper, irrespective of the supposed site of impaction of the embolus. It has been our experience, however, that despite careful manipulation of the catheter and its frequent passage and the establishment of free 'back-bleeding', complete patency of the arterial tree in its whole length is not always achieved. In such instances residual clot in the main artery, particularly at its bifurcation area, can readily be demonstrated by postoperative arteriography, usually dictated by a poor or unsatisfactory recovery of the peripheral circulation.

As the aim of embolectomy is to restore patency of the arterial tree, arteriography is clearly a technical facility which should be used. As the present case reports illustrate, without arteriography arterial clearance would not have been adequate in some instances despite the repeated passage of the Fogarty catheter. Without the objective evidence of clearance which arteriography produces the surgeon must therefore remain uncertain of the outcome of his operation. Alternatively, in some instances operative arteriography will also demonstrate that clearance is not possible, or in rarer instances that damage, usually to the peroneal artery, has resulted (Mavor, Walker, Dhall, and Pegg, 1972).

As reported, operative arteriography has improved our results, particularly where there has been some delay before operation. It is safe, simple, and causes little delay, and in our opinion should become an essential and routine part of the operation of arterial embolectomy.

CARCINOMA OF COLON SIMULATING CROHN'S DISEASE

BY B. J. STOODLEY AND C. V. MANN
ST. MARK'S HOSPITAL, LONDON

SUMMARY

1. Three cases are described where carcinomatous involvement of the colon was mistaken for Crohn's disease of the large bowel.

2. The need to obtain histological proof is emphasized.

3. Ascitic fluid should be examined histologically in a patient diagnosed as having Crohn's disease.

4. Selective mesenteric angiography was used and is considered a valuable tool in diagnosis.

THREE patients are described who were initially diagnosed as having Crohn's disease. Subsequent investigations proved the diagnosis to be that of carcinoma in each case. The diagnosis of Crohn's disease of the colon based solely on the evidence of barium-enema examinations may be erroneous and should be confirmed by additional techniques whenever possible.

CASE REPORTS

Case 1.—A 45-year-old Greek woman was referred to St. Mark's Hospital with a 2-year history of pain in the right iliac fossa and a low backache. In 1964 for 3 months the patient had had diarrhoea, up to twenty motions daily, with occasional slight bleeding. The diarrhoea had been relieved a little by Dexamethasone given by her own physician. She had lost nearly 8 kg. in weight. There was no history of previous illness.

Examination showed an obese woman with some tenderness over a vague mass in the right iliac fossa. On rectal examination there was a stricture palpable at 6–8 cm. from the anal verge. On sigmoidoscopy the mucosa was oedematous below the stricture but was normal above it to 20 cm. A biopsy of the stricture was reported as showing non-specific, chronic, inflammatory changes only.

Barium-enema examination (*Fig.* 1) confirmed the rectal stricture; irregular strictures in the sigmoid, transverse, and ascending colon were also observed, together with 'rose-thorn' spiculations in the transverse colon and a 'cobblestone' appearance of the lateral wall of the ascending colon. Between these 'skip' areas the colon was normal. These radiological appearances were thought to be typical of Crohn's disease. A barium-meal and follow-through examination was normal. The erythrocyte sedimentation rate was 49 mm. per hour Westergren.

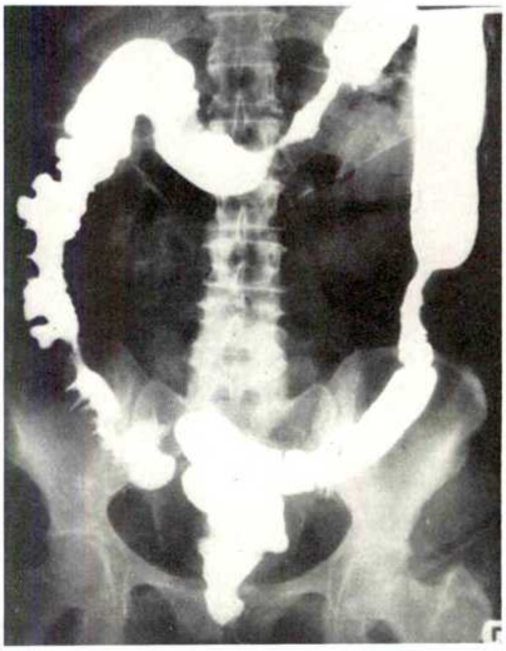

FIG. 1.—*Case* 1. Barium-enema film showing appearances typical of Crohn's disease.

A diagnosis of Crohn's disease was made.

On 3 March, 1964, a colectomy with an ileosigmoid anastomosis was carried out, the rectal stricture being dilated at the same time. It was noted that most of the colon felt rubbery. The remainder of the intra-abdominal organs, including the stomach and small intestine, appeared normal. There was no operative finding inconsistent with the diagnosis of colonic Crohn's disease.

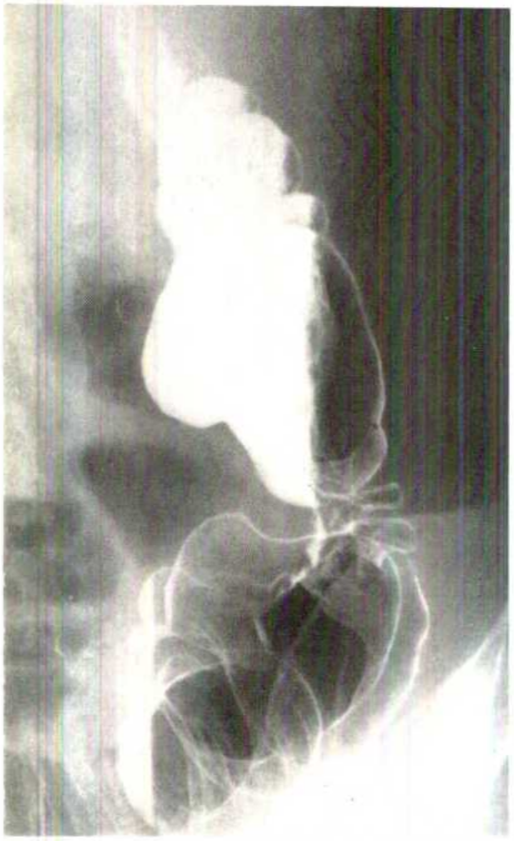

FIG. 2.—*Case* 3. Barium-enema film showing the descending colon with an asymmetrical 'purse-string' stricture.

The pathological report on the operative specimen was of multiple strictures caused by a widespread infiltration of the bowel wall by a high-grade anaplastic carcinoma with occasional signet-ring-type cells. The mucosa was not ulcerated. The stomach was suggested as the site of the primary neoplasm.

Apart from the regular use of Hegar's dilators for the stricture no further treatment was advised.

In May, 1967, a barium meal showed a small prepyloric ulcer. This slowly progressed to form a pyloric stenosis.

In April, 1968, a laparotomy was done to relieve a pyloric obstruction, which was found to be due to a carcinoma. There was no obvious tumour in the liver, but there were multiple plaques of growth throughout the abdominal cavity. A gastrojejunostomy was performed. The patient returned to Greece later in the year and no further information as to her survival has been received.

Case 2.—A 22-year-old English woman presented at another hospital with a 14-month history of low backache. For 3 months she had had lower abdominal discomfort with left-sided pain. The patient complained of colic preceding defaecation and also of intermittent constipation and diarrhoea, with the passing of some blood and mucus occasionally.

Examination of the abdomen at that time was normal, but an extrarectal mass was felt high anteriorly on rectal examination. Sigmoidoscopy showed mucosal oedema. A biopsy of the rectal mucosa adjacent to the mass showed only oedema.

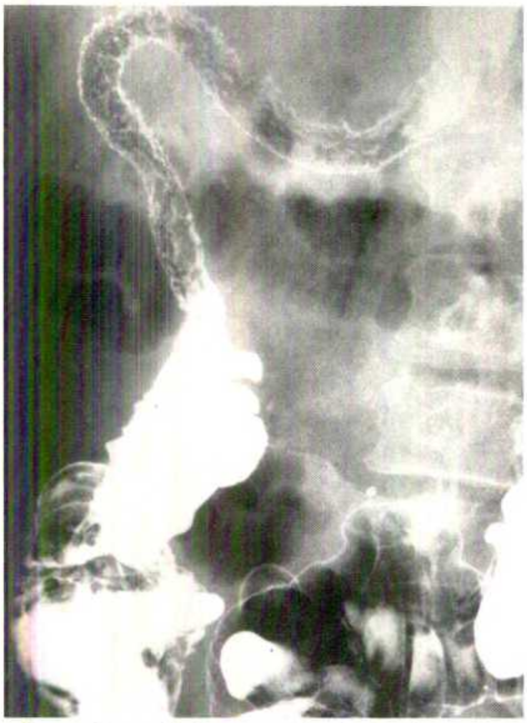

FIG. 3.—*Case* 3. Barium-enema film showing the ascending colon and part of the transverse colon with 'cobblestoning', fissure formation, and a sharp stricture.

Barium-enema examination disclosed a stricture in the sigmoid colon, 10 cm. in length, with marked fissuring consistent with Crohn's disease. The erythrocyte sedimentation rate was 28 mm. per hour Westergren.

A diagnosis of Crohn's disease was made and treatment with Salazopyrin, 0·5 g. four times a day, was commenced, but the symptoms worsened and the patient lost 10 kg. in weight. At this stage she was referred to St. Mark's Hospital.

The abdomen was slightly distended and the colon was loaded with faeces. A mass was present in the rectovaginal pouch. The rectal mucosa appeared oedematous and there was much mucus in the lumen.

Treatment with prednisolone enemata was commenced, but obstructive symptoms were developing and these necessitated a transverse colostomy on 4 Sept., 1970. Some ascitic fluid was noted and examination of the pelvis showed a circumferential stricture of the upper half of the rectum above 10 cm. The posterior fornix of the vagina was indented. Biopsies taken from the mucosa of the rectum and from the transverse colon showed no evidence of Crohn's disease. At a further examination under anaesthesia on 15 Sept. the mass was found to have extended down the rectovaginal septum, and large para-aortic lymph-nodes were palpable. Deep biopsies from the rectovaginal septum and the posterior wall of the rectum each showed infiltration by anaplastic, mucus-secreting, signet-ring cells of high-grade malignancy.

A course of 5-fluoro-uracil, 750 mg. daily intravenously for 5 days, was given prior to further surgery.

On 8 Oct. a laparotomy showed ascites and gross thickening of the sigmoid colon and rectum which were fixed in the pelvis. Many tumour masses were found; all the peritoneal surfaces were studded with mucus-secreting adenocarcinomatous nodules (a frozen-section report). The liver contained no metastases. An intraperitoneal dose of 1 g. of 5-fluoro-uracil was instilled; a further intravenous course had to be stopped after 3 days because of nausea.

The patient died 4 months after the last operation.

Case 3.—A 49-year-old English man was referred to St. Mark's Hospital with a 3-year history of postprandial, retrosternal pain with increasing anorexia and a loss of weight of 7 kg. He complained of increasing attacks of loose stools, with up to five or six motions per day.

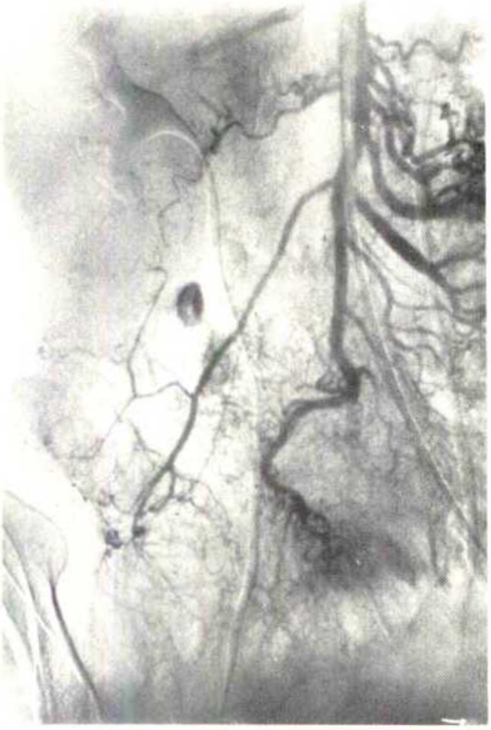

FIG. 4.—*Case* 3. Selective angiogram showing the interruption in the marginal artery supply to the ascending colon, near the lower pole of the kidney.

Examination revealed an ill man with a hard mass in the right iliac fossa. Sigmoidoscopy at that time was normal to 20 cm. A rectal biopsy was normal.

Barium-enema examination showed an asymmetrical stricture in the descending colon with a 'purse-string' appearance (*Fig.* 2). There was a second stricture in the transverse colon having both 'cobblestone' and fissure formations, and a third, very sharp stricture in the ascending colon (*Fig.* 3). These appearances were reported as being almost pathognomonic of Crohn's disease, a diagnosis of carcinomatosis having been considered and rejected as being most unlikely. The erythrocyte sedimentation rate was 25 mm. per hour Westergren. Admission was arranged with a view to resecting the colon.

In the period before admission a barium-meal and follow-through examination was done. This showed a prepyloric filling defect.

On admission an impassable stricture was found to have developed in the rectum at 14 cm. A deep biopsy of this stricture showed an intact mucosa with infiltration of the submucosa by a high-grade carcinoma, consistent with a primary in the stomach.

Laparotomy on 17 Sept., 1970, confirmed the presence of ascites with widespread intraperitoneal tumour deposits, especially in the upper abdomen and transverse mesocolon. The whole colon felt thickened.

Selective angiography was carried out, for reasons discussed later. This showed interruptions in the marginal artery supply to the colon (*Fig.* 4) such as would be expected in carcinomatosis and not with Crohn's disease.

The patient died 2 months later.

DISCUSSION

The radiological features of Crohn's disease of the colon are held to be transverse fissures, longitudinal and deep, ragged, mural ulcerations, pseudodiverticula, strictures, pseudopolypoid changes, eccentric involvement of the bowel, 'skip' lesions, and internal fistula and sinus tracks (Marshak and Lindner, 1970). There is often involvement of the terminal ileum in addition to these findings.

In each of the 3 cases described here the barium-enema appearances were consistent with a diagnosis of Crohn's disease of the colon and rectum, having many of the characteristics listed above. In addition, all 3 patients were comparatively young.

In *Cases* 2 and 3 biopsies of the rectal strictures altered the diagnosis from Crohn's disease to that of carcinoma. In *Case* 1, however, the diagnosis was made only when the colectomy specimen was examined histologically. The value of *deep* biopsies of any rectal stricture of uncertain origin is emphasized, the stricture not necessarily being of intrinsic origin.

Where no stricture is present and a rectal mucosal biopsy is either negative or inconclusive, selective angiography of the superior and inferior mesenteric arteries may prove helpful. In *Case* 3 marginal artery interruptions were easily demonstrable. These are not found in Crohn's disease and are usually due to tumour invasion. A further benefit of this examination is that it may demonstrate the presence of a tumour circulation, which is of value when considering the use of antimitotic agents.

Although cytological studies of peritoneal fluid were not carried out in any of these cases it is recommended that, when ascites is present in a patient who is considered to have Crohn's disease, paracentesis should be done and the deposit examined for malignant cells.

Acknowledgements.—Thanks are expressed to Dr. H. Herlinger for the angiograms, to Mr. H. E. Lockhart-Mummery and Mr. P. R. Hawley for permission to publish *Cases* 1 and 2 respectively, and to Mr. N. Mackie who kindly prepared the photographs.

PROSTATECTOMY AND DEEP-VEIN THROMBOSIS

BY A. N. NICOLAIDES,* E. S. FIELD, V. V. KAKKAR, A. J. YATES-BELL, S. TAYLOR, AND M. B. CLARKE
THE DEPARTMENTS OF SURGERY, UROLOGY, AND MEDICAL PHYSICS, KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

In a study of 50 patients who had undergone prostatectomy the incidence of deep-vein thrombosis was measured, using the ^{125}I-fibrinogen test. Of these, 12 (24 per cent) developed deep-vein thrombosis. This preliminary study showed that in patients who had had a transurethral resection the incidence of deep-vein thrombosis was 6·8 per cent, while in patients who had had a retropubic prostatectomy it was 47·6 per cent.

RECENT venographic studies have suggested that the incidence of deep-vein thrombosis is high after prostatectomy (Becker, Borgström, and Saltzman, 1970), and it has been reported that pulmonary embolism is the commonest cause of death after this operation (Antila, Markkula, and Iisalo, 1966). These studies have prompted the present investigation, in which an attempt has been made to determine not only the incidence of deep-vein thrombosis but also the time and site of formation of thrombi and whether any group of patients is particularly at risk.

The true incidence of deep-vein thrombosis cannot be estimated clinically because signs are unreliable in diagnosing the condition (Flanc, Kakkar, and Clarke, 1968; Negus, Pinto, Le Quesne, Brown, and Chapman, 1968). The ^{125}I-fibrinogen test, however, is an accurate method of detecting thrombosis at the earliest stage (Atkins and Hawkins, 1965; Flanc and others, 1968; Negus and others, 1968). There is no doubt that effective attempts to treat deep-vein thrombosis and to prevent pulmonary embolism are more successful when carried out early (Kakkar, Howe, Flanc, and Clarke, 1969). By using a ratemeter (Kakkar, Nicolaides, Renney, Friend, and Clarke, 1970) the technique is rapid and simple and can be used as a routine screening procedure in a large number of patients. This technique was adopted in the present study.

MATERIALS AND METHODS

Selection of Patients.—Fifty consecutive patients admitted for routine prostatectomy were studied. Their ages ranged between 55 and 92 years. Patients with clinical signs or a history of recent deep-vein thrombosis were excluded.

Transurethral resection was performed in patients with obstructive symptoms due to prostates which were small and fibrous, in those with benign glands which were estimated to weigh less than 30 g., and in those with glands which were thought to be malignant. Retropubic prostatectomy was reserved for large benign glands. All the patients had an indwelling catheter for approximately 4–5 days after operation.

Diagnosis of Deep-vein Thrombosis.—All the patients were screened by the ^{125}I-fibrinogen test, using the Pitman 235 isotope localization monitor (Kakkar, Nicolaides, and others, 1970). Human fibrinogen was obtained in the form of Antihaemophilic Factor Concentrate (Kabi). Carrier-free ^{125}I in sodium hydroxide solution with a specific activity of 120 m.c. per ml. was obtained from the Radiochemical Centre, Amersham, England. The fibrinogen was iodinated, using the 'jet iodination' method of McFarlane (1963). Each patient was given 100 μc. of ^{125}I fibrinogen intravenously the day before operation, after blocking the thyroid gland with sodium iodide. The legs were scanned 2 hours after the injection of ^{125}I fibrinogen, immediately after operation, on the day following operation, and then on alternate days. All the patients were examined daily for local tenderness in the calf or thigh and for pitting oedema at the ankle. If the radioactivity increased or if clinical signs of thrombosis developed the legs were scanned daily. On average, the legs were scanned for 9 days. Using the Pitman monitor, the radioactivity of the various positions in the legs was expressed as a direct percentage of the heart-count. Patients were considered to have deep-vein thrombosis when an increase of 20 was observed in the percentage value of radioactivity at the same place on two different days or between two adjacent sites, provided that this increase persisted for more than 24 hours (Kakkar, Nicolaides, and others, 1970).

Table I.—INCIDENCE OF DEEP-VEIN THROMBOSIS

OPERATION	NO. OF PATIENTS		
	No Deep-vein Thrombosis	Deep-vein Thrombosis	Total
Retropubic prostatectomy	11	10 (47·6 per cent)	21
Transurethral resection	27	2 (6·8 per cent)	29

Fisher's exact test: $P = 0{\cdot}0012$.

RESULTS

Twelve of the 50 patients studied developed deep-vein thrombosis, giving an overall incidence of 24 per cent. Twenty-one patients had a retropubic prostatectomy, and 10 (47·6 per cent) of these developed deep-vein thrombosis. Twenty-nine patients had a transurethral resection of the prostate but only 2 (6·8 per cent) of these developed deep-vein thrombosis (*Table I*). The difference between the two groups was significant (Fisher's exact test: $P = 0{\cdot}0012$). The distribution of various factors known to predispose to deep-vein thrombosis (Kakkar, Howe, Nicolaides, Renney, and Clarke, 1970) in the patients studied is such that these two groups are comparable (*Table II*).

---

[*] Present address: Department of Surgery, St. Mary's Hospital, Paddington, London.

There was no significant difference between the mean age of the patients. Obese patients and patients who had a history of deep-vein thrombosis were equally distributed in the two groups. The presence of malignancy, according to previous studies (Kakkar, Howe, and others, 1970), would, if anything, predispose to thrombosis. However, none of the patients with carcinoma of the prostate developed deep-vein thrombosis after transurethral resection.

In all the 12 patients who developed deep-vein thrombosis the thrombi started in the calf. In 3 of these, thrombi were bilateral. Thrombi were detected in 9 limbs during the first 48 hours after operation, in 1 limb on the third day, in 1 limb on the fourth day, in 3 limbs on the fifth day, and in 1 limb on the seventh day after operation.

Table II.—DISTRIBUTION OF FACTORS FAVOURING DEEP-VEIN THROMBOSIS

OPERATION	MEAN AGE (years; ± S.D.)	NO. OF PATIENTS				
		Obesity	History of Deep-vein Thrombosis	History of Pulmonary Embolism	Varicose Veins	Presence of Malignancy
Retropubic prostatectomy	69·6 ± 11·7	4	1	0	0	0
Transurethral resection	64·3 ± 9·4	5	1	0	0	7

In 1 patient the thrombus extended into the popliteal vein, but in the remaining patients the thrombi were confined to the calf. In none of the patients did the thrombi extend into the femoral vein and none had overt clinical evidence of pulmonary embolism.

DISCUSSION

The findings of this preliminary study support the high incidence of deep-vein thrombosis recently reported in patients undergoing prostatectomy (Becker and others, 1970). Above all, however, they demonstrate that patients who have a retropubic prostatectomy are far more likely to develop deep-vein thrombosis (47·6 per cent).

It has already been shown that the incidence of deep-vein thrombosis is related to the severity of the operation (Kakkar, Howe, and others, 1970). Furthermore, stasis, which is believed to be an important factor in the aetiology of venous thrombosis, is less during a transurethral resection because the legs are elevated (Nicolaides, Kakkar, and Renney, 1971). In addition, the absence of pain after transurethral resection allows the patients to be more active during the early postoperative period. The facts that 60 per cent of the thrombi are first detected during the first 48 hours after operation and that they all start in the calf may be useful guides in the future for planning prevention. In the meantime the high risk of deep-vein thrombosis in patients undergoing open prostatectomy should be another factor to be borne in mind when deciding the type of operation to be performed.

Experience in the management of postoperative patients in general surgery (Murray, 1971) may well serve as a guide in the management of deep-vein thrombosis. In practice, the thrombi first develop in the calf (Flanc and others, 1968), and particularly in the soleal veins (Nicolaides, Kakkar, Field, and Renney, 1971). In only 20 per cent of these patients does the process extend more proximally into the popliteal, femoral, or iliac veins. If the thrombus is limited to the calf the risk of pulmonary embolism is, for all practical purposes, negligible, but if the popliteal and more proximal veins are thrombosed the risk of pulmonary embolism rapidly increases to about 50 per cent (Kakkar and others, 1969).

It would thus appear that, when considering the threat to life, it is those patients with a thrombus above the popliteal vein who are most at risk, and it is for these patients that early therapy is particularly important. Extension of the thrombus can be easily detected with the Pitman isotope localization monitor and treatment can then be instituted at the proper time. In the absence of an effective method of prophylaxis this screening test, combined with prompt treatment when necessary, offers the best chance of preventing pulmonary embolism. The details and results of treatment have been described elsewhere (Murray, 1971).

Acknowledgements.—We are grateful to Professor J. G. Murray for his encouragement and help, to Mr. Harland Rees and Mr. Derek Packham who allowed us to study their patients, to Pfizer Ltd. (U.K.) for financing a research fellowship for A. N. Nicolaides, to the King's College Hospital Research Fund for financial assistance to E. S. Field, to Mr. S. Serunkuma and Miss. W. Bevis for invaluable technical assistance, and to Mrs. M. G. Shelton for secretarial help.

SHORT NOTES OF RARE OR OBSCURE CASES

HYDATID DISEASE OF THE SPLEEN

REPORT OF AN UNUSUAL CASE

By M. TORBATI

DEPARTMENT OF SURGERY, PAHLAVI MEDICAL CENTRE, UNIVERSITY OF TEHERAN, IRAN

SUMMARY

A case of an unusually large hydatid cyst of the spleen measuring 53 cm. in diameter and containing 21 litres of fluid and scolices is reported in a 40-year-old farmer. He had a brief history of nausea, intermittent vomiting, and shortness of breath.

Surgical removal of the spleen with the cyst was followed by complete recovery.

ECHINOCOCCOSIS (Batsch, 1786) is a well-known disease and it is endemic in some sheep-raising countries. The incidence in peons in Uruguay is thought to be as high as 50 per cent (Manson-Bahr, 1966). In Iceland 16·6–33 per cent of humans are infected and 28 per cent of dogs harbour the adult worms (Dungal, 1946).

The disease is common in Iran, and in some south-western areas about 4·3 per cent of sheep carcasses are infected (Khalili, 1962). At the university hospitals in Teheran an average of 120–130 cases are operated on each year (Azizi, 1966). This constitutes about 2 per cent of all the minor and major surgical operations.

Hydatid disease of the spleen is relatively rare and comprises approximately 4 per cent of the cases of hydatid disease presenting to the Pahlavi Medical Centre, University of Teheran. Jidejian (1953) reports an incidence of 3·6 per cent, while Dévé (1933) mentions 2·7 per cent.

The symptoms of these cysts in the spleen are vague. The cyst sometimes reaches an enormous size before giving rise to any complaints. Occasionally the patient has a sensation of a swelling or heaviness in the left side of the abdomen; in some other cases nausea, anorexia, and intermittent vomiting are reported.

Since January, 1966, 19 cases of echinococcosis of the spleen have been seen in the Pahlavi Medical Centre, University of Teheran. Left upper abdominal pain associated with heaviness and a sensation of swelling in this area were present in 10 cases. In 1 case, a 24-year-old housewife, the only symptom was gastric bleeding. This was found to be due to splenic vein thrombosis leading to portal hypertension and extensive varices of the short gastric veins. Two cases were discovered during other abdominal operations and the remaining patients presented with a history of nausea, anorexia, and loss of weight. One of these patients complained of constant diarrhoea. Hydatid cysts are usually slow growing. In some organs, especially in the spleen, they can reach an enormous size and be asymptomatic. It was therefore thought worth while to present a case which demonstrates how large a hydatid cyst can become before giving rise to symptoms.

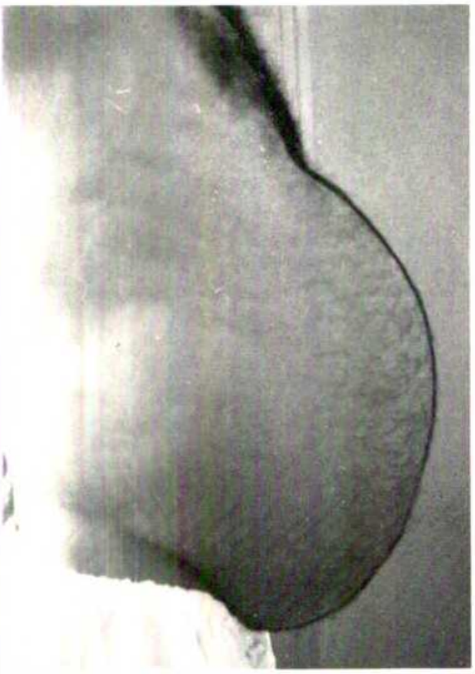

FIG. 1.—The patient before operation with an abdominal circumference of 118 cm.

CASE REPORT

A 40-year-old farmer was referred to the Surgical Unit of the Pahlavi Medical Centre for the diagnosis and treatment of a large abdominal mass. He had had no symptoms until 3 months previously. Since that time he had experienced left upper abdominal pain associated with nausea and intermittent vomiting. In the past 2 months he had noticed progressive abdominal distension and had had episodes of dyspnoea on exertion.

INVESTIGATIONS.—The patient was in a very poor general condition. His weight on admission was 96 kg., his height, 172 cm., and his abdominal circumference, 118 cm. (*Fig.* 1). His blood-pressure was 110/70, and his pulse-rate was 96. There was no clinical abnormality of the heart, lungs, or nervous system. An electrocardiogram was normal. A postero-anterior radiograph of the chest showed elevation and limited movement of both diaphragms.

The haemoglobin was 14·7 g. per 100 ml. and the peripheral white-cell count was 4600 per c.mm. (neutrophils, 70 per cent; lymphocytes, 12 per cent; eosinophils, 8 per cent; monocytes, 10 per cent). The erythrocyte sedimentation rate was 55 mm. in the first hour; the blood-urea and electrolytes were normal. An intradermal (Casoni) test was negative.

OPERATION (15 Sept., 1970).—The operation was carried out through a midline incision from the xiphoid process to the symphysis pubis. A large cyst measuring 53 cm. in diameter (*Fig.* 2) was found arising in and largely displacing the spleen. The liver showed no abnormality; the stomach, transverse colon, and jejunum were displaced and adherent to the posterior surface of the cyst. The surface of the cyst was pale, smooth, and, in some parts, calcified. Two other daughter cysts measuring 5 and 7 cm. in diameter were found attached to the omentum and were removed (*Fig.* 3).

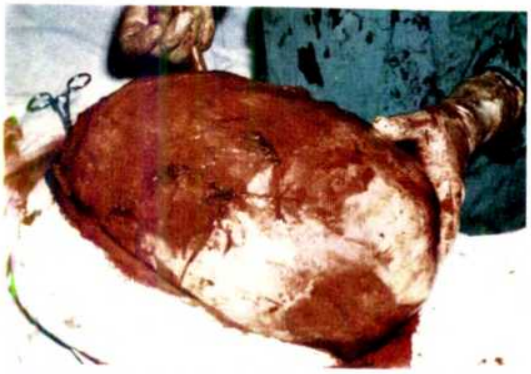

FIG. 2.—Operative view of the hydatid cyst of the spleen. White areas at the lower pole correspond to calcified portions of the cyst wall.

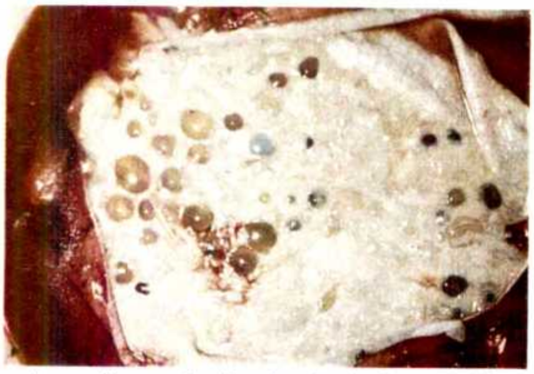

FIG. 4.—The cyst after dissection, showing the germinal layer and scolices.

An attempt to reach the splenic pedicle was soon given up. The fluid contents were then aspirated and 21 litres of a clear watery fluid containing thousands of scolices were removed (*Fig.* 4). After treating the cavity with 1 per cent formalin it was possible to remove the cyst completely with the spleen. The empty cyst weighed 9 kg.

Immediately after operation the patient developed signs of hypovolaemic shock. This was treated with transfusions of several units of blood. Subsequent recovery was uneventful and the patient was discharged from hospital 14 days after operation. His weight on discharge was 63 kg.

DISCUSSION

The hydatid cyst is the only parasitic cyst of the spleen and it is said to be twice as common as the non-parasitic variety (Fowler, 1953). Hydatid cyst of the spleen may be primary or secondary to ruptured liver cysts. It is found in about 2–4 per cent of patients with *Echinococcus* infections (Dévé, 1933; Jidejian, 1953).

In the case of a solitary large cyst or multiple cysts an enlarged spleen may be found. In other cases a mass attached to the spleen may be palpated and confused with pancreatic or omental cysts.

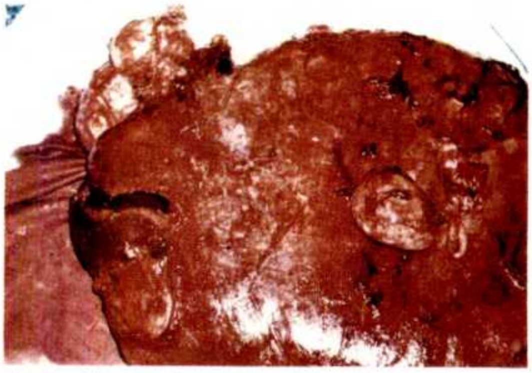

FIG. 3.—The operative specimen. Splenic tissue is seen at the lower pole and the daughter cysts at the left upper pole.

Calcification of the cyst wall which sometimes occurs may help in making a preoperative diagnosis (Neubauer and Wiandt, 1967). As in the present case, exogenous daughter cysts in the omentum are secondary. They are caused by herniation or rupture of both the germinal and laminated layers through weakened parts of the adventitia owing to intracystic pressure (Manson-Bahr, 1966).

Rupture of a splenic hydatid cyst can occur spontaneously caused by intracystic pressure or trauma. This can lead to severe shock, which is probably anaphylactic, and dissemination throughout the peritoneal cavity.

Symptoms vary with the size of the cyst. Small or uncomplicated hydatid cysts may be silent, while large cysts produce pressure on the neighbouring organs, leading to abdominal discomfort, a dull ache in the left upper quadrant, nausea, vomiting, and sometimes diarrhoea or obstipation.

The intradermal (Casoni) test is a valuable diagnostic procedure. It is positive in 90 per cent of hydatid infections (Dew, 1928); a positive reaction half an hour after intradermal injection is said to indicate a young cyst, whereas a reaction after 48 hours is often found in an older or biologically inactive cyst (Neubauer and Wiandt, 1967).

SUBCUTANEOUS RUPTURE OF THE BREAST: A SEAT-BELT INJURY

BY D. S. EASTWOOD
ST. JAMES'S HOSPITAL, LEEDS

SUMMARY

Subcutaneous rupture of the breast caused by a car seat belt is reported. The patient was 7 months pregnant, and there was difficulty in suppressing lactation; the management of this problem is discussed.

CASE REPORT

THE patient, aged 33 years, was a front-seat car passenger, wearing a lap-diagonal seat belt, when the car in which she was travelling was involved in a collision at moderately high speed. She sustained minor lacerations of the legs, a dislocation of the left first metacarpophalangeal joint, and abrasions and bruising of the chest and right breast owing to pressure of the diagonal strap of the seat belt; the line of the strap shows clearly in *Fig.* 1.

Twenty-four hours after the accident the patient miscarried; a 7-day course of stilboestrol (10 mg. t.d.s.) was given to suppress lactation. Engorgement of the left breast subsided satisfactorily, but the damaged right breast remained tense and tender; it was aspirated on the fifth day postpartum and a mixture of blood and milk was obtained. Aspiration was repeated on the eleventh day (500 ml.) and on the fifteenth day. Because of continued reaccumulation of milk a Zimmer suction drain was inserted on the twenty-first day; the daily aspirate was 300–500 ml. until the drain was removed on the thirtieth day. Milk continued to collect between the two halves of the breast and to drain from the stab incision. A further 5-day course of stilboestrol was given, and the effect of magnesium sulphate and of water deprivation was tried. Infection occurred and a mixture of milk and pus was evacuated on the forty-sixth day; milk continued to be secreted, as much as 250 ml. being expressed at one time.

At operation 7 weeks after the injury the breast was explored through a 5-cm. incision in the submammary groove. The breast tissue was found to be completely split in two and about four-fifths of the ducts were avulsed from the back of the nipple. The two halves of the breast were coapted by through-and-through nylon sutures held by aluminium stops, and a corrugated drain was left in place; firm bandaging and strapping were applied. The sutures were tightened on two occasions as the breast became less swollen, and pressure was maintained by Elastoplast strapping over adhesive sponge. The sutures were removed on the tenth postoperative day, by which time the drainage of milk was much reduced. Discharge ceased on the eighteenth postoperative day, 11 weeks after the original injury.

The breast continued to involute satisfactorily although it remained moderately grooved. A simple tension cyst 1½ cm. in diameter was removed from the peripheral part of the upper portion of the breast 8 months after the injury. Further surgery to improve the appearance of the breast is under consideration.

DISCUSSION

The common measures used to suppress lactation—stilboestrol, water deprivation, and firm bandaging—were not effective in this patient's damaged breast. Stilboestrol is not an effective agent for stopping lactation, failure of suppression or subsequent reinitiation of lactation not uncommonly following its use. The main effect of stilboestrol is in the reduction of pain and turgidity of the breast when suckling is discontinued, and there is evidence that it will even promote lactation if the flow of milk from the breast is encouraged. The splitting of the breast tissue and its avulsion from the ducts prevented the build-up of intragland pressure, and simple bandaging was ineffective as the two halves were merely held apart by it. The aspiration of the cavity between them is a measure which could be expected to encourage continued secretion. The situation is analogous to the production of witch's milk by squeezing the breasts in an infant, or paralactation induced by sucking in adult males or females outside the influence of pregnancy; with repeated emptying of the breasts full lactation can be

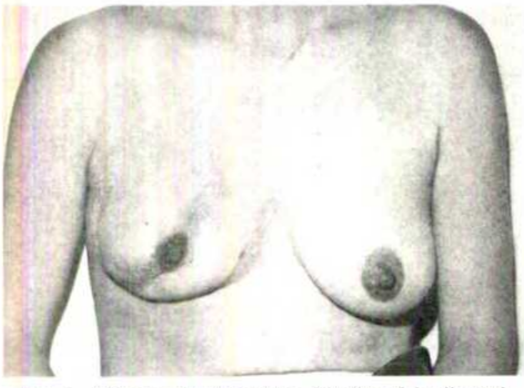

FIG. 1.—Eleven weeks after injury. The line of the diagonal strap of the seat belt can be clearly seen.

established (Bonser, Dossett, and Jull, 1960; Dossett, 1960).

Although it cannot be claimed that the drawing together of the two halves of the breast with sutures and the constant application of firm pressure were entirely responsible for stopping lactation in this patient—time and infection may well have played a part—it is suggested that this is a logical approach in this type of injury. The result would be similar to firm bandaging applied to the normal lactating breast which is a known effective measure in the suppression of lactation.

This type of procedure could reasonably be carried out soon after injury in any similar case. The use of adhesive sponge considerably aided the application of firm pressure and it could be peeled off with only moderate discomfort when the breast was restrapped as it became smaller.

It is of interest that on analysis of the breast secretion 7 days before drainage ceased the report was: 'Only a trace of lactose. This indicates that it is a true milk, but one which is rapidly reverting to colostrum.'

Acknowledgement.—I am indebted to Dr. J. S. Dossett for his advice and encouragement in the treatment of this patient.

RUPTURED ANGIOMATOUS SPLEEN PRESENTING AS A SEVERE COAGULATION DEFECT

BY R. C. HEADING, D. B. L. McCLELLAND, A. E. STUART, AND T. HAMILTON

DEPARTMENTS OF THERAPEUTICS, PATHOLOGY, AND CLINICAL SURGERY, UNIVERSITY OF EDINBURGH

SUMMARY

A case is described in which spontaneous rupture of an angiomatous spleen presented with an acute disorder of blood coagulation. Splenectomy was performed after successful correction of the coagulation defect by the administration of blood and blood-products. The presence of amyloidosis associated with myeloma may have increased the liability of the spleen to rupture. Indentation of the right lobe of the liver by the lower ribs produced a misleading appearance of the hepatic scintiscan.

THE association of a haemorrhagic diathesis with a large haemangioma was first described by Kasabach and Merritt in 1940. A number of cases have since been recorded and reviewed and the coagulation disorder has been shown to be a defibrination syndrome, sometimes associated with increased fibrinolysis (Thompson and Umlauf, 1964; Thatcher, Clatanoff, and Stiehm, 1968). The majority of these reports, however, were of infants or children with a long-standing history of bruising or a bleeding tendency where elective investigation of the coagulation process was possible and no great urgency was necessary in the correction of the coagulation defect. The present report describes the treatment of an adult presenting with an acute coagulation disorder associated with rupture of an angiomatous spleen.

CASE REPORT

The patient was an active 60-year-old married woman who had no significant medical or drug history. Twelve hours before her admission to hospital she had noticed bruising of both ankles. There had been no trauma. The bruising had spread up the legs and had also developed on the upper arms and shoulders. Some 4 hours after the bruising had first been observed the patient was aware of nausea and increasingly severe right-sided upper abdominal pain. There was no other significant history.

The patient was admitted in a state of hypovolaemic shock with a systolic blood-pressure of 65 mm. Hg. There was tenderness in the right hypochondrium, with no guarding. The bowel-sounds were normal and there were no intra-abdominal bruits. Plain radiographs of the abdomen were unrewarding and blood examination revealed a normal red-cell morphology, the presence of platelets, and normal total and differential white-cell counts. Coagulation studies (*Table I*) revealed a severe consumptive coagulopathy with no evidence of excessive

fibrinolysis. Because of the gravity of the patient's condition transfusion was initiated before these results were available, with initial clinical improvement, but there was increasing distension in the abdomen and it was thought that there was continued intra-abdominal bleeding. A total of 1 litre of fresh frozen plasma, 3 litres of fresh blood, and 4 g. of fibrinogen was given over a period of 9 hours, after which the coagulation state had returned to normal and it was possible to proceed to laparotomy, through a right paramedian incision. Three litres of blood and clot were removed from the peritoneal cavity and the source of blood-loss was found to be a tear on the phrenic surface of the spleen which was enlarged and of a dark-purple colour. The liver was moderately enlarged and smooth. Splenectomy was therefore carried out through a left subcostal incision. The patient made an uncomplicated recovery from the operation.

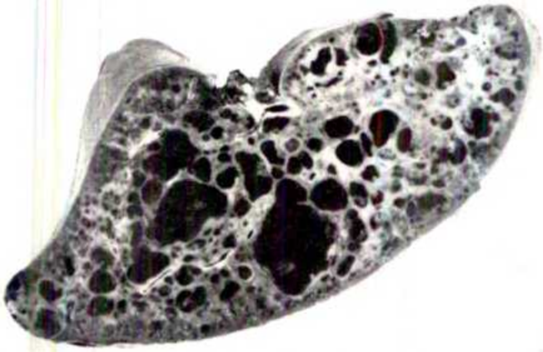

FIG. 1.—Cut surface of the spleen showing the numerous blood-filled spaces.

Pathological examination of the spleen showed that it was of the usual shape, moderately enlarged (385 g.), and contained a poorly defined haemorrhagic area in the region of a capsular laceration. The cut surface (*Fig.* 1) contained abundant blood-filled spaces, some of which measured between 1·0 and 1·5 cm. in diameter. Microscopic examination showed both cavernous and capillary types of vessel. The usual division into red and white pulp was lost and no Malpighian corpuscles were observed. Congo-red and thioflavine-T stains for amyloid showed subintimal deposits within the large vessels and a complete infiltration of the capillary walls. The vessels were devoid of thrombus; sections stained by the acid picro-Mallory and Martius yellow–soluble blue techniques (Lendrum, Fraser, Slidders, and Henderson, 1962) showed remarkably little fibrin.

Plasma electrophoresis showed an abnormal band in the fast γ-globulin region, and the bone-marrow contained an increased number of plasma-cells and some abnormal forms. There was no Bence-Jones protein in the urine, but a radiograph of the bony skeleton revealed collapse of the twelfth thoracic vertebral body and loss of the trabecular pattern in the first lumbar vertebra. These features suggest that the amyloidosis was associated with myeloma.

Postoperatively a disturbing feature was the progressive enlargement of the liver, which 3 weeks after the operation was firm, smooth, and clearly palpable 6 cm. below the right costal margin. The hepatomegaly was confirmed by a technetium-colloid scintiscan which suggested reduced uptake in the lateral aspect of the right lobe of the liver (*Fig.* 2). Abdominal aortic angiography showed no evidence of a vascular abnormality within the liver. In view of the finding of a rapidly enlarging liver and the possibility of a lesion in the right lobe further exploration was indicated.

At laparotomy there was now gross enlargement of both lobes of the liver and biopsies were taken. The lateral surface of the liver was clearly indented by the lower ribs and costal cartilages and it was deduced that this anatomical abnormality accounted for the apparent absence of uptake of isotope in this region of the liver. Histological examination of the liver biopsies showed extensive amyloid deposits forming a thick hyaline layer in the subendothelial spaces adjacent to the sinusoidal lumen.

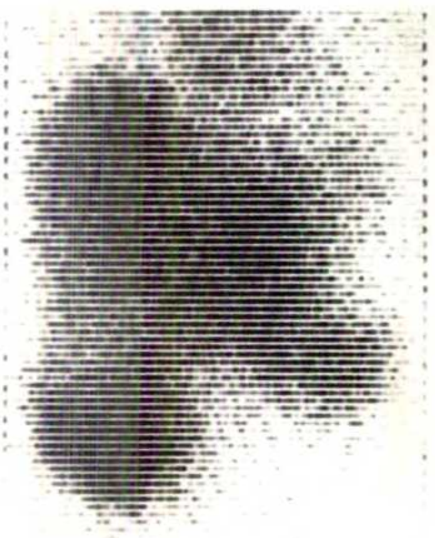

FIG. 2.—Technetium-colloid scintiscan showing reduced uptake in the lateral aspect of the right lobe of the liver.

DISCUSSION

There are several interesting and rather unusual features in this case. Although rupture is a recognized complication of splenic angiomatosis, the number of recorded cases is small (Husni, 1961). The usual clinical presentation is as an acute abdominal emergency and there appears to be no previous report of an associated abnormality of blood coagulation. Haemorrhagic shock, myeloma, and amyloidosis have all been associated with the defibrination syndrome (Hardaway, Brewster, and Elovitz, 1966; Rosner and Ritz, 1966), but in the patient described here spontaneous bruising undoubtedly preceded the development of haemorrhagic shock by several hours, and the return to a normal coagulation state after initial treatment and splenectomy suggests that the myeloma and amyloid were not primarily responsible. The patient is thus believed to have exhibited an acute form of the coagulation disturbance described with large haemangiomata.

It is generally agreed that complete surgical excision of an angioma is the most successful means of correcting the associated coagulation abnormalities. However, the successful initial correction of the coagulation disorder in this case by the administration of blood-products alone is in contrast to previous reports of defibrination associated with angiomata where it is suggested that anticoagulation with heparin (Hillman and Phillips, 1967) or phenindione

(Blix and Jacobsen, 1963) is required. Even so, complete correction has not always been achieved. Hillman and Phillips (1967) suggest that some danger may be associated with the use of blood-products alone since an induced imbalance of coagulation and lysis may result in rapid clotting within the angioma and infarction of the organ, but in spite of the considerable transfusion no infarction or clot formation was found in the spleen of our patient. Thus there is no evidence that the administration of blood products alone was potentially hazardous in this case.

The association of amyloidosis with myeloma is well known (Cohen, 1967) and this aspect of the case requires no further comment. However, it is possible that the deposition of amyloid in the spleen of this patient may have increased its susceptibility to trauma and it is notoriously difficult to exclude minimal trauma in cases of 'spontaneous' rupture of the spleen. The case also provides a convincing illustration of the rapidity with which hepatic enlargement due to amyloid deposition may occur, and in this context it is of interest that splenectomy appears to facilitate the experimental production of amyloidosis in animals (Calkins, Cohen, and Larsen, 1960). The unusual and rather misleading appearance of the scintiscan from the large liver of this patient emphasizes the need to take anatomical variations into account in the interpretation of such investigations.

Acknowledgements.—We are grateful to Mr. T. J. McNair and Professor R. H. Girdwood for permission to report this case.

VISCERAL NEUROFIBROMATOSIS

AN UNUSUAL CAUSE OF OBSTRUCTIVE JAUNDICE

By BERNADETTE CURRY and NORMAN GRAY

PATHOLOGY DEPARTMENT AND SURGICAL DIVISION, SOUTHERN GENERAL HOSPITAL, GLASGOW

SUMMARY

A case of visceral neurofibromatosis presenting as obstructive jaundice is described. Laparotomy revealed an ampullary tumour which was presumed to be malignant. A palliative cholecystojejunostomy was performed but death occurred 10 days postoperatively as a result of obstructive jaundice. At necropsy the ampullary tumour was found to be a benign neurofibroma.

THE association of visceral lesions with von Recklinghausen's neurofibromatosis is an uncommon but nevertheless a well-recognized entity. Perhaps many more cases remain unidentified because the visceral lesions do not produce clinical symptoms. The more commonly described presenting clinical features are chronic anaemia (Burton and Fitzgerald, 1970), gastro-intestinal bleeding, atypical dyspepsia and abdominal pain, a palpable mass, or bowel obstruction which may be due to intussusception, intraluminal encroachment, external compression, annular stenosis, or even volvulus (Logan, 1964; Lukash and Johnson, 1969; von Vroonhaven, 1970). One case of perforation due to an intestinal neurofibroma has been described (Warshauer and Nelson, 1953). Recently we have seen visceral neurofibromatosis which manifested itself as obstructive jaundice. This appears to be the first recorded case of such a combination.

CASE REPORT

The patient was a 61-year-old female who had attended hospital on a number of occasions. Her first admission in 1949 was for hysterectomy because of menorrhagia. She was admitted in 1950 for amputation of the right little finger following traumatic rupture of the flexor and extensor tendons.

In 1959 she was investigated as an in-patient for her complaint of multiple small skin nodules over the chest and arms and vague ill health accompanied by a productive cough. Her skin showed raindrop freckling with numerous soft subcutaneous nodules, several of which were pedunculated. Radiology showed a sliding hiatus hernia and unresolved pneumonia which responded to treatment. A diagnosis of cutaneous neurofibromatosis was made. There was no family history of von Recklinghausen's disease.

Her next admission in 1963 was for drainage of an appendix abscess, when she was advised that further surgery would be necessary. She failed to report back until 1965 when elective appendicectomy was carried out. On both occasions she had postoperative basal pneumonic consolidation.

In 1970 the patient presented with jaundice, epigastric pain, anorexia, and recurring bouts of diarrhoea of several weeks' duration. She had lost 19 kg. in weight over a period of 5 months. On examination she was deeply jaundiced and the liver was enlarged to three fingers below the right costal margin. There was a firm painless epigastric mass. Von Recklinghausen skin lesions were noted together with scratch marks over the abdomen and both arms. Liver-function tests indicated obstructive jaundice. Occult blood was found in the stools and there was an *Escherichia coli* urinary infection. The peripheral blood picture revealed a very marked neutrophil polymorph leucocytosis (24,000–30,000 per c.mm.) but no anaemia. Barium studies were unhelpful. A provisional diagnosis of carcinoma of the head of the pancreas was made and laparotomy was carried out.

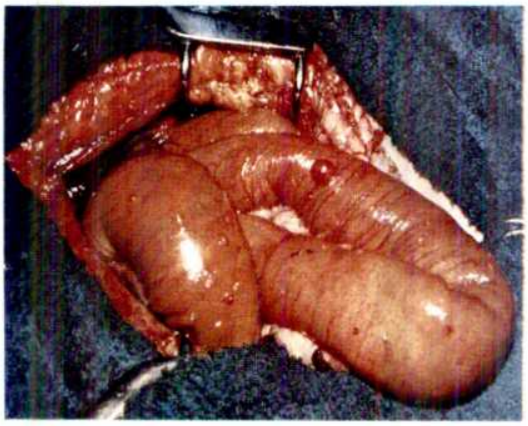

FIG. 1.—Jejunal neurofibromatosis at operation.

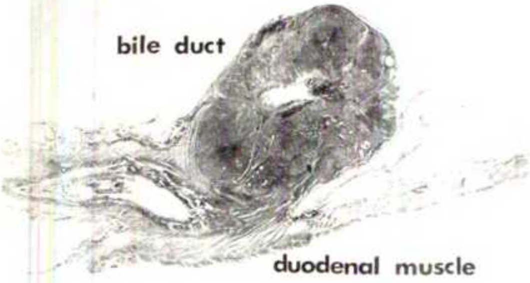

FIG. 3.—Low-power view of neurofibroma of ampulla of Vater. H. and E. (× 3.)

OPERATION.—The abdomen was opened through a right paramedian incision. An enlarged green liver with a greatly dilated common bile-duct and a distended gall-bladder were found. Approximately twelve discrete nodules were present along the proximal small bowel (*Fig.* 1) and a large irregular-shaped mass obstructed the duodenal ampullary region. The lymph-nodes alongside the duct and in the porta hepatis were enlarged.

It was considered that there had been malignant change in a neurofibromatous lesion; palliative cholecystojejunostomy was performed, a lesion in the small bowel was biopsied, and the abdomen was closed without drainage.

The patient's postoperative course was poor and apart from slight improvement in the degree of jaundice she gradually deteriorated, despite supportive therapy, and died 10 days later.

BIOPSY OF BOWEL TUMOUR.—The specimen submitted for histology was a discrete, smooth nodule, 10 mm. in diameter. The cut surface was pale yellow with a slightly whorled appearance.

Microscopy showed a simple neurofibroma which was not encapsulated and was incompletely surrounded by smooth muscle.

NECROPSY REPORT.—Externally there was deep jaundice, diffuse freckling of the skin, and numerous small polypoid subcutaneous nodules on the trunk, thighs, and arms.

The relevant findings were confined to the abdominal cavity. There was a generalized peritonitis with a bile-stained exudate in the peritoneal cavity. Along the duodenum and antimesenteric border of the upper small bowel there were approximately twelve small discrete tumours, the largest being 15 mm. in diameter. Most of them formed polypoid protrusions on the serosal surface. Proceeding distally along the bowel the lesions appeared with decreasing frequency and there was none in the distal small or entire large bowel. A 25-mm. diameter submucosal nodular tumour protruded into the duodenum around the ampullary opening, extending through the duodenal muscle to form a similar-sized nodular mass on the adventitial surface with the distal common bile-duct lying to the left lateral side. The bile-duct was dilated and contained submucous gas bubbles. The lymph-nodes in this area were enlarged. The gall-bladder was thick-walled, congested, and friable. The cholejejunostomy anastomosis appeared intact but was separated easily during handling. The liver (2460 g.) was enlarged, deeply bile-stained, soft, and crepitant. Both the spleen and the pancreas were soft and focally cystic. The kidneys were deeply bile-stained.

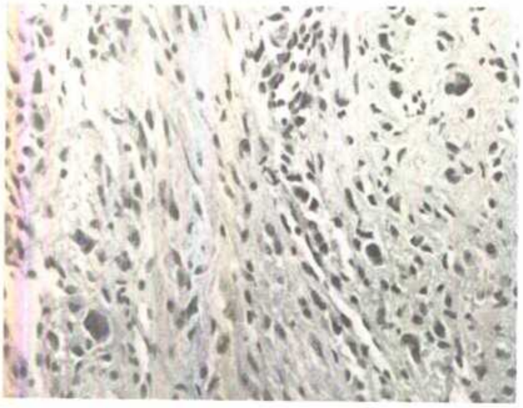

FIG. 2.—High-power view of area of neurofibroma showing several pleomorphic nuclei. H. and E. (× 134.)

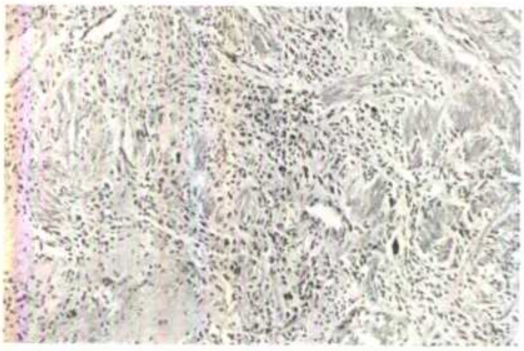

FIG. 4.—Low-power view showing neurofibromatous tissue intermingled with ampullary smooth muscle. H. and E. (× 92.)

There were no tumours in other organs.

HISTOLOGY.—The ampullary tumour, a neurofibroma, was partially encapsulated with several markedly sclerosed lobules. Small groups of ganglion cells were included in the submucosal tumour margin. Some areas showed a prominent vascular pattern with thrombus in many of the vascular channels. The tumour was very oedematous and contained a mild chronic inflammatory infiltrate. The cellular pattern was variable with some areas of attempted cellular regimentation and others where nuclear atypism was marked (*Fig.* 2). No mitotic figures were found.

The course of the bile-duct through the ampullary tumour was traced by means of serial sections. It was found in the centre of the submucosal portion of the tumour (*Fig.* 3). The mucosal lining was completely autolysed; some mucus glands and a chronic inflammatory infiltrate were present in the submucosa, and immediately subjacent to this the tumour intermingled with the ampullary muscle (*Fig.* 4). In the underlying duodenal muscle coat microscopic neurofibromatous nodules were studded at intervals along the myenteric plexus, and in sections showing the main tumour in this layer, direct continuity could be demonstrated between large abnormal nerves, the neurofibromatous nodules arising in the myenteric plexus, and the main ampullary tumour. Using Glees and Marsland's method, small numbers of nerve-fibres were demonstrated running through the tumour.

The oesophagus contained a microscopic neurofibroma at its lower end. Histology of one of the ileal nodules showed a poorly circumscribed neurofibroma which contained several small groups of ganglion cells. Random blocks of stomach and large bowel showed no neural abnormality.

Microscopically the kidney showed proximal tubular necrosis.

A section from a skin nodule showed a discrete but unencapsulated tumour with plexiform neuromatous and neurofibromatous components; pilar smooth muscle and sweat glands were included in the tumour. Microscopic neurofibromatous nodules and large abnormal nerves were present in the surrounding dermis.

DISCUSSION

The incidence of malignant degeneration in visceral neurofibromatosis is difficult to assess but it has been reported to be as high as 15 per cent (Levy and Khatib, 1960). At laparotomy in the present case the ampullary tumour was thought to have undergone malignant change because of its relatively large size and its irregular, craggy shape. Histologically the tumour was not discrete but merged and became closely intermingled with normal structure of this area, this being characteristic of von Recklinghausen's disease (Willis, 1967).

The number of simple duodenal neurogenic tumours which have been recorded as giving rise to clinical symptoms is very small. Three were submucosal polypoid ganglioneuromas (Dahl, Waugh, and Dahlin, 1957; Gemer and Feuchtwanger, 1966; Goldman, 1968), one of which had associated cutaneous neurofibromatosis; all were situated several centimetres proximal to the ampulla of Vater. Two cases of duodenal neurofibroma have been described: one presented as a gastro-intestinal haemorrhage (Curran and Forsythe, 1961) the second, as in the present case, had cutaneous neurofibromatosis and preoperatively was diagnosed on the basis of clinical and radiological findings as carcinoma of the head of the pancreas (von Vroonhaven, 1970). It differed from the present case in that the clinical presentation was of a high bowel obstruction, and at operation the lesion was situated about 3 cm. distal to the ampulla of Vater.

Only 1 case of obstructive jaundice due to a benign neurogenic tumour has previously been described (Oden, 1955). This was a neurolemmoma arising in the extraduodenal portion of the common bile-duct; there were no features of generalized neurofibromatosis. Non-epithelial tumours of the duodenal ampulla are rare (Nitshe and Suckie, 1947; Edmondson, 1967), and in particular no previous ampullary neurofibroma has been described.

The distribution of the visceral lesions in this patient was also unusual. The terminal ileum followed by the stomach are commonly cited as being most frequently involved (Logan, 1964; Mazare, Champetier, Micoud, and Verdier, 1968). Recorded lesions in the oesophagus are very rare; Russell and Rubinstein (1970) mention 1 case. Visceral ganglioneuromatosis is an uncommon association of von Recklinghausen's neurofibromatosis.

Acknowledgement.—We are grateful to Mr. A. Litton, F.R.C.S., for permission to publish clinical details.

REVIEWS AND NOTICES OF BOOKS

Management of Constipation. Edited by SIR FRANCIS AVERY JONES, C.B.E., M.D., F.R.C.P., and EDMUND W. GODDING, F.P.S. 8⅞ × 6 in. Pp. 197 + xi. 1972. Oxford: Blackwell Scientific Publications. £2.

THIS excellent paperback is the first serious attempt at a comprehensive treatment of constipation since Sir Arthur Hurst's monograph of over fifty years ago. Constipation appears both as a primary disorder (simple constipation) and as a symptom secondary to a large number of medical and surgical conditions. This presents obvious difficulties in producing a coherent account of its many manifestations. That this has been achieved is due to the physiological approach which has been maintained throughout this book—an approach which must make a special appeal to surgeons.

The book proceeds logically from a description of normal colon physiology (A. N. Connell) to therapeutic agents (E. W. Godding), diagnosis (J. M. Hinton), and constipation management in adults (F. Avery Jones), in paediatrics (T. E. Oppé), in geriatrics (A. N. Exton-Smith), and in obstetrics (D. E. Burgess).

Much important new knowledge of colon physiology and the pharmacology of drugs has been gained during recent years and this has had a marked influence on the character of this book. However, it is clear that there is still a long way to go before a completely scientific basis of bowel movement can be laid down. The alimentary canal has to function, not only as a digestive, absorptive, and excretory organ, but also as a modulator and regulator of the diverse exogenous and endogenous stimuli, and of the many insults, to which it is constantly subjected. The mechanisms involved are, of necessity, highly flexible and complex and are seen as part of the homeostatic requirements of the body as a whole. It is not surprising that motility studies, which now employ a wide range of techniques, have only partly succeeded in evaluating the components of intestinal neuromuscular activity.

In the chapter on therapeutic agents an analytical method based on physiological principles and known pharmacology has produced order out of chaos. In the case of laxatives the indictment of a number of laxatives, some old, some new, is forthright and fairly stated. As would be expected, Senokot is revealed as the most physiologically acceptable of the chemical laxatives.

The section on per rectum evacuants is timely and the condemnation of soap enemata will be strongly supported by proctologists; their total prohibition would seem overdue.

This book is the most authoritative statement on the subject of constipation which has yet appeared in English or in any other language, and with its publication the dea of constipation as no more than a minor ailment should disappear. There are few who will not find something of value in it, including medical, nursing, and pharmaceutical practitioners. It has a special place in postgraduate teaching.

Conférences de Séméiologie Chirurgicale. Vol. 5. By JEAN MOUÏEL, Paris, and CLAUDE REGENSBERG, Paris. 10¼ × 8 in. Pp. 225. Illustrated. 1971. Paris: Baillière et Fils. No price given.

THIS synopsis is meant to serve as a guide while preparing for examinations in surgery as part of the French medical curriculum. It is a kind of programmed instruction, bringing together step by step the information required. The layout is most professional and the text very expert, admitting an impressive amount of factual knowledge within a comparatively limited space. Twelve volumes have been planned, the present one being the fifth to appear. It deals with gynaecology and the mammary gland, the emphasis being on the pathology and the signs and symptoms. The illustrations are limited in number and are rather mediocre. The student wishing to acquire insight and wanting to sharpen his wits will find this book of little use, but he who has to 'cram' will find that it has a great deal to offer. The language is so concise that a limited knowledge of French is sufficient.

Handbook of Orthoptic Principles. Second edition. By G. T. WILLOUGHBY CASHELL, M.B., B.S. (Lond.), F.R.C.S. (Edin.), F.R.C.S. (Eng.), Reading, and ISOBEL M. DURRAN, D.B.O.T., Oxford. 8½ × 5½ in. Pp. 136 + x. Illustrated. 1971. Edinburgh: Churchill Livingstone. £1·50.

THE second edition of this useful paper-back has been very carefully revised, and it will retain its place as a most useful handbook for all those who have to undertake the treatment of the various forms of squint. There can be no doubt that this small book fulfils its purpose admirably. The illustrations are well chosen and are of a high order. The index is new and complete.

Pädiatrischer EKG-Atlas. Second edition. By J. STOERMER, Göttingen, and W. HECK, Bremen. 11½ × 8¼ in. Pp. 316 + xi, with 256 illustrations. 1971. Stuttgart: Georg Thieme Verlag. DM.130.

THIS second edition of an atlas relating to the paediatric electrocardiogram has been totally revised. The authors have illustrated all standard congenital abnormalities and acquired diseases of the cardiovascular system in relation to the electrocardiogram, and there are numerous case histories to illustrate the electrocardiographic findings.

The book is beautifully illustrated by serial electrocardiograms and is well printed. There is a very extensive bibliography and the quality of the illustrations is excellent throughout.

This volume should be of considerable interest to cardiologists and cardiac surgeons involved in paediatric cardiac surgery, but the text could be enhanced by the comments of a paediatric cardiac surgeon and by the addition of radiological illustrations.

A Text-book of X-ray Diagnosis. Fourth edition. Vol. 6. Edited by S. COCKRANE SHANKS, C.B.E., M.D., F.R.C.P., F.F.R., Consulting Radiologist, University College Hospital, London, and PETER KERLEY, C.V.O., C.B.E., M.D., F.R.C.P., F.F.R., D.M.R.E., Consulting Radiologist, Westminster Hospital and National Heart Hospital, London. 9⅜ × 7⅛ in. Pp. 859 + xvi, with 904 illustrations. 1971. London: H. K. Lewis. £11.

THE new Volume 6 of this great work is devoted to bones and joints, and consists of 11 parts.

Part 1 is concerned with the normal bones and joints, including the spinal column. The radiographs are of a high quality.

Part 2 deals with the important problem of the general pathology of bone. The photomicrographs illustrating the various pathological conditions of bone could not be bettered.

In Part 3 the congenital deformities of bones and joints come under review, while in Part 4 the traumatic conditions of these structures are considered.

Part 5 deals with the inflammatory conditions of bones and joints and the illustrations in this section are excellent.

Part 6 is devoted to the important condition of osteochondritis, while Part 7 deals with static and paralytic lesions of bones and joints.

Part 8 is concerned with tumours and cysts and is well set out and illustrated.

In Part 9 the constitutional diseases of bones and joints come under review.

Part 10 is concerned with the soft tissues and includes calcification and ossification of the soft tissues.

Part 11 is devoted to the localization of foreign bodies.

This comprehensive work by the cream of British radiologists is a great credit to British medicine. When it is considered that the first edition appeared just before the Second World War and was reprinted five times the usefulness of this work is evident.

As a reference volume this book could not be bettered.

Actions of Alcohol. Vols. 1 and 2. By HENRICH WALLGREN, Helsinski, and HERBERT BARRY, III, Pittsburgh. 9 × 7 in. Pp. 870 + xxvi, with 18 illustrations. 1970. Amsterdam: Elsevier Publishing Company. $55.50.

THIS two-volume work is a comprehensive review of the experimental work on the effects of alcohol on the living organism, based on an integration of knowledge in the fields of biochemistry, physiology, and psychology.

Volume 1 details the biochemical, physiological, and psychological effects of alcohol (ethyl alcohol), while volume 2 is devoted to the chronic and clinical aspects.

Volume 1 deals with a wide variety of subjects, including alcoholic beverages, lethal blood levels, temperature regulation, and the metabolism of ethanol. At the end of each chapter there is a summary and a very full list of references.

Volume 2 is concerned with the detectability of alcohol, physical dependence, joint action of drugs and alcohol, characteristics of alcoholics, and the chronic effects and clinical aspects of alcohol.

This work is a compilation of international research and it will appeal to scientists in all branches of alcohol research. As a reference work it could not be bettered.

An Atlas of the Anatomy of the Ear. By BRANISLAV VIDIĆ, S.D., St. Louis, and RONAN O'RAHILLY, M.D., Wayne State. 9½ × 6½ in. Pp. 110, with 50 illustrations and 50 additional colour slides. 1971. London: W. B. Saunders Co. Ltd. £10·20.

THERE can be little doubt that the anatomy of the middle and internal ear is difficult to visualize for the average student and practitioner. Now that operations are frequently performed on the middle ear, it is important that the anatomy of this part of the human body should be understood. This atlas with its 50 colour slides (2 × 2 in.) and a small viewing box contributes enormously to the easy understanding of the middle and inner ear.

A black-and-white drawing with levels on the various structures is supplementary to each colour slide. This enables the viewer to see the relationship of the various anatomical structures.

The book contains an author index as well as a subject index. There is also a glossary of eponymous terms.

This is a useful atlas for students and also for all those who are contemplating becoming aural surgeons.

Critical Surgical Illness. Edited by JAMES D. HARDY, M.D., F.A.C.S., Mississippi. 10 × 7 in. Pp. 679 + xv, with 206 illustrations. 1971. London: W. B. Saunders Co. Ltd. £11·90.

THIS is a book for surgeons, for the various contributors, all experts in their own surgical field, discuss in detail the treatment of certain conditions and especially the post-operative treatment.

The 30 comprehensive chapters range over a large number of surgical conditions, from post-traumatic pulmonary insufficiency to haematologic crises in surgery. At the end of each chapter there is a useful list of references so that the reader may increase his knowledge of the particular subject under discussion. The illustrations throughout the book are good and do enhance the written word.

Quite a feature of this book is the inclusion of a brief biographical sketch of the author of each separate chapter.

This book should be in the library of every surgeon both at home and abroad, for it contains a wealth of sound practical surgery as practised in the United States of America.

Clinical Heart Disease. By SAMUEL ORAM, M.D. (Lond.), F.R.C.P. (Lond.), Senior Physician and Director of the Cardiac Department, King's College Hospital, London. 9½ × 7 in. Pp. 920 + vii. Illustrated. 1971. London: William Heinemann Medical Books Ltd. £12.

THIS book is a 'classic' and is by far the best that has so far been published on the important subject of clinical heart disease. The author has a long clinical experience of all varieties of heart disease. His book gives in one volume a comprehensive account of modern cardiology, including applied embryology, anatomy, and physiology. The emphasis is on clinical cardiography and it is stimulating to read the indications for surgical treatment in certain cardiac conditions.

The illustrations throughout this book are excellent: the line drawings are clear and concise, the radiographs have been well chosen, the electrocardiograms are definite, and the clinical pictures are telling.

At the end of each chapter the main points have been summarized under the heading Salient Features, and readers, especially students, will find these most useful. Another feature of this book is the advice on selected reading from books, monographs, and papers.

A very comprehensive and useful appendix on cardiorespiratory data is given at the end of the volume. These important facts and figures are difficult to remember as they are so numerous. The various pressures, oxygen saturation, oxygen capacity, cardiac output, and circulation times are but a few of the items recorded in these data.

An excellent production and a great credit to British medicine.

Vascular Disorders of the Intestine. Edited by SCOTT J. BOLEY, M.D., New York. 10 × 7 in. Pp. 657 + xviii. Illustrated. 1971. London: The Butterworth Group. £13·75.

MUCH progress has been made in the past 20 years regarding the causation and results of vascular disorders of the intestine. In this book, with its many contributors from all over America, the accumulated clinical evidence regarding all aspects of mesenteric vascular disease is considered.

This large volume is divided into six sections.

Section 1 deals with the anatomy, physiology, and pathology of the mesenteric circulation. The histopathology of intestinal ischaemia is discussed at length and the electron microscope has helped in this investigation.

Section 2 is devoted to the radiological aspects of mesenteric vascular disease. The value of magnification arteriography in intestinal vascular disease is stressed and is beautifully illustrated.

In Section 3 the experimental aspects of the mesenteric circulation come under critical review, and the effects of mesenteric ischaemia are carefully considered, including acute superior mesenteric vascular insufficiency.

Section 4 deals with the diagnosis and treatment of alterations of the mesenteric circulation, including the rate of flow.

Section 5 is devoted to vascular disorders of the small bowel, including the coeliac axis syndromes, while Section 6 is given over to a consideration of vascular disorders of the colon.

This volume is full of new and important information regarding the splanchnic circulation. Physiologists, pathologists, radiologists, and clinicians will find this book a mine of information.

Color Atlas of Cancer Cytology. By Masayoshi Takahashi, M.D., Tokyo. 11¾ × 8¼ in. Pp. 354 + v. Illustrated. 1971. Stuttgart: Georg Thieme Verlag. DM.178.

This large atlas contains some 652 beautifully coloured pictures of sections of cancer cells from various organs of the body. The volume is divided into two parts dealing with general cancer cytology in one section and practical cytology as it is applied to various organs and tissues in the other. The electron microscope plays an important part today in establishing the diagnosis of malignant disease when only a small clump of cells are available in a specimen. The author discusses the general outline of cancer cytology and the criteria of malignancy. The description of cell typing of malignant cells is excellent and the instructions for the preparation of smears and fixation are very clear.

In the central nervous system aspiration cytology directly from a tumour or cyst is advocated. Imprint smears can be made from the fresh-cut surface of an excised tissue specimen and may be valuable.

This is the most comprehensive atlas of cancer cytology that has so far been published and it should prove a most valuable reference volume.

At the end of the book there is an extensive list of references, but one is surprised to find no mention of J. Bamforth's book on cytological diagnosis which was published in 1966.

Clinical Otology. An International Symposium. Edited by Michael M. Paparella, M.D., Albert Hohmann, M.D., and John S. Huff, M.D., Minneapolis. 9¾ × 6½ in. Pp. 249 + xiv. Illustrated. 1971. London: Henry Kimpton. £13·25.

This volume represents the published proceedings of the first International Symposium of Clinical Otology sponsored by the Department of Otolaryngology, University of Minnesota School of Medicine, held in June, 1970.

The book is divided into five parts. Part 1 deals with audiology and diagnostic considerations. The techniques of stapedectomy are well described and illustrated, and the complications of this operation are discussed at some length.

Part 2 is devoted to the subject of congenital deafness. There is an excellent chapter on prostheses for microtia and other deformities of the ear. In Part 3 reconstructive surgery is considered at some length, including transplants in otology.

Part 4 deals with vestibular deafness in all its aspects.

Part 5 is devoted to sensorineural hearing loss, including noise-induced deafness, and the management of sudden deafness.

Although the great majority of contributors come from many centres in America there are chapters by Italian otologists and others from Denmark.

This is a book which every medical library should have on its shelves for reference purposes.

Concepts of Disease. Edited by Joel G. Brunson, M.D., Mississippi, and Edward A. Gall, M.D., Cincinnati. 10 × 7 in. Pp. 1134 + xiii. Illustrated. 1971. London: Collier-Macmillan. £11·95.

This large work, in which the 38 contributors have covered the whole field of general pathology, is an authoritative volume.

Professor Brunson contributes an excellent chapter on the cell and its ecology and in the considerable list of references at the end one is somewhat surprised to find the name of Roy Cameron omitted. Cameron's enormous volume on *The Cell* is surely the most important work on that subject that has so far been published.

The chapter on cytopathology by William Christopherson makes stimulating reading. Other interesting chapters are devoted to the effects of ionizing radiation, nutritional factors in disease, thrombosis, embolism, infarction, immunity, neoplasms revisited, and diseases peculiar to pregnancy and the neonatal period.

As one would expect in a work such as this, photomicrographs predominate and the electron micrographs are excellent. At the end of each chapter there is a complete list of references, mostly American.

This is a standard textbook of human pathology and it is an excellent reference volume. It should prove of real value to medical students and all clinicians.

Aspirin, Platelets and Stroke. Background for a Clinical Trial. Compiled and edited by Williams S. Fields, M.D., Houston, and William K. Hass, M.D., New York. Pp. 163 + xii. 1971. Missouri: Warren H. Green. $10.50.

This is an interesting volume containing 12 chapters by 29 contributors, all of whom are interested in the treatment of the ischaemic stroke syndrome. Many investigators consider that the treatment of this syndrome should consist of the giving of aspirin, which has been shown *in vitro* to produce marked collagen-induced platelet aggregation and the subsequent platelet release reaction. Also, animal experiments have clearly demonstrated a reduction of intra-arterial clotting following the administration of aspirin in comparatively small doses. When there is a marked constriction of the extracranial carotid vessels as shown by angiography, then surgery is clearly indicated.

Care of the Surgical Cardiopulmonary Patient. Edited by William E. Neville, M.D., New Jersey. 9 × 6 in. Pp. 313 + ix. Illustrated. 1971. London: Lloyd-Luke (Medical Books) Ltd. £8·20.

The importance of this book today is self-evident, for the increasing number of operations on the heart and lungs demands an ever-ready vigilance. Also thoracic trauma is common in road accidents and from war wounds.

The ten contributors to this book have covered in a most comprehensive manner the modern methods of pre- and postoperative treatment of the cardiopulmonary patient. The problems of cardiopulmonary arrest, myocardial revascularization, thoracic trauma, and acute renal failure are all considered in detail. The action of and indications for adrenergic drugs are dealt with in a lucid and interesting way.

This book will appeal to all those who have to work in intensive care units as well as to house-surgeons and surgical registrars.

Spinal Dysraphism. Spina Bifida Occulta. By C. C. MICHAEL JAMES, Ph.D. (Edin.), F.R.C.S. (Edin.), Newcastle upon Tyne, and L. P. LASSMAN, M.B., B.S. (Lond.), F.R.C.S., Newcastle upon Tyne. 8½ × 5½ in. Pp. 144 + viii. Illustrated. 1972. London: The Butterworth Group. £4·40.

THIS is a useful monograph on a subject that is not well known amongst the general practitioners of today. So often children with this defect are allowed to develop severe disabilities without the apparent possibility of treatment of the primary condition.

The authors of this book have wisely refrained from publishing their clinical records until they had collected 100 cases and had fully investigated these cases before and after operation.

The book is divided into two parts. Part 1 is devoted to clinical considerations, including the embryology and pathology of the condition. The principles of surgery are discussed fully and the postoperative care and complications are described in some detail.

Part 2 consists of an analysis of 100 cases and the results after laminectomy during the period 1957 to 1965.

This book is written in a clear, lucid style and is illustrated with good clinical pictures, radiographs, and excellent photographs of operative techniques.

This book will be in demand by paediatric physicians and surgeons, as well as orthopaedic surgeons and neurosurgeons.

Basic Skills for Surgical Housemen. By KENNETH C. CALMAN, Lecturer in Surgery, Western Infirmary, Glasgow. 7⅛ × 4⅘ in. Pp. 126 + vii. Illustrated. 1971. Edinburgh: Churchill Livingstone. £1.

THIS is a useful paper-back for the guidance of students, house-officers, and nurses. The techniques and procedures which are required by medical residents are described in some detail and are illustrated by clear line drawings. Procedures such as venepuncture, arterial blood sampling, urethral catheterization, the insertion of chest drains, the management of cardiac arrest, abdominal paracentesis, bronchoscopy, and tracheostomy are well described.

This pocket-book contains much useful information for the resident, student, and nurse, and its price is moderate.

Biological Tissue in Heart Valve Replacement. Edited by M. I. IONESCU, M.D., Consultant Thoracic Surgeon, General Infirmary; Leeds, D. N. ROSS, B.Sc., M.B., Ch.B., F.R.C.S., Consultant Surgeon, Guy's Hospital, London; and G. H. WOOLER, T.D., M.D., M.A., F.R.C.S., Honorary Thoracic Surgeon, General Infirmary, Leeds. 8½ × 5½ in. Pp. 925 + xxix. Illustrated. 1972. London: The Butterworth Group. £22.

THIS is an important book, for it marks the progress that has taken place during the past few years concerning heart-valve replacement. It is pleasing to note that this book is edited by three outstanding British thoracic surgeons. The numerous contributors to this volume come from Canada, France, Holland, Roumania, Switzerland, United States of America, and Great Britain. The majority are thoracic surgeons from various centres in England.

The enormous collection of material concerned with biological tissue in heart-valve replacement speaks for itself, and the various contributors have given their clinical experience with many types of valves. The various techniques used in heart-valve replacement are well described and illustrated. There can be no doubt that this book provides a critical account of our present knowledge of this type of surgery. The book is a great credit not only to the editors but also to the numerous contributors.

This is an ideal reference volume and should be found in every medical library.

The Complete Handbook for Medical Secretaries and Assistants. By ROBERT LEE DENNIS, M.D., San José, and JEAN MONTY DOYLE, R.R.L., San José. 11 × 8½ in. Pp. 559 + xiii. Illustrated. 1971. Edinburgh: Churchill Livingstone. £4·50.

THIS is a comprehensive volume giving essential information regarding medical terms and reports, and also the format of letters to doctors and the filing of medical notes, book-keeping, and insurance. There is also an up-to-date list of surgical instruments, dressings, drugs, and anaesthetics. There are sections on tumours and the electrocardiogram.

Any secretary knowing the contents of this large volume would be worth her weight in gold.

Ergebnisse der Bluttransfusionsforschung. Vol. 11. Edited by M. MATTHES, Freiburg i. B., N. KLEINE, Freiburg i. B., and L. P. HOLLANDER, Basel. 9½ × 6½ in. Pp. 466 + viii, with 117 illustrations. 1971. Basel: S. Karger. £12·65.

THIS massive volume reports the proceedings of the fourteenth meeting of the German Society for Blood Transfusion held in April, 1970. The papers presented cover a wide field with particular reference to immunology. Apart from 58 separate papers, the book contains a special lecture by Dr. R. Race on blood groups in human genetics, a long opening speech, and a panel discussion on exchange transfusion in adults. Unfortunately, the papers have been presented as they were read and have not been edited or shortened. None of the papers contains a summary and the majority are in German. The book is beautifully printed and well illustrated and is likely to be of interest to those who attended the meeting.

Geburtshilfliche Operationen. Eleventh edition. By HEINRICH MARTIUS and GEHARD MARTIUS, Berlin. 9 × 6 in. Pp. 189 + xvi, with 177 illustrations. 1971. Stuttgart: Georg Thieme Verlag. DM.24.

THIS is the eleventh edition of a classic textbook for students and practitioners about obstetric procedures. It was first published in 1933. The book is generously and well illustrated by half-tone diagrams, and various obstetric manœuvres are well described.

It is perhaps unfortunate that the book deals only with technical procedures and it leaves out entirely the problems of antenatal and postnatal care, and it does not discuss at all the management of the newborn baby. However, because of the clarity of the diagrams it must be a success with medical students.

“...not only are the two primary pathogens, *Strep pneumoniae* and *H influenzae*, sensitive, but so are the secondary invaders such as klebsiella which often replace them after antibiotic treatment.”[1]

“Of the easily administered primary treatments for urinary tract infection, this combination is probably the best.”[1]

“...clearly superior to either of the other treatments...”[2]

“...one is struck by the tremendous success rate, certainly superior to any antibacterial we have tested...”[3]

“...indeed one cannot remember any other drug performing so well...”[3]

“It rapidly cleared purulent sputum with improvement in all 50 cases.”[4]

SEPTRIN* Tablets, Adult Suspension, Paediatric Suspension and Paediatric Tablets contain trimethoprim and sulphamethoxazole.

CHURCHILL LIVINGSTONE

MANUAL OF SURGICAL THERAPEUTICS

Edited by R. E. CONDON and L. M. NYHUS

1970 *390 pages* *48 illustrations*

Spiral bound **£3·25**

The authors provide comprehensive information on the diagnosis and treatment of shock, trauma, and cardiac disorders. Preoperative and postoperative care are covered in detail. Surgical infections, bacteriology, and complications are discussed with complete sections on drug usage, side effects, and administration.

TEXTBOOK OF OPERATIVE SURGERY

ERIC L. FARQUHARSON

With revision by R. F. RINTOUL

1971 *Fifth Edition* *972 pages*

1,049 illustrations **£8·00**

'The book will continue to be of value to all who are working for the higher surgical qualifications, and will be of help to all those practising general surgery. It can be strongly recommended.'—*Practitioner.*

CONTEMPORARY BURN MANAGEMENT

Edited by HIRAM C. POLK, Jr. and H. HARLAN STONE

1972 *400 pages* *108 illustrations* **£9·50**

The authors present virtually all the major advances in the care of acute burn injury during recent years. The latest methods of coping with shock, infection, wound care, wound coverage, and immunological problems are presented by the experts responsible for the development of new techniques. Various procedures recommended for the treatment of different aspects of burn illness are compared and contrasted, and each section contains a carefully considered summary assessing these methods of care.

AN AID TO CLINICAL SURGERY

PETER R. SCOTT

1971 *336 pages* *60 illustrations* **£4·00**

The purpose of this book is to offer a concise aid to the study of clinical surgery rather than such comprehensive cover of the subject as is already available in the many standard texts. To this end every effort has been made at impartiality and clarity, with deliberate restriction of the subject matter to common clinical fields. Consideration of the surgical specialities of orthopaedics, urology, cardio-thoracic surgery and otorhinolaryngology has been limited to certain aspects of general concern.

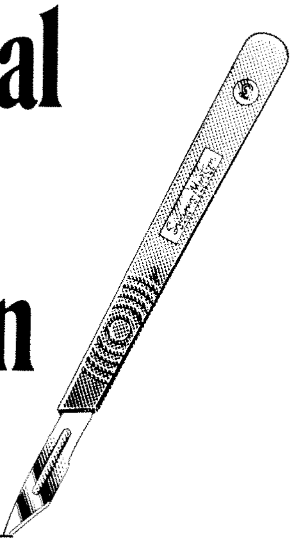
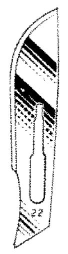
Swann-Morton surgical blades have an edge over the others



Swann-Morton of Sheffield are one of the largest manufacturers of surgical blades in the world. The Company achieved this leading position through the unvarying high quality of its products.

Swann-Morton blades are manufactured of the finest tempered surgical steel, precision-ground to give edges of the high degree of sharpness essential for the most delicate surgery. Swann-Morton blades are safe, stable and economical. They are sterilized by gamma radiation, packed in quick-peel foil envelopes and colour-coded for easy recognition. They can also be kept indefinitely under any conditions of storage and climate.



Here are details of the Swann-Morton range of products:

Sterilized stainless steel blades
Sterilized carbon steel blades
Standard carbon steel blades
Sterile disposable scalpels
Sterile disposable stitch cutters
Surgical handles
Autoclavable plastic surgical handles

Matburn M

The supreme four section operation table. . .*

This is the supreme four-section operation table: grouped head-end control, the fullest range of positions and a series of over fifty accessories give the M the flexibility to meet the demands of any branch of surgery, and any procedure from routine examination under anaesthesia to advanced neurosurgical operations.

Built to the highest standards of engineering skill and precision, Matburn M combines absolute rigidity with easy mobility when required.

*More Matburn M Operation Tables are sold in this country every year than any other table.

ESCHMANN

no fear no infection no pain

with a Porges golden balloon catheter

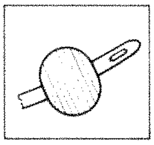
No pain : it has an impeccably smooth surface and the balloon when deflated leaves no protrusion. This allows easy insertion and withdrawal.

No fear : the patient feels completely reassured. He will be utterly relaxed during catheterization. A large surface for vesical support is obtained through even inflation of the balloon, ensured by reinforcing ribs.

No infection : the incorporation of active bacteriostatic compounds into the latex prevents any urinary tract infection.

Our research department has devoted all its efforts to the production of catheters which satisfy all clinical requirements :

The Porges balloon catheter



the golden catheter
created for the patient's safety and comfort.

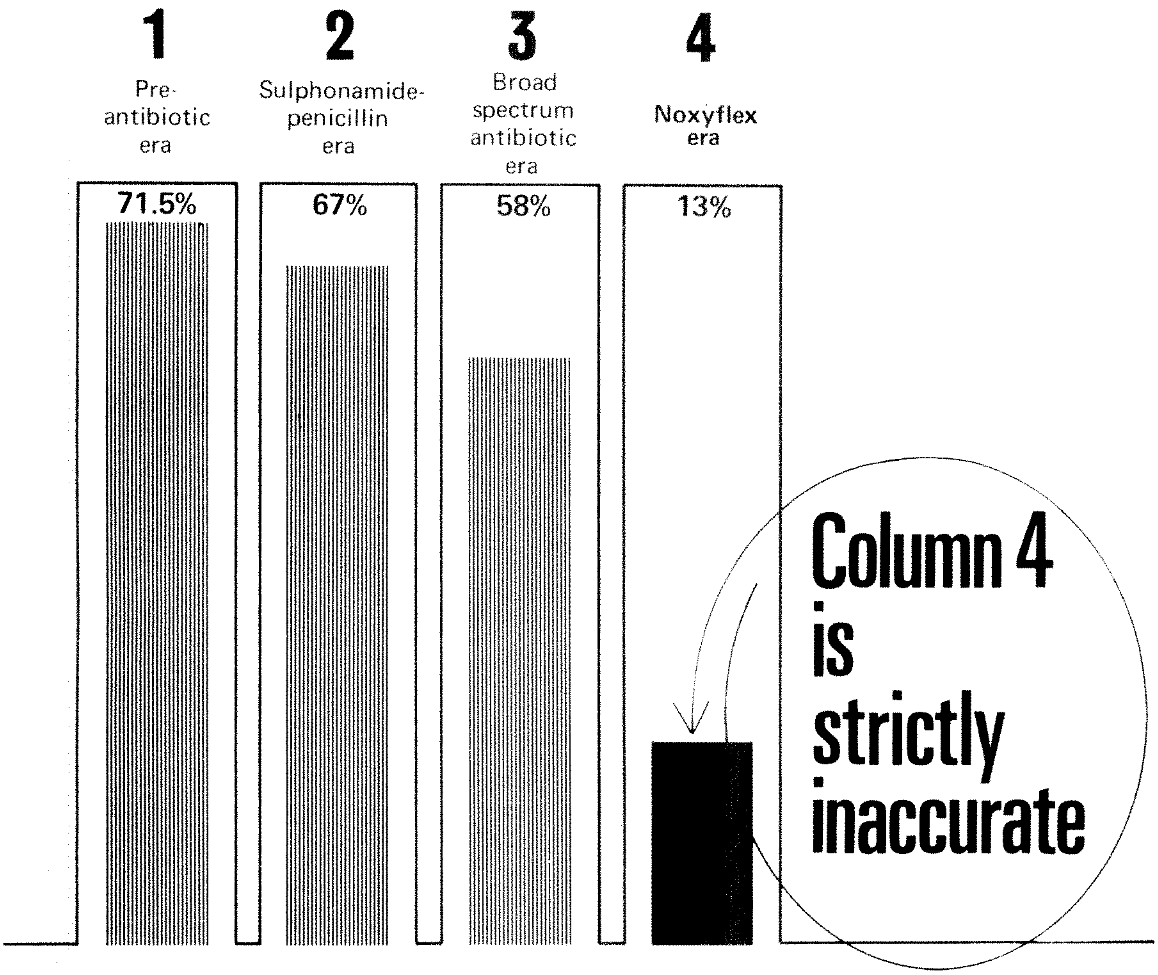
The graph below compares mortality rates due to faecal peritonitis, era by era.
It is not pedantically accurate because its sources differ. But the point is fairly made.



Why inaccurate? Because column 4 refers to 23 cases of faecal peritonitis which were treated successfully with Noxyflex. But the *3 deaths which occurred were due to causes other than peritonitis - as post-mortem revealed. **The mortality rate due to peritonitis can therefore be regarded as zero.**

* The whole graph, and the causes of the deaths referred to are the subject of the new Noxyflex folder "Why three deaths?" You will receive at least one copy!

When bacterial contamination of the peritoneum is diagnosed or suspected: Noxyflex

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 57. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners Ltd., St. Martin's House,* 159 *Clapham High Street, London, S.W.*4.

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

Warranty

RAY-TEC* X-Ray Detectable Swabs

Johnson & Johnson Limited (hereinafter called "the Company") agree to indemnify and hold

....

(hereinafter called "the Hospital")

harmless for and from any liability, damages, suits, actions, or other injuries it may sustain, in an amount not to exceed £100,000 arising out of and due solely to the failure of any RAY-TEC X-Ray Detectable Swabs to be revealed on an X-Ray plate with standard techniques and equipment.

This commitment shall ... such liability, damages, suits, actions, or injuries ... where the personnel performing and ... RAY-TEC X-Ray Detectable ... exercised normal ... ical and radio ...

There are some things that you never notice until they are missing...

security is one of them

RAY-TEC* X-ray detectable swabs offer security to the patient, the surgical team – and to the hospital.

For the patient the radio-opaque, barium sulphate impregnated monofilament is soft, non-irritant, non-toxic and unaffected by body fluids.

For the surgical team the presence of the filament can easily be detected even after saturation with blood and exudates.

For the hospital . . .
RAY-TEC* X-ray detectable swabs offer the security of their unique £100,000 indemnity against non-detection on an X-ray plate by standard techniques. This warranty operates in addition to implied warranties under Statute or Common Law.

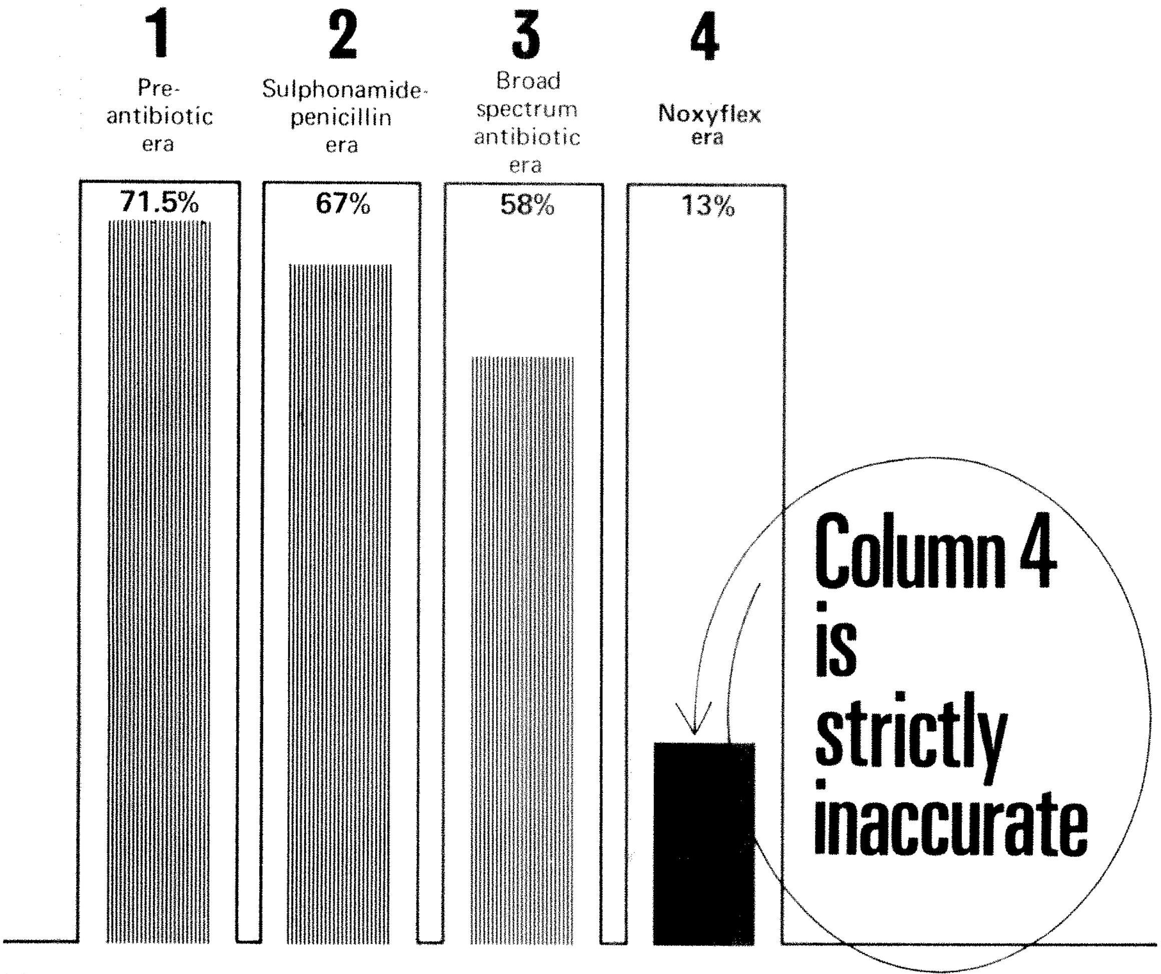
The graph below compares mortality rates due to faecal peritonitis, era by era.
It is not pedantically accurate because its sources differ. But the point is fairly made.



Why inaccurate? Because column 4 refers to 23 cases of faecal peritonitis which were treated successfully with Noxyflex. But the *3 deaths which occurred were due to causes other than peritonitis - as post-mortem revealed. **The mortality rate due to peritonitis can therefore be regarded as zero.**

* The whole graph, and the causes of the deaths referred to are the subject of the new Noxyflex folder "Why three deaths?" You will receive at least one copy!

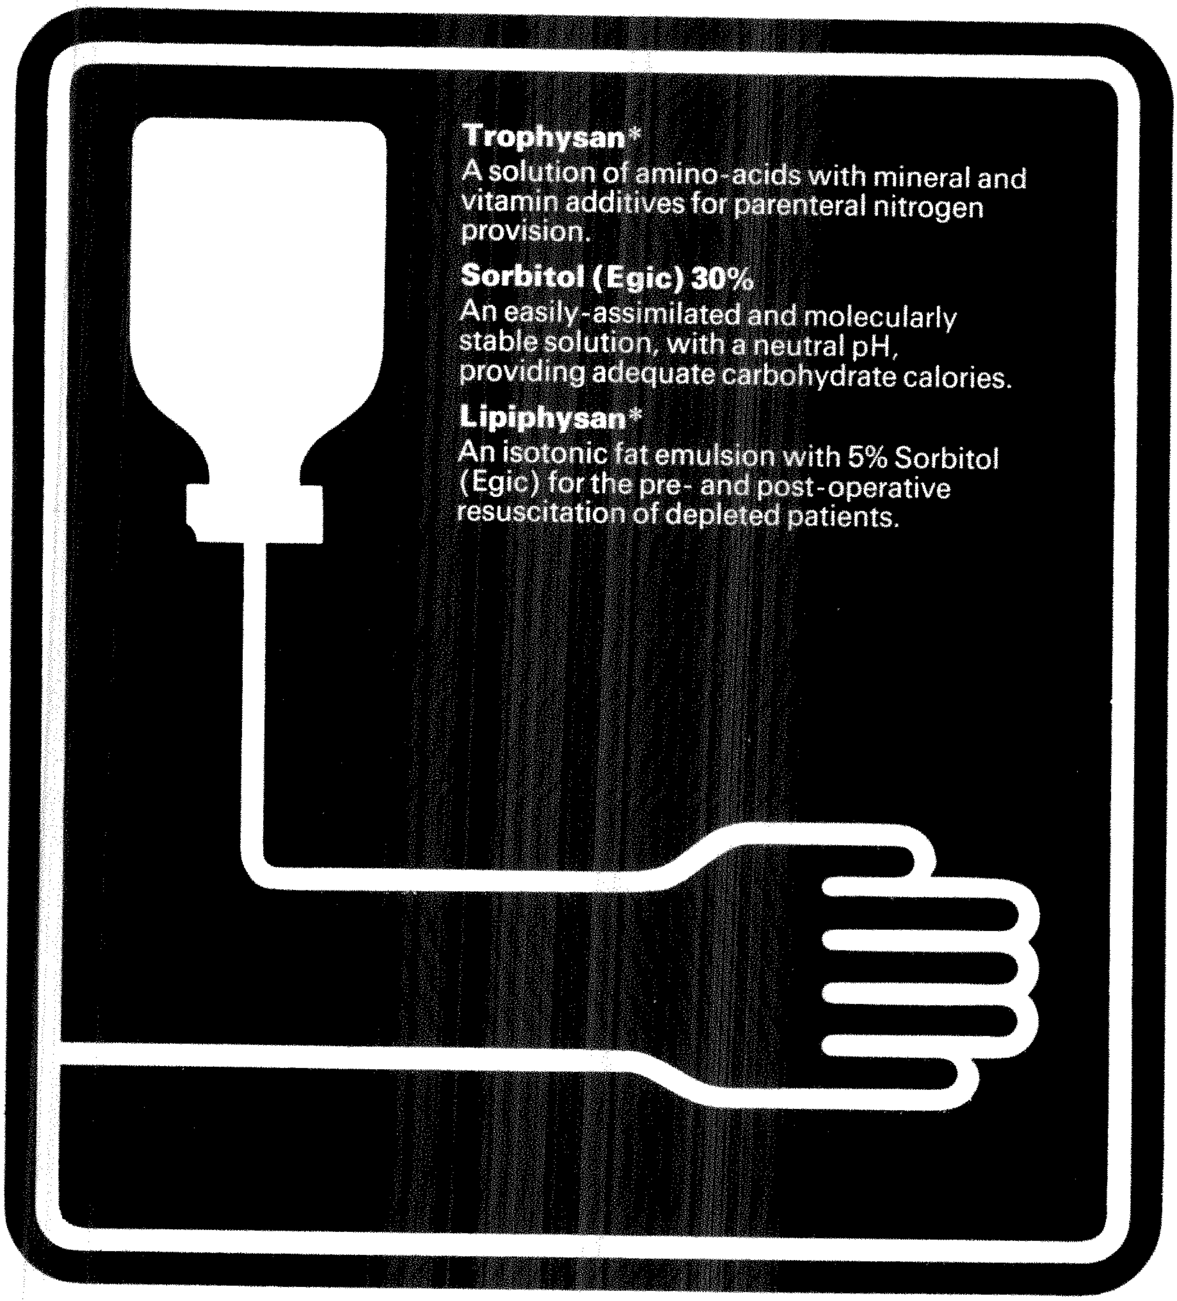
The problem of nutritional deficiency in surgery

In surgery of the GI tract the malnourished patient is a poor surgical risk. Pre-operative parenteral nutrition ensures adequate provision of nitrogen and calories and the correction of any electrolytic imbalance. This is best achieved by the use of SERVIER intravenous nutritional solutions.



Trophysan*
A solution of amino-acids with mineral and vitamin additives for parenteral nitrogen provision.

Sorbitol (Egic) 30%
An easily-assimilated and molecularly stable solution, with a neutral pH, providing adequate carbohydrate calories.

Lipiphysan*
An isotonic fat emulsion with 5% Sorbitol (Egic) for the pre- and post-operative resuscitation of depleted patients.

When nutritional deficiency is a problem, Servier has the solution.

MALIGNANT TUMOURS OF THE BILE-DUCTS

By KENNETH W. WARREN, JOHN C. MOUNTAIN,* AND WILLIAM LLOYD-JONES†

DEPARTMENT OF SURGERY, LAHEY CLINIC FOUNDATION, BOSTON, MASSACHUSETTS

SUMMARY

The 77 cases of malignant neoplasm of the extrahepatic bile-ducts treated at the Lahey Clinic between 1965 and 1969 are reviewed. Exploratory laparotomy was performed in 68 cases, although in 9 cases operation was not indicated because of the patients' poor condition. Of the 68 surgical patients, 24 (35 per cent) had a radical procedure, of which 17 survived for more than 1 year and 5 are still alive more than 3 years later, 3 having no evidence of recurrent disease. Forty-one patients had palliative treatment usually with some form of decompression procedure of the obstructed common bile-duct, and in 15 patients this was combined with hepatic artery infusion chemotherapy. Of these patients, 16 survived for more than 1 year, including 9 from the group treated by hepatic artery infusion chemotherapy. Only 1 patient is still alive after more than 3 years.

Of all the patients, 44 per cent survived for more than 1 year, 23 per cent for more than 2 years, and 8 per cent for more than 3 years. The mean survival time was 13 months. These results compare favourably with those of the previous survey from the Lahey Clinic, and it is concluded that the improvement is the result of the increase in the radical resection rate from 18 to 31 per cent and in the institution of hepatic artery infusion chemotherapy in palliative cases.

MALIGNANT tumours of the bile-ducts have been associated with a very poor prognosis despite the fact that the majority of these tumours tend to be slow growing without widespread metastases. This is mainly because of the difficulty of early diagnosis and the proximity of these tumours to vital structures. Braasch, Warren, and Kune (1967) reviewed the total experience of the Lahey Clinic in treating neoplasms of the bile-ducts from 1920 to 1965 and reported 173 cases. Only 25 patients (14 per cent) were known to have survived 1 year or more and only 7 for more than 3 years.

During the past 5 years an attempt has been made whenever possible to be more radical in the surgical management of this condition as suggested by Quattlebaum and Quattlebaum (1965). Hepatic artery infusion chemotherapy was first performed for non-resectable lesions in 1965. We have therefore reviewed the records of patients treated from 1965 to 1969 to determine whether this more radical surgical approach together with infusion chemotherapy for the non-resectable lesions has resulted in a better prognosis.

RESULTS

Between 1965 and 1969 77 patients (44 men and 33 women) with primary malignant neoplasms of the bile-ducts were treated at the Lahey Clinic Foundation. The youngest patient was 31 years, the oldest 79 years, and the average age was 57 years. The peak incidence was in the sixth decade (*Fig.* 1).

The site of origin of the neoplasms is shown in *Fig.* 2. The commonest site was found to be the common hepatic duct (28 cases), followed by the retroduodenal portion of the bile-duct (18 cases) and the supraduodenal portion of the common bile-duct (11 cases). In 7 patients the neoplasm arose from the left hepatic duct, but in no patient did a neoplasm arise in the right hepatic or cystic duct. In 13 patients it was impossible to determine the site of origin of the neoplasm because the entire extrahepatic ductal system was involved.

Of the 77 patients, 69 were found to have adenocarcinoma, of which 49 were well-differentiated infiltrating lesions, 18 were anaplastic infiltrating tumours, and 2 were papillary tumours. One patient had a leiomyosarcoma. Insufficient material was obtained in 5 patients to classify the tumour. In 2 other patients, although obvious widespread malignant disease was present at laparotomy, biopsy revealed negative findings.

---

* Present address: Westminster Hospital, London.

† Present address: Liverpool Royal Infirmary, Liverpool.

Definite metastases were present in 35 of the 77 patients (45 per cent). The periductal lymph-nodes were involved in 25 patients and the coeliac lymph-nodes in 12. Direct extension into the liver occurred in 18 patients, of whom both lobes were involved in 13, the left lobe in 3, and the right lobe in 2. The peritoneum was obviously involved in 7 patients, and 1 patient also had osseous metastases.

The commonest presenting symptom was jaundice, occurring in 71 patients (92 per cent). Loss of weight and anorexia were also common. Upper abdominal pain was present in 23 patients (30 per cent) and chills and fever occurred in 22 patients (29 per cent). Jaundice was present on examination at the Lahey Clinic in 61 patients (79 per cent). The discrepancy between the presence of jaundice on examination at the Lahey Clinic and a history of recent jaundice is due to the fact that 60 of the 77 patients had had previous exploratory surgery elsewhere, and 21 (27 per cent) had a biliary drainage tube in situ or a biliary fistula on arrival. Except for hepatomegaly, which was present in 42 patients (55 per cent), other signs were usually absent. A palpable gall-bladder was present in only 3 patients (4 per cent), an enlarged spleen occurred in 2 patients (2 per cent), and a palpable abdominal mass and ascites were present in 1 patient each.

The liver-function tests showed evidence of bile-duct obstruction in almost all the cases. The serum bilirubin was raised above 1·5 mg. per 100 ml. in 55 out of 70 patients (79 per cent), with a maximum level of 47 mg. per 100 ml. in 1 patient. The serum alkaline phosphatase was raised above 4 Bodansky units in 67 out of 69 patients (97 per cent), and the level was more than 20 Bodansky units in 32 patients (46 per cent). The serum glutamic oxaloacetic transaminase was raised above 50 U. in 21 out of 37 patients (57 per cent). In only 6 patients, however, was it raised above 100 Somoygi units, and the highest recorded value was 177 Somoygi units. A low serum-protein level less than 5·6 g. per 100 ml. was found in only 4 patients, although the serum albumin was less than 3·5 g. per 100 ml. in 26 patients. The serum prothrombin level was less than 65 per cent in 20 patients.

Straight roentgenograms of the abdomen were not helpful in making the diagnosis of extrahepatic biliary tract neoplasia. It was performed in 36 patients and was reported as being normal in 29. Only 4 patients were shown to have hepatomegaly, and another 2 who had had previous biliary-tract surgery had air in the biliary tree. Intravenous cholangiography was also unhelpful. Of the 13 patients on whom it was performed, only 2 showed a dilated common bile-duct, 3 patients had a normal-calibre duct delineated, while the remainder showed no opacification. T-tube cholangiography on patients who had been operated on elsewhere was performed in 15 cases; in 13 of these a dilated bile-duct was demonstrated, the exact site of the obstruction being obvious in 10. In 2 patients the procedure was unsuccessful. In 32 patients an upper gastro-intestinal series was performed; 20 were reported as being normal, while the remaining 12 (38 per cent) showed extrinsic pressure deformity of the stomach or duodenum. Hepatic scintiscanning was performed in 8 cases, 7 of which were reported as being abnormal, showing cirrhosis in 2 and hepatic metastases in 5. These preoperative diagnoses were found to be correct in 6 of the 7 patients. Coeliac angiography was performed in 9 patients. It was unsuccessful in 1, normal in 3, and showed hepatic metastases in 5. Percutaneous cholangiography was performed in only 2 patients. It was unsuccessful in 1 and successful in the other. Operative cholangiography was usually performed using a No. 18 Foley catheter with the balloon inflated. It was performed in 15 patients and was successful in delineating the site of the stricture in 13 of them.

Table I.—TREATMENT AND SURVIVAL OF 77 PATIENTS WITH A MALIGNANT TUMOUR OF THE BILE-DUCT

PROCEDURE	TOTAL NO. OF CASES	SURVIVAL				
		0–4 wk.	5–26 wk.	27–52 wk.	1–3 yr.	3+ yr.

Total	77	18	9	16	28	6

* One patient has not had a recurrence.

† Two patients have not had a recurrence.

Summary of survival:—
12 months or more, 34 patients (44 per cent).
24 months or more, 18 patients (23 per cent).
36 months or more, 6 patients (8 per cent).
No recurrence, 3 patients.

Of the 77 patients, 60 had had an exploratory operation for obstructive jaundice before their referral to the Lahey Clinic for further assessment and treatment (*Table I*). Resection of the tumour was accomplished in 24 patients, the majority of which were tumours of the distal duct treated by pancreatoduodenectomy (15 patients). It was possible, however, to perform a resection and hepatico-enterostomy or end-to-end anastomosis in 7 patients and a left hemi-hepatectomy and hepatico-enterostomy in 2 others for neoplasms of the proximal duct.

A palliative procedure was performed in 41 patients. This entailed dilating the neoplastic stricture and inserting a rubber stent, either a T-tube or a Y-tube depending on the position of the stricture, in 10 patients, creating a by-pass biliary intestinal anastomosis proximal to the tumour with or without the insertion of a rubber stent in 11 patients, and using hepatic artery infusion chemotherapy associated with the insertion of a stent in 15 patients. Only external drainage of the proximal obstructed duct was possible in 5 severely ill patients, and in 3 patients only biopsy of the neoplasm was possible. On 9 occasions no surgery was attempted as the patient was too ill on admission to the hospital.

Of the 68 patients who underwent surgery, 10 (15 per cent) died in the postoperative period. The principal causes of death were hepatic coma in 3 patients; biliary peritonitis, 2; pneumonia, 2; endotoxic shock, 1; pancreatitis, 1; and secondary haemorrhage, 1.

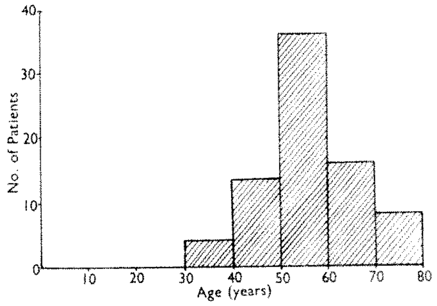

FIG. 1.—Age and sex incidence of 77 patients with malignant tumours of the bile-ducts (1965–9).

Non-fatal morbidity occurred in 16 patients (24 per cent). Several of these patients had more than one complication. Complications included wound infection in 6 patients; pneumonitis and atelectasis, 6; biliary fistula, 3; wound dehiscence, 2; subphrenic abscess, 2; intraperitoneal abscess, 2; pancreatic fistula, 1; and duodenal fistula, 1.

Of the 77 patients, 34 (44 per cent) survived for more than 1 year and 18 (23 per cent) survived for more than 2 years. Six patients (8 per cent) are known to be alive after more than 3 years, but only 3 are apparently still free of a recurrence of the disease. Of these 6 long-term survivors, 5 had a resection procedure while 1 was treated by hepatic artery infusion chemotherapy. The average survival period for all the patients was 13 months.

DISCUSSION

Malignant neoplasms of the bile-ducts are rare tumours. According to Courvoisier (1890) the first case was described in 1508. Renshaw (1922), however, considered the first recorded case to be that reported by Fardel in 1840, and that the first hepatic duct carcinoma was described by Schneppel in 1878.

Several large series of cases have been reported in recent years by Kuwayti, Baggenstoss, Stauffer, and Priestley (1957), Sako, Seitzinger, and Garside (1957), Lippman, McDonald, and Longmire (1959), Thorbjarnarson (1959), Strohl, Reed, Diffenbaugh, and Angerson (1963), and Braasch and others (1967). According to Sako and others (1957), 564 cases of primary carcinoma of the extrahepatic bile-ducts with microscopic proof of diagnosis had been recorded up to June, 1954.

The exact incidence of this condition is difficult to determine. The reported autopsy incidence ranges between 0·01 and 0·85 per cent (Mohardt, 1939; Kirshbaum and Kozoll, 1941; Sako and others, 1957). Neibling, Dockerty, and Waugh (1949) found 1 carcinoma of the bile-ducts in every 210 biliary-tract operations, while Thorbjarnarson (1959) found approximately 3 carcinomas of the gall-bladder to every 1 bile-duct carcinoma. Between 1965 and 1969, 1766 biliary-tract operations were performed at the Lahey Clinic, and 16 carcinomas of the gall-bladder were seen, giving an incidence of 1 carcinoma of the bile-duct for every 23 biliary-tract operations and 5 carcinomas of the bile-duct to 1 gall-bladder carcinoma. This difference in incidence is due to the fact that the majority of bile-duct neoplasms treated at this institution are referred from elsewhere.

● AMPULLA OF VATER LESIONS EXCLUDED
● IN 13 PATIENTS, ENTIRE EXTRAHEPATIC DUCT SYSTEM INVOLVED

FIG. 2. Site of origin of 77 malignant tumours of the bile-ducts (1965–9). In 13 patients the entire extrahepatic duct system was involved. (Lesions of the ampulla of Vater are excluded.)

The slightly higher incidence in the male sex which has previously been reported (Sako and others, 1957; Braasch and others, 1967) is again seen in this series. The present series also confirms that the majority of cases occur in the 50–70 age-group (*Fig.* 1). The average age of 57 years is similar to that of the previous series reported from the Lahey Clinic. The youngest reported case was a 23-year-old woman (Neibling and others, 1949), and the oldest was 93 years of age (Thorbjarnarson, 1959).

The majority of malignant neoplasms of the bile-ducts can be classified into well-differentiated, papillary, and anaplastic adenocarcinomas. In our series all the tumours, except for one, on which positive histology was obtained were adenocarcinomas. The exception was a leiomyosarcoma. This incidence is similar to that reported in a previous series. Cases of leiomyosarcoma were also reported by Thorbjarnarson (1959) and Braasch and others (1967). Other rare neoplasms that have been reported include adenoacanthoma (Braasch and others, 1967), squamous-cell carcinoma (Braasch and others, 1967), and rhabdomyosarcoma (Horn, Yakovac, Kaye, and Koop, 1955; Farinacci, Fairchild, Sulak, and Gilpatrick, 1956).

The macroscopic pathological appearance of carcinoma of the bile-ducts has been classified into medullary, infiltrating, and papillary types (Lippman and others, 1959), but it is difficult to classify any case into one type as areas of each type of tumour may be seen. The infiltrating type is usually slow growing and may incite a surrounding fibroblastic reaction that will make it particularly difficult to differentiate from a benign stricture. According to Altemeier, Gall, Zinninger, and Hoxworth (1957) and Thorbjarnarson (1958), this type of tumour is more common than was once thought, and differentiation from sclerosing cholangitis may be almost impossible.

In the present series the commonest site for the origin of bile-duct tumours was the common hepatic duct (*Fig.* 2), but previous series have recorded the distal common bile-duct as being the commonest site (Sako and others, 1957; Braasch and others, 1967). In all the reported series, however, it has been impossible to determine the exact site of origin of the neoplasm in 10-20 per cent of the cases, and it is often difficult to be sure whether the tumour has originated from the duodenum or the gall-bladder and not the bile-ducts. These factors probably account for the variability of site incidence in different series. In this present study, however, it is interesting that there were 7 cases in which the neoplasm arose from the left hepatic duct while none originated in the right hepatic duct. No tumour was considered to have arisen from the cystic duct.

The incidence of metastases in the present series of 45 per cent of the cases is similar to that found by previous workers (Renshaw, 1922; Thorbjarnarson, 1959), although an incidence of over 70 per cent has been recorded (Neibling and others, 1949; Kuwayti and others, 1957). We also confirmed that in nearly all the cases the spread was localized to the vicinity of the bile-duct, with involvement of the liver, peritoneum, and local lymph-nodes, and that widespread metastases occur extremely late in this disease. The patient with osseous metastases was only diagnosed as having a primary bile-duct carcinoma at autopsy.

The clinical features on initial examination were very similar in incidence to those recorded in the previous series from the Lahey Clinic (Braasch and others, 1967). Although obstructive jaundice was present in nearly all our patients, there were rarely any features that would lead to the correct diagnosis being made before operation. In carcinomas of the distal bile-duct an enlarged gall-bladder may be palpated, but this also occurs with carcinoma of the head of the pancreas. Kuwayti and others (1957) found a palpable gall-bladder in 32 per cent of their cases, but it occurred in only 4 per cent in the present series. This discrepancy is due in part to the fact that 60 of our patients had been referred from elsewhere having already had exploratory surgery.

Radiology is rarely useful in making a correct preoperative diagnosis, although an upper gastrointestinal series may show distortion of the stomach or duodenum. It may, however, be of considerable help to the surgeon in determining the correct procedure applicable in a particular patient. Preoperative hepatic scintiscanning and coeliac angiography have been performed with increasing frequency at the Lahey Clinic over the years of this study. Although it is impossible to differentiate metastatic lesions in the liver from metastases from another primary neoplasm or from a hepatoma, the extent of the spread of the tumour can be assessed preoperatively by this investigation. Whether or not the hepatic pathology is the result of a bile-duct neoplasm can only be determined by laparotomy.

If a previous exploration has been performed operative cholangiography or T-tube cholangiography is an essential and accurate procedure in determining the site and extent of the neoplastic stricture. This information may also be obtained preoperatively, and a differential diagnosis from other causes of obstructive jaundice may be obtained by percutaneous transhepatic cholangiography. This procedure has rarely been performed at the Lahey Clinic for neoplastic obstruction of the bile-duct because in these cases usually no doubt exists that the patients have 'surgical jaundice' requiring an operation; the procedure is not without risk, and as a result of the procedure the proximal dilated duct is partially decompressed and may make delineation of the duct at operation more difficult. Percutaneous cholangiography, however, may prove more effective with increasing experience.

Even at operation it may be difficult to confirm the diagnosis, especially in the infiltrating type of lesion that is liable to be confused with sclerosing choledochitis (Altemeier and others, 1957) or with a benign biliary-duct stricture if previous biliary or gastric surgery has been performed. The diagnosis can only be excluded after multiple biopsies of the bile-duct have been reported to be negative.

The types of operative procedures that are available for the treatment of bile-duct neoplasms were summarized in the previous report from the Lahey Clinic (Braasch and others, 1967). The type of operation performed depends on the site of the neoplasm and the extent of the spread of the disease. The procedures can also be classified into radical, when an attempt is made to excise the neoplasm completely, and palliative, when the obstructive jaundice is relieved by insertion of a rubber stent through the neoplastic stricture or by performing a by-pass biliary-intestinal anastomosis. Until recently the majority of the radical procedures performed were for neoplasms of the distal duct, when a pancreatoduodenectomy is often possible, but radical resection for hepatic duct and supraduodenal bile-duct tumours was rarely attempted. In the series of Braasch and others (1967) 32 of 173 patients had a radical resection, of which 27 were pancreatoduodenectomies, while in the current series it was possible in 24 of 77 patients with only 15 pancreatoduodenectomies. The number of resections of the proximal ducts has therefore increased.

Since 1965 hepatic artery infusion chemotherapy has been used with increasing frequency for non-resectable malignant lesions of the bile-ducts at the Lahey Clinic after its introduction by Watkins and Sullivan (1964) for primary and secondary hepatic carcinoma. In the series reported by Braasch and others (1967) only 2 patients had received a course of hepatic artery infusion chemotherapy and no conclusions could therefore be made regarding its use. Fifteen patients have now received this treatment and it is therefore possible to assess its effect on the prognosis.

The prognosis after operation for carcinoma of the bile-ducts has been very poor in all the reported series. Braasch and others (1967) found that only about 14 per cent of patients survived for 1 year or more and 4 per cent for more than 3 years. All but 1 patient had had a distal common-duct tumour treated by pancreatoduodenectomy. One of the longest survivors after operation was reported by Altemeier and others (1957). Their patient lived for 5½ years and required seven operations. One of the patients reported in the previous series from the Lahey Clinic (Braasch and others, 1967), who was alive 3 years after undergoing a pancreatoduodenectomy for a distal duct carcinoma, eventually survived 7 years. He required two further surgical procedures for obstructive jaundice secondary to recurrent disease during this time. The poor prognosis of bile-duct tumours was also shown by Neibling and others (1949), who reported a mean survival period of only 3 or 4 months.

The present series reports considerable improvement in the immediate prognosis compared with the previous report from the Lahey Clinic; 44 per cent of the patients in the present series were alive at 1 year compared with 14 per cent in the previous series, while 8 per cent were alive at 3 years compared with 4 per cent. The average survival period of 13 months in the present series also compares favourably with that reported by Neibling and others (1949). This improvement in the immediate prognosis appears to be associated with the increased performance of radical operation especially for the proximally situated tumours: radical operations were performed in 18 per cent of the cases in the series of Braasch and others (1967) while they were carried out in 31 per cent of the cases in the present report. It therefore confirms the suggestion made by Quattlebaum and Quattlebaum (1965) that an attempt at more radical operation would improve the prognosis of this condition. Hepatic artery infusion chemotherapy has also resulted in an improvement in the prognosis of those patients receiving palliative treatment. Of the 15 patients who were thus treated, 9 were still alive after 1 year and 1 patient is still alive more than 3 years later.

THE DELAYED HYPERSENSITIVITY RESPONSE IN PRIMARY BREAST CARCINOMA AS AN INDEX OF HOST RESISTANCE

BY ROGER J. MITCHELL*

UNITED BRISTOL HOSPITALS

SUMMARY

An attempt has been made to correlate the Varidase test with possible immunological phenomena as assessed histologically. It would appear statistically that the test is more likely to be negative in the presence of poor differentiation, suggesting that there may be some form of immunological suppression in these cases. In the majority of these poorly differentiated cases there was an absence of lymphocytic involvement of the tumour. However, no obvious connexion between Varidase and lymphocytic infiltration of the tumour or sinus histiocytosis has been found.

The Varidase test cannot therefore be assumed to be a reliable guide of the accepted histological criteria of host-defence reactions. Any information as to why this test should be so consistently depressed in the presence of malignant disease has not been forthcoming. This work is a preliminary report and is an attempt to assess the total immune competence of a group of adult patients in the presence of mammary carcinoma. It is freely acknowledged that further work into the long-term survival of these patients is necessary before further conclusions can be drawn.

IT is recognized that the delayed hypersensitivity response may be reduced in malignant disease.

---

* Present address: General Hospital, St. Helier, Jersey, Channel Islands.

Hughes and Mackay (1965) showed depression of the response to tuberculin in patients with carcinoma, and this depression became more marked as the disease progressed. Roberts and Williams (1968), using streptokinase, reported that the delayed hypersensitivity response was increasingly suppressed as the malignancy disseminated. Stjernswärd and Clifford (1970) also showed that the delayed hypersensitivity response to dinitrochlorobenzene (DNCB) is depressed in large Burkitt lymphoma tumours. In respect of humoral immunity Lytton, Hughes, and Fulthorpe (1964) showed that the circulating antibody response to tetanus toxoid was reduced in patients with malignant disease compared with patients equally debilitated but not suffering from malignancy.

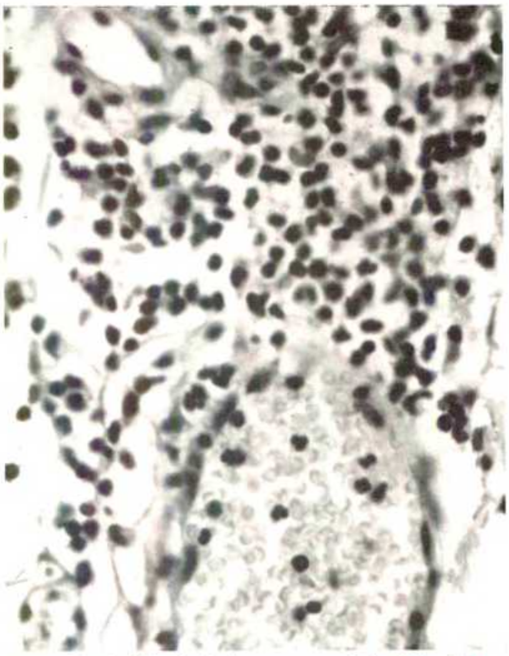

FIG. 1.—Typical histological appearance of the delayed hypersensitivity response.

The present study was undertaken to assess the cellular immune competence of a group of patients with primary carcinoma of the breast compared with a similar group of patients without known malignant disease. In addition, an attempt has been made to correlate these findings with appearances of suggested immunological significance in the primary tumour and regional nodes.

MATERIALS AND METHODS

A group of 45 women seen at the United Bristol Hospitals with primary breast carcinoma was studied. Patients with known secondary deposits from mammary carcinoma were not included in the present work.

The group was tested intradermally with streptokinase-streptodornase solution (Varidase, Lederle) following the work of Roberts and Williams (1968). Assuming that the adult population has at some time developed an immunity to the streptococcus, streptococcal antigen should when injected intradermally produce an immune reaction at the cellular level. Suppression of this response in the presence of malignancy becomes more marked as the disease progresses and is more evident in the group studied than in a group of controls without known malignancy. The two groups had a similar incidence of streptococcal infections in their past histories. The carcinoma group included 2 patients who had had rheumatic fever compared with the controls who included 1 case of rheumatic fever. There were no cases of acute nephritis in either group. The Varidase test was performed in order to provide an index of possible host resistance.

Nature of the Varidase Test.—The Varidase test was assumed by Roberts and Williams (1968) to indicate a delayed hypersensitivity response. This is confirmed by histological study of a reaction at 48 hours in a sample removed from the author's arm. There is perivascular cuffing with lymphocytes and invasion by round cells and macrophages. This histological appearance is characteristic of a delayed hypersensitivity response (Turk, 1967) (*Fig.* 1).

Technique.—Normal saline, 0·1 ml., containing 5 U. of Varidase was injected intradermally into the forearm. The reaction was read at 48 hours and compared with a normal saline control in the opposite arm. A response greater than 25 mm. with erythema and swelling was regarded as positive. Any transient erythema which was fading at 24 hours was regarded as negative, as were reactions of less significance.

Assessment.—Four variables were assessed in each patient:—

1. Delayed hypersensitivity (Varidase test).
2. Lymphocytic invasion of the tumour.
3. Sinus histiocytosis.
4. Grade of malignancy of the tumour.

1. *Varidase Test.*—This was recorded as either positive (+) or negative (−).

2. *Lymphocytic Invasion of the Tumour.*—This was graded as follows:—

An occasional lymphocyte	0
Scattered foci of lymphocytes, or a thin scattering	1
Numerous foci or germinal centres	2

3. *Sinus Histiocytosis* was graded as follows:—

No sinusoids	0
Sinusoids less than 5 cells thick	1
Sinusoids more than 5 cells thick	2
As above but with mixed cellularity	3

4. *Histological Grade of Tumour*:—

Well differentiated	1
Intermediate	2
Poorly differentiated	3

This assessment was based on the work of Patey and Scarff (1928). They graded tumours by consideration of tubule formation, hyperchromatism, and nuclear pleomorphism. The difficulties of grading tumours on morphological grounds have for the present purposes been accepted.

The histology of the tumour and the lymph-nodes was assessed on this basis by the author and compared with an independent histopathological opinion.

RESULTS

1. Varidase Test.—The results of the Varidase test are shown in *Table I*. The higher incidence of

Varidase negative in the carcinoma group is statistically significant ($\chi^2 = 4{\cdot}921$, $P < 0{\cdot}05$). Roberts and Williams (1968) showed that up to 70 per cent of patients with widespread disease were Varidase negative.

2. Varidase Test and Scarff Grading.—The results of the Varidase test compared with the Scarff grades (Patey and Scarff, 1928) are shown in *Table II*. These results suggest that the Varidase test is more likely to be suppressed in the presence of poor differentiation. This is statistically significant ($\chi^2 = 4{\cdot}213$, $P < 0{\cdot}05$).

Table I.—RESULTS OF THE VARIDASE TEST

VARIDASE	CARCINOMA OF THE BREAST	CONTROLS
V+	24	35
V−	21	10

Table II.—RESULTS OF THE VARIDASE TEST COMPARED WITH SCARFF GRADES*

VARIDASE	SCARFF GRADE		
	1	2	3
V+	1	11	12
V−	2	2	17

* Patey and Scarff (1928).

Table III.—RESULTS OF VARIDASE TEST COMPARED WITH SINUS HISTIOCYTOSIS

VARIDASE	SINUS HISTIOCYTOSIS			
	0	1	2	3
V+	2	9	6	7
V−	6	3	5	7

3. Varidase and Sinus Histiocytosis.—Sinus histiocytosis was present in very comparable degrees in all stages, irrespective of the Varidase test (*Table III*). From this study there is no evidence that the Varidase test has any correlation with sinus histiocytosis and this is confirmed statistically ($\chi^2 = 1{\cdot}906$).

4. Varidase and Lymphocytic Involvement of Tumour.—There is no apparent connexion between the Varidase test and the degree of lymphocytic involvement of the tumour (*Table IV*). This is confirmed statistically ($\chi^2 = 0{\cdot}122$).

5. Lymphocytic Involvement of the Tumour and Scarff Grading.—Comparing the Scarff grade with lymphocytic involvement of the tumour (*Table V*), poorly differentiated tumours were more likely to show no lymphocytic involvement. Comparing groups 1 and 2 with group 0 this is statistically significant ($\chi^2 = 4{\cdot}245$, $P < 0{\cdot}05$).

DISCUSSION

Host resistance to malignant disease has been under consideration since the early papers of Bashford, Murray, and Cramer (1908) and Lambert and Haines (1911), but it was not until recent years that the implications of reactive lymph-nodes or round-cell infiltration within and around the tumour came to be appreciated. Foote and Stewart (1946) first suggested that the lymphocytic invasion of a primary tumour might represent an immunological defence mechanism, and some series have shown this to be indicative of a favourable prognosis (Moore and Foote, 1949; Richardson, 1956). Black, Opler, and Speer (1955) noted that those patients with marked lymphocytic infiltration of the tumour had an observed survival of at least twice that expected from his series.

3	13	8	6

Geschickter (1945) first drew attention to the so-called 'medullary breast cancer with lymphoid infiltration' as a new clinical entity. This type of breast carcinoma is known to be associated with a good prognosis (Bloom, Richardson, and Field, 1970). According to Richardson's (1956) histological criteria there were no cases in this series which fell into the medullary group. In the series of Bloom and others (1970) there was an incidence of 7 per cent.

The majority of reports concerning sinus histiocytosis regard it as a favourable prognostic sign (Black, Kerpe, and Speer, 1953; Black, Opler, and Speer, 1954, 1956). Berg (1956) doubted whether sinus histiocytosis was an index of host resistance, regarding it as a normal structural feature of lymph-nodes. This was disputed by Black and Speer (1958), who regard sinus histiocytosis as an uncommon finding in lymph-nodes removed from non-cancerous patients. Sinus histiocytosis is a reactive change in the tissue of a host and if it is associated with an improved survival rate it may rightly be termed an expression of host resistance. This view was endorsed and developed by Hamlin (1968) in her extensive survey of possible host resistance based on histological criteria. She found a distinct correlation between marked sinus histiocytosis and good survival. Black (1970) again emphasizes the improved survival in a more recent report.

The degree of malignancy of the primary tumour has long been assumed to affect long-term survival. Following the work of Broders (1920), Patey and Scarff (1928) graded breast carcinomas into groups depending on their histological appearance. A high grade of malignancy is not, however, incompatible with long survival, and these subdivisions only serve further to demonstrate the unpredictability of forecasting long-term survival.

Acknowledgements.—I wish to thank the surgeons of the United Bristol Hospitals for access to their patients, and to Mr. A. J. Webb for his advice and encouragement. My thanks are also due to Dr. A. C. Hunt, lately Consultant Pathologist to the United Bristol Hospitals, for his help in the interpretation of the histology and to Miss E. H. L. Duncan of the University of Bristol Statistical Department for her advice.

SURGICAL OBJECTIVES IN UNRESECTED CANCER OF THE HEAD OF THE PANCREAS*

BY R. G. ELMSLIE AND A. H. SLAVOTINEK

DEPARTMENT OF SURGERY, THE UNIVERSITY OF ADELAIDE, SOUTH AUSTRALIA

SUMMARY

Twenty-seven patients with obstructive jaundice due to unresected cancer of the pancreas have been reviewed. The surgical objectives in treating this sort of patient were taken as the need to make a positive diagnosis and to palliate until death. There was failure to establish the diagnosis of cancer at operation (17 patients), failure to attain permanent biliary decompression (1 patient), failure to anticipate duodenal obstruction (3 patients), and failure to relieve pancreatic pain (8 patients). As a result of this review we have evolved a set of guide-lines which should be considered when treating patients with irresectable cancer of the pancreas.

SINCE Robson and Cammidge's (1907) dismal survey, in which only 2 of 66 patients with irresectable cancer of the pancreas survived cholecysto-enterostomy, there has been a gradually growing enthusiasm for palliation of irresectable cancer of the head of the pancreas. Indeed today the treatment of these patients is, or should be, an exercise in short-term palliation.

The objectives of surgical treatment in jaundiced patients presumed to have irresectable cancer of the pancreas are to make a firm diagnosis and to relieve distressing symptoms. Although most of these patients have only a short time to live, the scope of the operation should be extended to prevent anticipated symptoms which might otherwise necessitate a second operation. We have reviewed a series of such patients in order to find the reasons for failure to achieve these objectives. As a result we now feel that the traditional quick laparotomy and gall-bladder decompression can be justified only in the critically ill terminal patient.

THE PRESENT SERIES

This review concerns 27 patients with obstructive jaundice thought to be due to cancer of the head of the pancreas who were operated on between 1964 and 1970 by one of us. All but 1 patient had a biliary decompression procedure. Eleven patients were lost to follow-up. One patient died shortly after operation; the other patients survived to be discharged from hospital. The review took into account the following features: histological diagnosis, adequacy of biliary decompression, duodenal decompression, and relief of pancreatic pain.

DIAGNOSIS

The diagnosis of cancer of the pancreas was made histologically in 19 patients, either from operation biopsy specimens (6 patients) or at post-mortem examination (9 patients) or both (4 patients). The remaining 8 patients were considered to have cancer of the pancreas primarily because a dilated, blue, thin-walled common bile-duct was found at operation. Operative biopsies were taken from any obvious secondary deposit in the abdomen, from the paraduodenal peritoneum if it appeared abnormal, or from the coeliac and common-duct nodes; on one occasion a pancreatic biopsy was considered justified.

---

* Part of this paper was read at the Forty-fourth General Scientific Meeting of the Royal Australasian College of Surgeons held in Sydney in May, 1971.

Case 1.—A. S., a 63-year-old landowner, had a laparotomy and cholecystojejunostomy in June, 1967, elsewhere for presumed cancer of the head of the pancreas, and was told the likely course of events. A year later he was well, although extremely concerned about his future and about the timing of personal decisions concerning his estate. At a re-exploration in May, 1968, the pancreas was hard throughout. Biopsies of the peritoneum and lymph-nodes were negative for cancer but a transduodenal biopsy of the pancreas showed adenocarcinoma.

The unconfirmed operative diagnosis of cancer of the head of the pancreas was challenged in another 2 patients who developed pancreatitis 3 and 11 months after their initial operation. The provisional diagnosis was later proved: in the first patient by biopsy at a subsequent operation; in the second at a post-mortem examination.

Case 2.—E. G., a 78-year-old female, presented with jaundice in April, 1969. At laparotomy the pancreas was hard throughout and enlarged. The common duct was 4 cm. in diameter, thin-walled, and blue. Although biopsies of the paraduodenal peritoneum and the coeliac lymph-nodes did not contain malignant tissue, we still thought that the patient had cancer of the pancreas. In January, 1970, she developed severe upper abdominal pain with the serum amylase raised to 667 Somogyi units. In view of her good general health and a weight-gain of 6 kg. since operation the original diagnosis was questioned. However, when she finally died in December, 1970, a well-differentiated adenocarcinoma of the pancreas was found.

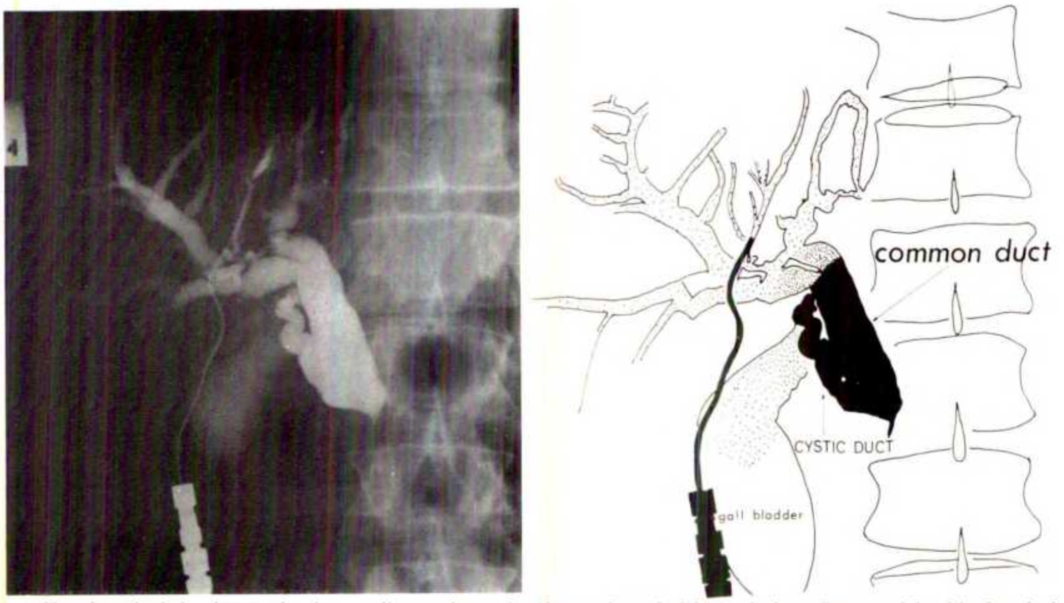

FIG. 1.—Transhepatic cholangiogram showing a malignant obstruction close to the end of the cystic duct. Because of the risk of cystic duct occlusion the gall-bladder was removed and the common duct used for decompression.

BILIARY DECOMPRESSION

One patient in the series had a massive tumour in the porta hepatis and did not undergo biliary decompression. Eighteen patients underwent biliary decompression via the gall-bladder. Nine patients had decompression of the hepatic duct because of either a previous cholecystectomy or a diseased gall-bladder, or a low cystic duct termination (*Fig.* 1). Despite precautions aimed at preventing the return of obstructive jaundice during the postoperative period, 1 of the patients who was followed up (*Case* 3) became jaundiced owing to extension of the growth to the cystic duct.

Case 3.—W. W., a 68-year-old male, developed obstructive jaundice. At laparotomy in January, 1969, a cholangiogram taken through the gall-bladder (*Fig.* 2) showed obstruction of the common bile-duct well below the presumed site of entry of the cystic duct; a cholecystenterostomy was performed. Six months later jaundice reappeared. At reoperation the gall-bladder was collapsed and the cancer (outlined by transhepatic cholangiography) now occluded the entry of the cystic duct (*Fig.* 2). A high decompression of the common hepatic duct produced permanent relief of jaundice until the death of the patient 5 months later.

DUODENAL DECOMPRESSION

Four patients in this series had a gastro-enterostomy at the time of their biliary decompression. One patient had frank duodenal obstruction, and the other 3 had distortion of the duodenum in the barium meal. Another 3 patients, each with a normal barium meal at the initial operation, developed duodenal obstruction with vomiting owing to extension of the tumour after the initial operation, and each subsequently underwent gastro-enterostomy. Two of these patients had a positive biopsy of the paraduodenal peritoneum at their first operation, and in the other

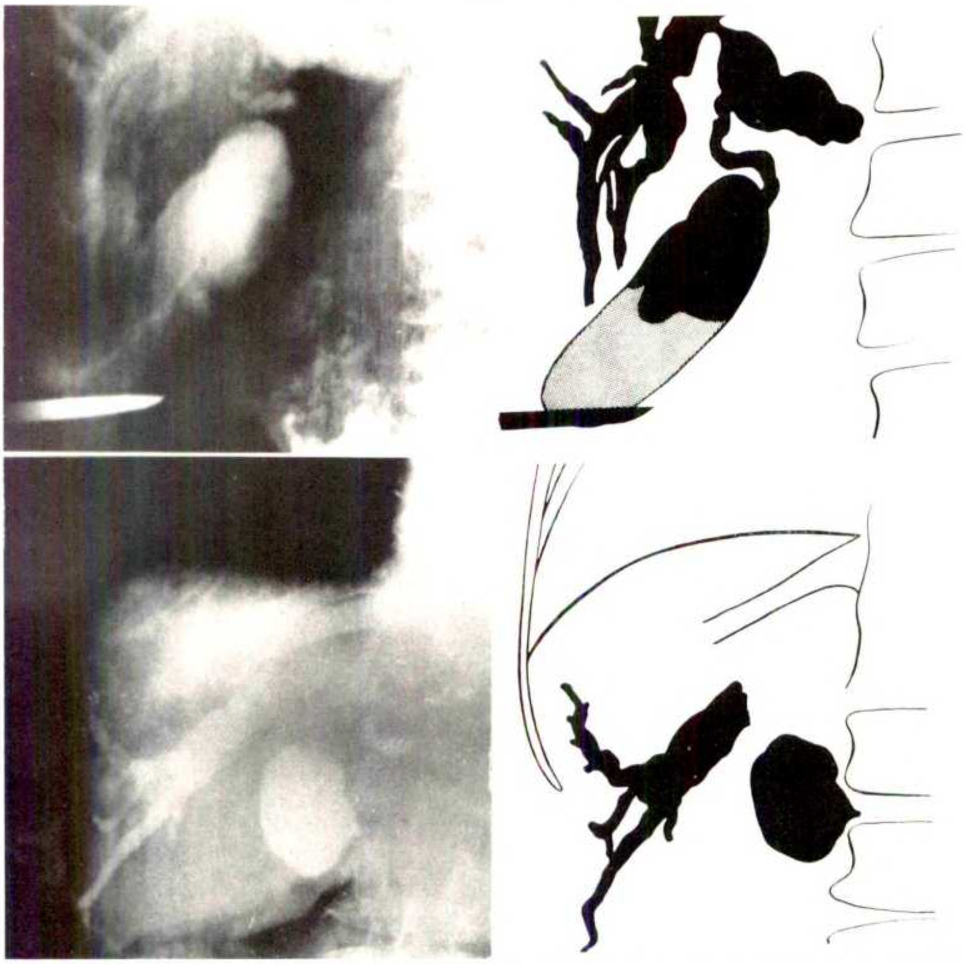

FIG. 2.—Cholangiograms of *Case* 3. The upper cholangiogram, taken at operation, appears to show a high cystic-duct termination well away from the obstruction. The lower cholangiogram taken just before the second operation fails to outline the gall-bladder or cystic duct which had become obstructed by upward extension of the growth.

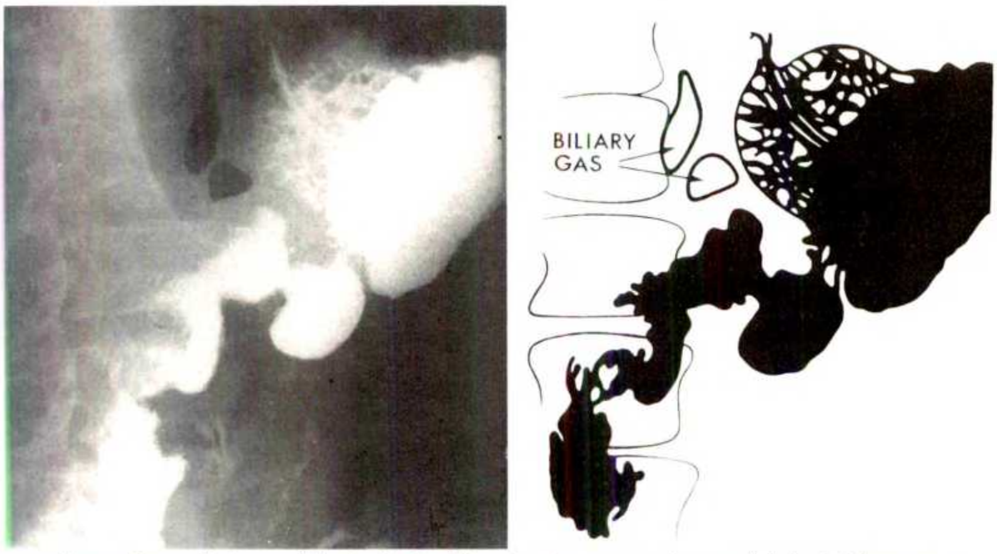

FIG. 3.—*Case* 5. Barium meal showing duodenal distortion due to presumed cancer of the head of the pancreas.

patient it was noted that the plane between the pancreas and the inferior vena cava was obliterated. Duodenal obstruction subsequent to the biliary decompression operation can be rapid and debilitating, and negate the palliative advantage of the relieving of jaundice, as the following case records show.

Case 4.—P. F., a 46-year-old male, had a cholecystoenterostomy and entero-anastomosis in June, 1967, for cancer of the head of the pancreas proved by paraduodenal biopsy. The preoperative barium meal was normal. Five weeks later the patient developed vomiting, and a barium meal showed a dilated stomach and a deformed second part of the duodenum. Gastro-enterostomy restored gastro-intestinal patency for the 4 remaining months of life.

Case 5.—D. Mc., a 69-year-old male, had a choledochoduodenostomy for presumed cancer of the pancreas in April, 1969. Attempted mobilization of the pancreas failed owing to obliteration of the plane between it and the inferior vena cava. The barium meal prior to operation was normal. Four months later the patient developed vomiting and the barium meal showed deformity of the antrum, pylorus, and duodenum (*Fig.* 3). In August, 1969, a gastro-enterostomy was performed. The patient was reasonably well until December, 1969, when he was lost to follow-up.

RELIEF FOR PANCREATIC PAIN

Nine patients had pancreatic pain preoperatively and were submitted to alcohol injection of the coeliac ganglia region during their biliary decompression operation. There was a fall in blood-pressure in all 6 patients in whom the pressure was closely monitored. One patient was relieved of pain until his death 3 months later. Six patients were unrelieved. Two patients obtained temporary relief.

Case 6.—R. O. H., a 43-year-old male with severe, persistent, deep epigastric pain, presented with jaundice which was initially diagnosed as being caused by chronic pancreatitis. A barium meal showed distortion of the duodenum. Because of increasing jaundice a transhepatic cholangiogram was performed and showed complete obstruction of the common bile-duct. At laparotomy in November, 1967, the paraduodenal peritoneum was biopsied and indicated the presence of cancer. In view of the cholangiogram findings of low cystic-duct entry, and duodenal involvement, as well as the severe pain experienced by the patient, a high hepaticojejunostomy, gastro-enterostomy, and injection of the coeliac ganglia region with 2 ml. of absolute alcohol were undertaken. Although there was an immediate fall in blood-pressure after the injection of alcohol, the pain was relieved for only 4 weeks. The patient died 5 months after the operation, unjaundiced and without vomiting, but with constant severe debilitating pain requiring morphine. At post-mortem examination the primary tumour occupied the whole pancreas; there were many lymph-node and hepatic metastases.

DISCUSSION

This survey is incomplete in two respects: the diagnosis of cancer was not always proved and the follow-up is incomplete. Despite this defect it does serve to emphasize the high number of surgical failures: failure to diagnose correctly, failure to relieve jaundice permanently, failure to anticipate duodenal obstruction accurately, and failure to combat pain.

Misgivings over the surgical treatment of irresectable cancer of the pancreas have been expressed by many authors. Cattell and Warren (1953), concerned about this aspect, listed four palliative procedures including ligation of part of the arterial supply of the pancreas. Since then the failure of gall-bladder decompression alone to palliate successfully has been considered by various authors (Warren, 1950; Glassman and Johnston, 1955; Elmslie, 1968; Gallitano, Fransen, and Martin, 1968; White, Murat, and Morgan, 1968).

The diagnosis of cancer of the pancreas is frequently elusive. Glenn and Thorbjarnarson (1964), using operation and autopsy data, reported metastases (including lung and skeletal metastases) in less than 143 patients in a series of 236 patients with cancer of the pancreas. When biopsies are not positive we have found the guide-line of Smith and Sherlock (1964) to be of great value. They stated: 'If there is jaundice and an irregular enlargement of the head of the pancreas which might be neoplastic, the surgeon should look at the common bile duct for the answer. The grossly dilated thin-walled, translucent, duct typical of obstruction by a tumour is very different from the white, opaque, thick-walled, adherent, duct typical of chronic pancreatico-biliary infection.' The transhepatic cholangiogram is also of value in making this distinction (Glenn and Thorbjarnarson, 1964; Elmslie and Newstead, 1969). In exceptional circumstances, as in the present *Case* 1, if doubt still exists transduodenal needle biopsy can be employed on the understanding that if chronic pancreatitis alone is found in the specimen the primary disease could still be cancer of the pancreas (Schultz and Sanders, 1963).

Although jaundice does sometimes appear as a terminal event owing either to hepatic metastasis or to extreme cholangitis, the failure of jaundice to remit or the reappearance of jaundice after operation is usually evidence of failure of the operative procedure to achieve biliary decompression. In one series (Gallitano and others, 1968) biliary drainage failed to relieve jaundice in 25 per cent of the patients; presumably the cystic duct was blocked in some of these patients. At operation it cannot be assumed that the distended gall-bladder is necessarily patent to the common duct. The advantage of cholangiography, either before or at operation, is twofold. Not only does it locate the upper limit of the block relative to the cystic duct but also it demonstrates whether or not the cystic duct is patent (Elmslie and Newstead, 1969). Reobstruction in 1 of our patients (*Case* 3) may have been due to misinterpretation of the original cholangiogram. We do not claim to have produced evidence in favour of routine common-duct decompression. However, it seems reasonable to advocate cholecystectomy and common-duct decompression if the patient is in relatively good health and if doubt exists about the termination of the cystic duct.

Occasional non-mechanical vomiting as an accompaniment of nausea is not uncommon in patients with cancer of the head of the pancreas. The progression of the disease towards duodenal obstruction is generally regarded as a signal for gastro-enterostomy at the time of biliary decompression. Our experience suggests that it should also be performed if at operation there is suspected spread to the paraduodenal peritoneum and if the plane between the pancreas and the inferior vena cava is difficult to display. In Glassman and Johnston's (1955) series of 20 patients 3 required gastro-enterostomy soon after biliary decompression; consequently they suggested gastro-enterostomy as a routine procedure. With this approach the patient at risk is the one with pancreatitis misidentified as cancer. One patient presumed now to have pancreatitis but initially thought to have cancer has developed ulceration at the gastrojejunal stoma (Proudman, 1971).

In the past abdominal surgeons operating on cancer have been particularly concerned with survival periods. Now that the technical advances in this sort of surgery have reached their limit, more emphasis is being placed on the quality of the survival period and nowhere is this better exemplified than in irresectable cancer of the head of the pancreas causing pain. In the present series alcohol was injected into the coeliac ganglia region if the pain was 'pancreatic' (boring, epigastric, or lumbar pain, occasionally paroxysmal, sometimes nocturnal, and frequently relieved by lumbar flexion). Pain due to biliary or hepatic distension (dull, mild, and in the right upper quadrant) was relieved by biliary decompression alone. The almost uniform failure of alcohol injection in our series should not be taken to represent a failure of the principle. Rather it could well be a measure of the technique used. Two possible reasons for failure were the volume of alcohol used and the preliminary dissection of the area before the injection was undertaken. The volume of absolute alcohol was 2 ml. in the earlier injections (1966–8) and 5 ml. in the later ones—volumes which are considerably less than those used by White and others (1968) (10 ml. of absolute alcohol) and by Bridenbaugh, Moore, and Campbell (1964) (50 ml. of 50 per cent alcohol). Furthermore, in our hands some dissection usually preceded the injection; sometimes in mobilizing the pancreas from the right and at other times by dividing the posterior parietal peritoneum above the pancreas thus opening the retroperitoneal space which contains the ganglia and their connexions. Presumably two reasons for the excellent results obtained by dorsal injection (Bridenbaugh and others, 1964) are the large volume and the integrity of the restraining peritoneum in front of the injection. None of the patients in our series was submitted to coeliac block by the dorsal route.

CONCLUSIONS

In the light of this review certain guide-lines can be given for the treatment of obstructive cancer of the head of the pancreas which is considered, for one reason or another, to be irresectable. First, a quick gall-bladder decompression is not a satisfactory palliative procedure unless the patient is near death. Secondly, a determined effort should be made to arrive at the correct diagnosis—by radiological display of the block, by looking at the common duct, by mobilization of the head of the pancreas, by biopsy of the surrounding peritoneum and lymph-nodes, and occasionally by transduodenal biopsy of the swelling. Thirdly, the relationship of the entry of the cystic duct into the common duct and the upper level of the growth should be considered. When they are adjacent, the common duct (rather than the gall-bladder) should be used for decompression. Fourthly, if at operation there is evidence of spread towards the duodenum a gastro-enterostomy should be undertaken. Finally, a small volume of absolute alcohol injected into the coeliac ganglia region at the conclusion of this sort of operation is unlikely to be of benefit, particularly if the posterior peritoneum has been divided. As a result of this review we will undertake alcohol injection via the dorsal route postoperatively (Bridenbaugh and others, 1964) in those patients who have pain whether or not they have had an attempted block at operation. These measures may not prolong the patient's life but they should make it more tolerable.

Acknowledgements.—We should like to thank our colleagues at the Queen Elizabeth Hospital, Adelaide, and the Prince Henry and Prince of Wales Hospitals, Sydney, who shared in the management of these patients. Our secretary Mrs. E. Mazel gave valuable help in preparing the manuscript.

ABDOMINAL AORTIC ANEURYSM AND HORSE-SHOE KIDNEY

BY JOHN E. FRAWLEY, G. H. DICKSON, C. W. JAMIESON, AND H. H. G. EASTCOTT
ST. MARY'S HOSPITAL, LONDON

SUMMARY

Successful abdominal aortic replacement for aneurysm in 3 patients with horse-shoe kidney is reported. The anatomy of the horse-shoe kidney, particularly in relation to its blood-supply, is described. Because of the lack of correlation between the radiological and operative findings it is suggested that the final decision for replacement of the aorta must be taken at operation. Techniques for grafting which obviate the need to divide the isthmus of the horse-shoe kidney and decrease the operating time are described.

THE horse-shoe kidney is prone to acquired disease in 80–90 per cent of cases and with advancing years the likelihood of this increases. Atherosclerotic aneurysm of the abdominal aorta is seen in the elderly, frequently as one manifestation of generalized atheroma, and such patients must be considered as liable to some diminution of renal reserve owing to renal artery atherosclerosis or hypertensive arteriosclerosis (Szilagyi, Smith, and Whitcomb, 1959). Since the blood-supply to a horse-shoe kidney is frequently anomalous and may arise from multiple sites on the abdominal aorta or iliac arteries the combination of horse-shoe kidney with abdominal aortic aneurysm poses a difficult problem in the preservation of renal function with operative treatment of the aneurysm. We report here our experience of 3 patients with this rare combination, which has previously been reported in only 18 cases (Julian, 1956; Phelan, Bernatz, and De Weerd, 1957; Szilagyi and others, 1959; Wilder, Kock, and Stein, 1963; Mannick, Brooks, Bosher, and Hume, 1964; Lynn and Bruce, 1965; Minken and Rob, 1967; Cox and Machado, 1968; Killen, Scott, and Rhamy, 1968; Cohn, Stoney, and Wylie, 1969; Scott, De Bakey, and Mani, 1969). In 16 of these replacement of the aneurysm was undertaken successfully.

The kidney develops from the urogenital ridge. Development is progressive in a caudal direction with the formation of primitive pronephros, followed by the temporarily functioning mesonephros, and finally the metanephros which forms the definitive kidney and derives its drainage system from a lateral bud from the mesonephric duct. With differential growth the kidney ascends to its definitive position. It is postulated (Arey, 1965) that convergent growth of the lateral buds of the mesonephric duct which are to form the drainage systems of the definitive kidneys may result in fusion of the metanephric masses across the midline, so that the definitive kidney is the horse-shoe type. Ascent of this fused kidney is impeded and it tends to be sited lower than normal with the isthmus usually at the level of the fourth or fifth lumbar vertebrae, that is, at or near the level of the abdominal aortic bifurcation.

The developing kidney derives a segmental blood-supply from the aorta. With progressive development the more cephalad vessels disappear along with the mesonephros and maximal development occurs caudally in the region where the definitive kidney will develop. In this region the arteries form a network, the rete arteriosum urogenitale, which supplies in varying degrees the developing suprarenal and urogenital organs. Eventually some roots from the aorta degenerate and the area which they have supplied is taken over by a neighbouring root. Finally, the kidney comes to be supplied by one artery from the aorta, which divides in the hilum to supply the five definitive segments of the kidney. Graves (1971) has suggested that the persistence of some of these segmental roots from the aorta accounts for the variation of origin of the segmental renal arteries which may be manifest by a number of separate vessels from the aorta supplying particular segments of the kidney. These anomalous vessels are not 'accessory' or 'extra' arteries but normal segmental arteries supplying a particular segment of the kidney. Such arteries are true end arteries, there being no communications between them from segment to segment within the kidney.

Graves (1971), in a precise study of the renal blood-supply by arteriography and injection of coloured resins, has shown that the supply of the horse-shoe kidney is similarly segmental in nature. His studies indicate that the isthmus of the horse-shoe kidney represents the posterior segment of the lower pole and that vessels running to the isthmus from the iliac arteries or aorta below the isthmus represent the posterior branches of the lower segment artery which have taken origin from the nearest point on the aortic axis to the fused developing metanephros.

Venous drainage of the horse-shoe kidney may also be anomalous and the common variations are the isthmus vein running across the front of the aorta to the inferior vena cava and the left renal vein coursing behind the aorta to the inferior vena cava, an anomaly which occurs in about 2 per cent of patients (Culp and Bernatz, 1961).

POSSIBILITY OF AORTIC REPLACEMENT

Papin (1914) recorded 139 horse-shoe kidneys in 126 of which the arterial supply was accurately documented (*Table I*). He divided the arterial supply of the horse-shoe kidneys into three major groups:—

Group 1: Normal renal arteries (20 per cent of cases).

Group 2: Three to five renal arteries (66 per cent of cases).

Group 3: More than five renal arteries (14 per cent of cases).

In group 1 replacement of the abdominal aorta below the level of the renal arteries should not pose a problem in the preservation of the renal blood-supply.

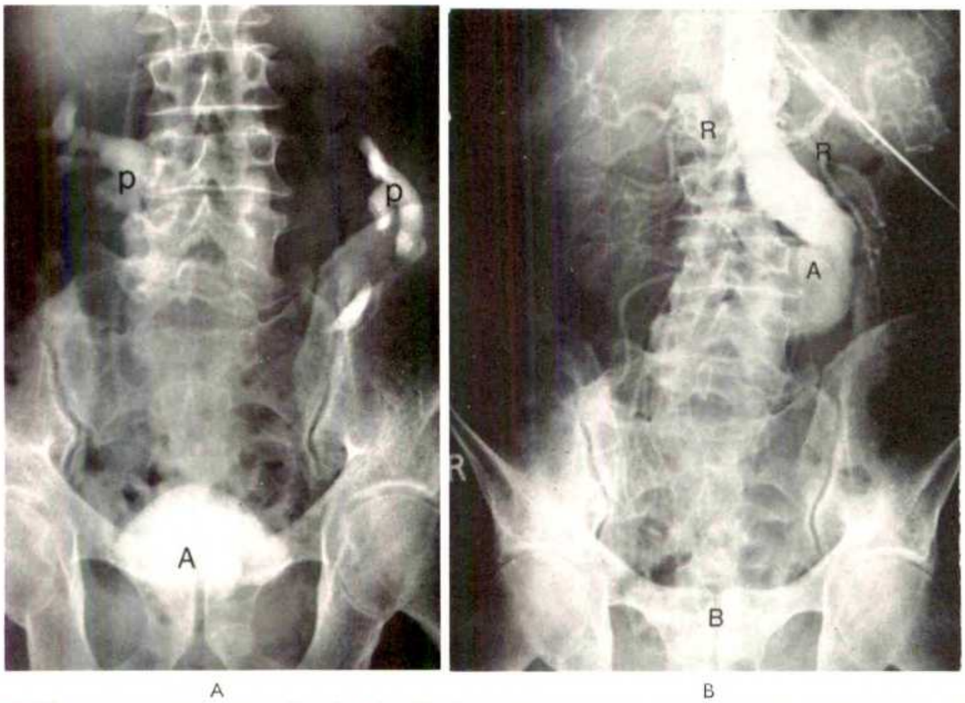

FIG. 1.—A, The intravenous pyelogram outlines the pelves (P) of the horse-shoe kidney and the low position of the kidney is well demonstrated. On the left the kidney is rotated with the calices medial and the pelvis lateral, while the right half of the horse-shoe is not rotated. The ureters are not seen. B, The aortogram shows two renal arteries (R) arising from the aorta above the aneurysm (A).

Table I.—ARTERIAL SUPPLY OF 126 HORSE-SHOE KIDNEYS (PAPIN, 1914)

No. of Arteries	*No. of Cases*	
1	1	Group 1 (20 per cent)
2	26	
3	40	Group 2 (66 per cent)
4	23	
5	20	
6	9	Group 3 (14 per cent)
7	3	
8	2	
9	0	
10	2	

In group 2 the horse-shoe kidney was supplied by three to five renal arteries and in all of these there were two arteries at the normal site and additional vessels from varying sites distal to these. The aorta was the commonest site of origin of additional arteries (73 per cent), the remainder arising from the common iliac arteries except in 2 cases (internal iliac and middle sacral). The additional vessels were distributed equally between the main renal substance and the isthmus. In this group replacement of the aorta below the level of the vessels at the normal site is theoretically possible, but additional vessels from the aorta may have to be sacrificed and one or more segments of the kidney will be rendered ischaemic. Additional vessels from the iliac arteries may well be preserved if the iliac vessels are not to be replaced with the aorta, but division of such vessels may be necessary for mobilization of the horse-shoe kidney in gaining access to the aorta. Again, a segment of the kidney will be rendered ischaemic. From Graves's (1971) studies it would seem that in this group the supply to the apical, upper, middle, and posterior segments of both kidneys would be preserved in most cases, and that ischaemia would be confined to the lower segments which include the isthmus.

In group 3 the renal vessels were small and multiple, and from the description would almost certainly render surgical replacement of the aorta with the preservation of renal function impossible.

It would seem, then, that aortic replacement in a patient with a horse-shoe kidney without producing renal ischaemia is possible only in the group with normal renal arteries, that is, in 20 per cent of cases of horse-shoe kidney. In the remaining 80 per cent of cases some degree of renal ischaemia is likely to result from aortic replacement, which seems possible in those with three to five arteries (60 per cent), and is probably impossible in those with more than five renal arteries (14 per cent).

CASE REPORTS

Case 1.—A 65-year-old man presented complaining of intermittent claudication in both legs at 200 m. and a thumping sensation in the lower abdomen. There were no other symptoms or any past history of cardiovascular disease. Examination revealed hypertension of the order of 230/135 without cardiomegaly. In the mid-abdomen there was a pulsatile mass 10 cm. in diameter and the peripheral pulses below the femoral were absent in both legs. Harsh bruits were audible over the abdominal aorta and over both common femoral arteries. The patient was admitted to hospital for assessment for aneurysm replacement.

An intravenous pyelogram (I.V.P.) revealed the presence of a horse-shoe kidney (*Fig.* 1 A). In view of this an aortogram was obtained which showed an aneurysm of the abdominal aorta below the level of two renal arteries (*Fig.* 1 B). The blood-urea was 40 mg. per 100 ml.

It was decided to delay aortic replacement until the hypertension had been controlled. However, in spite of vigorous treatment the hypertension did not improve and the aneurysm increased in size over the following 3 months. The patient was therefore readmitted for an aortic replacement graft on 8 Feb., 1971.

At operation (*Fig.* 2) the findings were not as expected from the radiological appearances. There was a left common iliac aneurysm and an aortic aneurysm. The kidney was supplied by two renal arteries as suggested on the aortogram. A large isthmic vein crossed the aneurysm to the junction of the left renal vein with the inferior vena cava. The kidney had three pelves. On the right side a single ureter descended in front of the isthmus to the bladder. The left half of the kidney had two pelves, one from the isthmic region and one from the lateral aspect of the kidney (the lateral position being due to rotation), the ureters joining below the kidney to descend to the bladder. The renal substance appeared normal and there were no palpable calculi.

The aortic aneurysm and left common iliac aneurysm were isolated by clamping the aorta below the level of the renal arteries, the right common iliac artery, and the left internal and external iliac arteries. The aortic aneurysm was opened and the lumbar arteries were controlled by oversewing from within. A bifurcation graft was sutured to the neck of the aneurysm from within, and after division of the right common iliac artery and left common iliac aneurysm the limbs of the graft were passed intraluminally from the aneurysm and brought out through

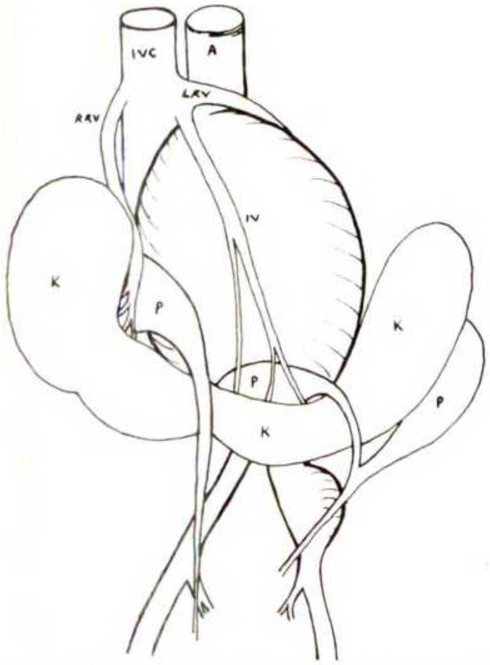

FIG. 2.—Diagrammatic representation of the operation findings in *Case* 1. The renal arteries were behind the aneurysm on the left side and behind the vena cava on the right side. IVC, Inferior vena cava. IV, Isthmic vein. A, Aorta. RRV, Right renal vein LRV, Left renal vein. K, Kidney. P, Pelvis.

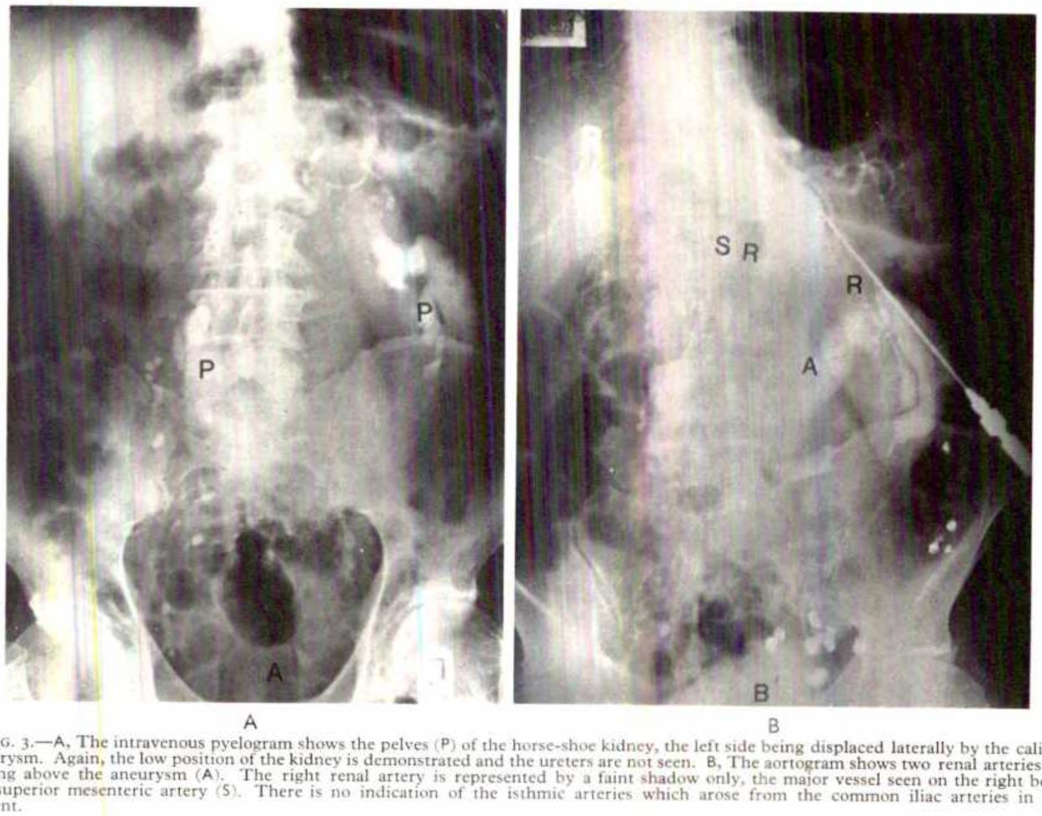

A B

FIG. 3.—A, The intravenous pyelogram shows the pelves (P) of the horse-shoe kidney, the left side being displaced laterally by the caliceal aneurysm. Again, the low position of the kidney is demonstrated and the ureters are not seen. B, The aortogram shows two renal arteries (R) arising above the aneurysm (A). The right renal artery is represented by a faint shadow only, the major vessel seen on the right being the superior mesenteric artery (S). There is no indication of the isthmic arteries which arose from the common iliac arteries in this patient.

the divided ends. The right limb of the graft was sutured end to end to the common iliac artery, and the left limb end to side to the external iliac artery after ligation of the common iliac stump below the aneurysm. Occlusion time to the right leg was 35 minutes and to the left 50 minutes. The total operating time was 2 hours 10 minutes. Using this technique it was not necessary to mobilize the kidney from the aneurysm and the isthmus did not require division. The patient had an uneventful recovery and has remained well. His hypertension has settled to 160/100 without hypotensive therapy.

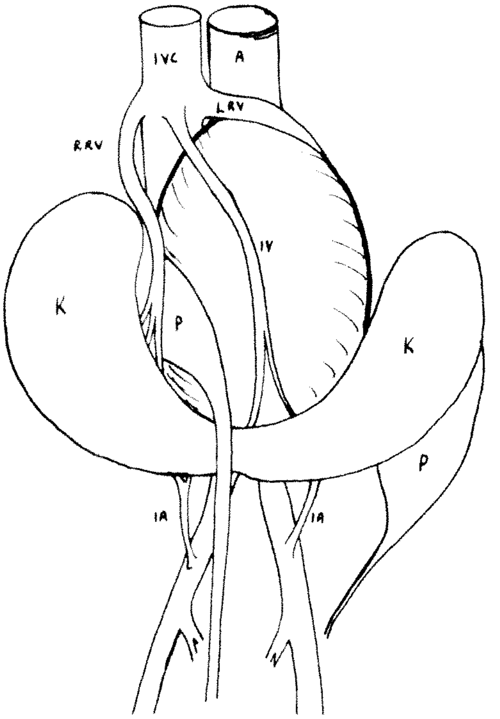

FIG. 4.—Diagrammatic representation of the operation findings in *Case* 2. The renal arteries were behind the aneurysm on the left side and behind the vena cava on the right side. IVC, Inferior vena cava. IV, Isthmic vein. A, Aorta. RRV, Right renal vein. LRV, Left renal vein. K, Kidney. P, Pelvis. IA, Isthmic artery.

Case 2.—A 75-year-old man presented with anorexia and weight-loss. There were no other symptoms or any past history of cardiovascular disease. On examination there was marked pallor, a large, pulsatile, mid-abdominal mass, 16 cm. in diameter, and normal peripheral pulses in both legs. There were no bruits. The patient was admitted to hospital for assessment for aneurysm replacement.

Investigation revealed a hypochromic, microcytic anaemia with a haemoglobin level of 50 per cent. Examination of the stool for occult blood proved positive and barium studies of both the upper and lower alimentary tract revealed diverticulosis coli. A horse-shoe kidney was seen on I.V.P. and a subsequent aortogram showed a large aneurysm of the abdominal aorta below the level of two renal arteries (*Fig.* 3 A, B). The blood-urea was 28 mg. per 100 ml.

The anaemia was considered to be due to poor diet combined with bleeding from diverticulosis coli and it responded well to iron therapy. Replacement of the abdominal aorta was undertaken on 21 June, 1971.

As in the first case the operation findings were not as expected from the radiological appearances (*Fig.* 4). The aneurysm was confined to the aorta. A large isthmic vein crossed the aneurysm to the inferior vena cava. In addition to two renal arteries at the normal site there were two isthmic arteries each arising from the corresponding common iliac artery and not suspected from the aortogram. A vein from the isthmus accompanied each of these vessels and drained into the common iliac vein. Two ureters descended to the bladder in front of the isthmus. The renal substance appeared normal and there were no palpable calculi.

The aortic aneurysm was isolated by clamping the aorta below the level of the renal arteries and each common iliac artery proximal to the origins of the isthmic arteries. The technique used was as in the first case except that it was possible to place a tube graft within the aneurysm, the lower end being sutured to the aortic bifurcation. The isthmic arteries were preserved. Occlusion time to both legs was 40 minutes and the total operating time was 3 hours. Again, it was not necessary to mobilize the kidney from the aneurysm and the isthmus did not require division. The patient had an uneventful recovery and has remained well.

Case 3.—A 68-year-old man had been noted to have a large abdominal aortic aneurysm when he had suffered a left hemiplegia 2½ years previously. The aneurysm had increased in size over the month before consideration for operation and had been accompanied by abdominal discomfort and tenderness of the sac. Rupture was considered to be imminent. On examination he was a frail man with a mild residual left hemiplegia. There was a large, pulsatile, central abdominal mass and all his peripheral pulses were present.

Investigation by high lumbar aortography and intravenous and retrograde pyelography confirmed that he had a large aortic aneurysm and revealed a horse-shoe kidney with some small radiolucent calculi in the left renal pelvis. The renal arteries seemed normal in their site of origin.

The findings were again not accurately predicted by investigation. Three isthmic veins and two small isthmic arteries were associated with the common iliac vessels. There was no isthmic vein draining proximally in this case and large renal vessels connected fairly normal renal hila to the aorta and inferior vena cava at the normal anatomical level and just proximal to the aneurysm.

It was necessary to divide the small isthmic vessels to obtain access to the distal extremity of the aneurysm. The kidney was then lifted up like an apron to expose the anterior surface of the aneurysm. The aorta and common iliac arteries were controlled, the aneurysm opened, and a Dacron tube graft was then sutured within the aortic lumen. The patient's postoperative course was stormy but he survived the procedure and his renal function remained good.

DISCUSSION

Because the horse-shoe kidney embraces the abdominal aorta and may present as an apparently pulsatile mid-abdominal mass, and because the presence of a horse-shoe kidney may not be suspected in a patient with an obvious aneurysm a clinical diagnosis of an aortic aneurysm and horse-shoe kidney is unlikely. Such a diagnosis can be made accurately only on radiology or at operation. Indeed, of the 18 cases reported in the literature, a clinical diagnosis was not made in any, a radiological diagnosis was made in 9 cases, and an operative diagnosis in 9 cases. In the 3 patients reported here a clinical diagnosis was not made. Routine I.V.P. established the presence of a horse-shoe kidney and subsequent aortograms confirmed renal arteries arising from the aorta above the aneurysm, indicating operability of the aneurysm with preservation of at least some renal blood-supply. However, owing to inadequate demonstration of distal additional arteries and anomalous venous drainage the technique for aortic replacement was of necessity decided at operation.

Our investigation of patients with aortic aneurysms normally includes intravenous pyelography but not lumbar aortography. An aortogram was, however, obtained in these patients because of the presence of a horse-shoe kidney. Nevertheless, preoperative assessment of the problems involved was difficult and inaccurate. Scott and others (1969) have stressed the importance of both intravenous pyelography and aortography in these patients. We agree with this, but add that the operative technique cannot always be planned accurately on the basis of these investigations and can be defined only after exposure at operation. Minken and Rob (1967) have pointed out that the renal blood-supply must be demonstrated at operation to ascertain the resectability of the aneurysm. They have also shown in their case the value of preoperative aortography in demonstrating renal arteries which could not be found by dissection.

Since the precise anatomy is unlikely to be established before operation, it is essential to spend time and care in defining the vascular supply of the kidney and especially the anatomy of the drainage system of the horse-shoe kidney. The danger of infection around the prosthetic graft in the event of a urine leak demands exposure of the drainage systems in the entire operative field to avoid inadvertent damage of a ureter or pelvis, and since the intrarenal caliceal pattern may also be distorted, division of the isthmus should be avoided if at all possible to obviate the danger of caliceal damage. Additional vessels of supply to the kidney should be preserved either by selective clamping (as in *Case* 2) or by reimplantation of large vessels from the aneurysm into the graft using the Carrell-patch technique. Smaller vessels from the aneurysm may be sacrificed provided, as in *Case* 3, that there is a major arterial supply arising above the aneurysm, but if the vessels sacrificed have not already been occluded by atheroma some degree of renal ischaemia is to be expected. We would recommend the technique of grafting described in *Cases* 1 and 2 whenever possible because it eliminates the need for division of the isthmus and greatly decreases the operating time, a factor which we believe is important in the postoperative recovery of the patient.

THE DIAGNOSIS OF PARATHYROID OVERACTIVITY IN A POPULATION OF RENAL STONE FORMERS

By ROY SCOTT, FRANCES DRYBURGH, ROBERT WILSON, IAN T. BOYLE, and DAVID POLLOCK*

ROYAL INFIRMARY, GLASGOW

SUMMARY

In recent years most cases of primary hyperparathyroidism have been revealed as a result of 'metabolic screening' of patients with renal calculi. It is recognized that elevation of serum calcium is the single most important finding in such cases (Keating, 1961; McGeown, 1961; Boonstra and Jackson, 1962; Dent, 1962; Oakland, 1963). However, in primary hyperparathyroidism the serum calcium may be minimally elevated or may fall within the normal range (McGeown and Bull, 1957; Kyle, Schaaf, and Canary, 1958; Pyrah, Raper, and Smith, 1958; Nordin, 1962; Hodgkinson and Edwards, 1963; Parfitt, Higgins, Nassin, Collins, and Hilb, 1964), and because of this observation further evidence of parathyroid overactivity is necessary in assessing patients with renal calculous disease. Such evidence may be obtained by measurements of phosphate handling by the kidneys.

The present study was undertaken to define the practical value of correlating various parameters of calcium and phosphorus metabolism on a large outpatient population of renal stone formers.

---

* Present address: 'The Ridge', 26 Radbrook Road, Shrewsbury.

MATERIALS AND METHODS

The conditions of the biochemical screening are essentially those of Nordin and Smith (1965) except that the patient is fasted overnight. The patient is asked to report to the ward at 8.30 a.m. and a 4-hour collection of urine is undertaken. To promote a urine flow 100 ml. of water are given hourly, and at approximately the mid-point of the collection period a sample (25 ml.) of venous blood is withdrawn without occlusion. On completion of the test the patient is given a meal and can then return home or to the place of employment. Ward patients with marginal or frankly abnormal results have the biochemical screening repeated as indicated. The routine is similar to that for the group of out-patients and a few patients proceeded to more extensive tests, such as the phosphate deprivation test, ^{47}Ca uptake, the cortisone-suppression test, etc. Serum samples are analysed by standard laboratory techniques for calcium, inorganic phosphate, alkaline phosphatase, proteins, creatinine, urea, sodium, potassium, chloride, CO$_2$ content, uric acid, and magnesium. Urine was analysed for calcium, urea, phosphate, and creatinine.

Table I.—ANALYSES OF THE INITIAL METABOLIC SCREENING IN 205 CONSECUTIVE STONE FORMERS

RESULT OF SCREENING	MALE	FEMALE	TOTAL
Total No. screened	111	94	205
Hypercalcaemia	25	14	39
Parathyroid tumour	3	2	5

Male	18	10·4–13·4	8·9–70·5	70·7–97·0	−0·08–+0·17	1·5–3·6
Female	10	10·4–11·0	4·8–13·5	82·0–95·5	−0·07–+0·05	2·7–3·5

Key to abbreviations: Ca, serum calcium; Cp, phosphate clearance; T.R.P., tubular resorption of phosphate; P.E.I., phosphate-excretion index; Mg. P. per cent, mg. of phosphate reabsorbed per 100 ml. glomerular filtrate.

RESULTS

The findings in 205 consecutive out-patients investigated in the year 1968 are shown in *Table I*. Hypercalcaemia was found in 25 male and 14 female patients (range: male, 10·4–13·6 mg. per cent; female, 10·3–12·6 mg. per cent).

Correlating the radiological evidence of calculus formation with the biochemical parameters related to the calculated indices of phosphate excretion (viz.: the phosphate clearance, percentage tubular reabsorption of phosphate, the phosphate-excretion index, and the mg. of phosphate reabsorbed per 100 ml. of glomerular filtrate) it was obvious that 3 male and 2 female patients had unequivocal evidence of hyperparathyroidism. These were proved by the removal of a parathyroid adenoma at operation. The range of the various parameters under consideration in 28 patients with hypercalcaemia who were not explored is shown in *Table II*.

In each of these patients the screening was repeated on at least two occasions or repeated calculations of the serum calcium failed to show a sustained hypercalcaemia. Some patients, nevertheless, have had a recurrent stone problem and further metabolic studies including phosphate-deprivation tests and steroid-suppression tests were undertaken. However, no patient's clinical state by itself has been severe enough to warrant an exploration for possible parathyroid overactivity. Included in these studies are five phosphate-deprivation studies which have *not* provided conclusive evidence of parathyroid overactivity.

The results of the first screening in 6 patients are shown in *Table III*. When the test was repeated some patients showed a minimal hypercalcaemia and the phosphaturia persisted. Despite equivocal phosphate-deprivation tests in all 6 patients it was decided that exploration was justifiable.

As can be seen in *Table III*, on the initial biochemical screening all of these patients had calcium levels which fell within the equivalent ranges of a group of blood donors. Apart from normal or minimal hypercalcaemia, all of these patients had an elevation of the phosphate-excretion index and a reduction of the mg. of phosphate reabsorbed per 100 ml. of glomerular filtrate. Male patients 1 and 2 did not have a demonstrable cervical adenoma and following operation have not shown any further clinical or biochemical problems. Female patient 1 had hyperplasia of two parathyroid glands. Male patient 3 was not explored because he had a severe degree of aortic stenosis and was considered to be unfit for a general anaesthetic. Male patient 4 and female patient 2 each had a parathyroid adenoma removed from one cervical parathyroid gland.

Table III.—RESULTS OF FIRST BIOCHEMICAL SCREENING IN 6 PATIENTS WITH NORMAL OR MINIMAL HYPERCALCAEMIA AND PHOSPHATURIA

SEX AND PATIENT	SERUM		URINE			
	Ca	Phos	Cp	T.R.P.	P.E.I.	Mg. P. Per cent
Male 1	10·6	2·4	23·7	77·1	+0·17	1·9
Male 2	10·8	2·0	21·5	79·0	+0·17	1·6
Male 3	10·8	2·0	25·0	67·0	+0·29	1·34
Male 4	10·0	2·6	59·0	71·0	+0·13	1·8
Female 1	10·6	1·7	7·0	88·0	+0·10	1·50
Female 2	10·8	2·2	18·7	76·8	+0·18	1·70

See Table II for key to abbreviations; Phos, serum inorganic phosphate.

Control Subjects.—A group of 16 male and 7 female laboratory staff was submitted to the 'routine' metabolic screening. No person in this group gave any history which might suggest a renal calculus and all were found to have normal calcium and phosphorus parameters. *Table IV* shows the range of the various calcium and phosphorus parameters measured.

Table IV.—RANGE OF VALUES IN CONTROL SUBJECTS (LABORATORY STAFF)

PATIENT	NO. OF PATIENTS	Ca	Cp	PERCENTAGE T.R.P.	P.E.I.	Mg. P. PER CENT
Male	16	8·1–10·4	6·3–16·5	82·4–94·2	0·07–+0·08	2·3–3·8
Female	7	9·1– 9·4	7·0–13·0	84·9–93·3	0·06–+0·00	2·9–3·4

See Table II for key to abbreviations.

Table V.—RANGE OF VALUES FOUND IN PATIENTS WITH PROVED PARATHYROID LESIONS (FIRST BIOCHEMICAL SCREENING)

PATIENT	Ca	Cp	PERCENTAGE T.R.P.	P.E.I.	Mg. P. PER CENT
Male	10·0–13·6	16·2–59·0	66·8–81·0	+0·13–+0·25	1·3–1·8
Female	10·0–12·2	7 –19·3	72 –78	+0·10–+0·26	1·3–1·7

See Table II for key to abbreviations.

Table VI.—CALCIUM VALUES FOR A GROUP OF BLOOD DONORS

PATIENTS	NO. OF PATIENTS	SERUM CALCIUM LEVEL		95 PER CENT LIMITS		
		Mean	S.D.	Lower	Upper	Range
Total	243	9·53	0·43	8·7	10·4	8·5–10·8
Male	145	9·52	0·41	8·7	10·4	8·7–10·7
Female	68	9·45	0·38	8·7	10·2	8·5–10·8

The corresponding results for the group of patients who were found to have parathyroid lesions are shown in *Table V*.

Comparison of Serum Calcium Levels in Stone Formers and in Control Subjects.—In order to assess the significance of hypercalcaemia a comparison has been made between the non-hypercalcaemic group of stone formers and a group of non-stone formers matched for age and sex.

Table VI shows the results as obtained in a group of blood donors who did not give any history suggestive of renal calculous disease. *Table VII* shows the comparison between the group of stone formers who were non-hypercalcaemic and the blood donors when matched for age and sex.

DISCUSSION

In order to prevent recurrence of stone disease (Twinem, 1937; Williams, 1963; Sutherland, 1964) it has been emphasized that intensive study of the metabolism of the individual patient with a calculus is more likely to be of practical value than epidemiological surveys (Prien and Frondel, 1947). Harrison (1959) stated that insufficient metabolic screening was undertaken in stone formers and this has been emphasized as recently as 1968 (Leading Article, *British Medical Journal*). Perhaps the reason for this is the wide variety of metabolic factors which have to be considered (Rose, 1968). Many authors including Hellstrom (1953) have stressed the serious effects of delay in diagnosing parathyroid overactivity in stone formers. When the greatest effort is directed towards the uncovering of this latter condition the incidence of parathyroid overactivity has been found to range from 2 to 22 per cent in various series (Beard and Goodyear, 1950; Baker and Connelly, 1956; McGeown and Montgomery, 1956; Hodgkinson and Pyrah, 1958; Melick and Henneman, 1958; Harrison, 1959; Litin, Diessneig, and Keating, 1961).

Table VII.—COMPARISON OF SERUM CALCIUM LEVELS IN STONE FORMERS AND IN CONTROL SUBJECTS

PATIENTS	AGE-GROUP (years)	STONE FORMERS			NON-STONE FORMERS		
		No.	Mean	S.D.	No.	Mean	S.D.
Normocalcaemic male	18–20	2	9·8	0·28	33	9·69	0·40
	21–30	8	9·6	0·34	49	9·60	0·42
	31–40	23	9·6	0·38	16	9·40	0·34
	41–50	20	9·5	0·57	13	9·58	0·47
	51–60	25	9·6	0·44	11	9·32	0·38
	61+	16	9·4	0·77	2	9·25	—
Normocalcaemic female	18–20	2	9·7	0·42	20	9·51	0·43

	31–40	14	9·3	0·61	7	9·44	—
	41–50	15	9·5	0·39	13	9·48	0·28
	51–60	18	9·6	0·51	6	9·47	—
	61+	10	9·1	0·86	—	—	—

If simple elevation of the serum calcium was all that was necessary to make the diagnosis of hyperparathyroidism then there would be no problem. Serum calcium can become elevated by conditions other than parathyroid overactivity, e.g., sarcoidosis, malignancy, thyrotoxicosis, multiple adenomatosis, and myeloma (Henneman, Demsey, Carrol, and Allbright, 1956; McGeown and Montgomery, 1956; Frei, Bentlel, Riesalbach, and Block, 1963; Goldsmith and Ingbar, 1966; Kerr and Smith, 1967; Anderson, Cooper, and Naylor, 1968; Dent and Watson, 1968; Buckle, Mason, and Middleton, 1969). In none of our patients with hypercalcaemia was there any evidence to suggest that any of the above causes was present. In addition to routine clinical screening, all the patients had a check of the erythrocyte sedimentation rate which was used as a non-specific method of revealing any gross pathology. Laboratory error, which is a possible cause of 'hypercalcaemia', must always be considered along with the clinical technique of withdrawing venous blood for biochemical estimations.

Estimation of urinary calcium values is not of value in making a definitive diagnosis because any of the above causes as well as idiopathic hypercalciuria can be associated with elevation of the urinary calcium output (Allbright, Henneman, Benedict, and Forbes, 1953; Henneman, Boweaccy, Forbes, and Dudley, 1958; Edwards and Hodgkinson, 1965; Chambers and Dormandy, 1967; Boyce, Garvey, and Goven, 1968; Bulusi, Hodgkinson, Peacock, and Nordin, 1970). It has become customary to relate serum calcium levels to certain measurements of phosphate excretion in the biochemical diagnosis of parathyroid tumour. It is necessary that such estimations be measured with the patient in hospital on a standard diet. Great difficulty arises in the interpretation of the different measurements of phosphate excretion in the urine (Yendt and Janorski, 1961; Wills, 1970).

That parathyroid hormone reduces the ability of the renal tubule to reabsorb phosphorus from the urine is undisputed, and because of this various authors have used the degree of phosphaturia as a measure of parathyroid overactivity. In 1953 Sirota showed the effect of removing a parathyroid adenoma on the tubular reabsorption of phosphate and in 1954 Schaaf and Kyle introduced the concept of measuring the percentage tubular reabsorption of phosphate as an indication of parathyroid overactivity. This parameter, however, varied according to the dietary phosphate and the degree of renal failure in addition to the effect of the parathyroid hormone. To overcome these difficulties Thomas, Connor, and Morgan (1958) introduced the clinical concept of measuring the actual mg. of phosphate reabsorbed per 100 ml. of glomerular filtrate. Kyle and others (1958) emphasized the value of measuring the total phosphate clearance as a measurement of phosphate excretion in making the diagnosis of parathyroid overactivity.

Another factor which causes problems in interpreting phosphaturia is that serum inorganic phosphate levels cause variations in the amount filtered across the glomeruli and the latter occurs in direct relationship to the former. To allow for this variable Nordin and Fraser (1956) introduced the mathematically derived phosphate-excretion index (P.E.I.), which allows a comparison of the relationship between serum inorganic phosphorus and tubular reabsorption of phosphate in the patient with the same relationship in a series of normal control subjects.

The reasons for such a multiplicity of estimations of phosphate excretion are that the degree of phosphaturia varies according to the phosphate intake, the vitamin-D intake, and renal function. To compensate for these factors and for the rate of glomerular filtration, or the effects of serum inorganic phosphate on the various indices, each of the authors cited devised a different index as a measurement of the parathyroid hormone control of tubule handling of phosphate. In addition there are more complicated tests based on either phosphate loading (Hyde, Jones, McSwiney, and Prutney, 1960; Anderson, 1964) or phosphate deprivation (Chambers, Gordan, Goldman, and Reifenstein, 1956).

These derived indices of phosphate excretion use essentially the same biochemical data, namely serum inorganic phosphorus and creatinine together with the coincident urine phosphate and creatinine excretion.

Considerable scepticism and doubt as to the value of these various phosphate indices exist (Hodgkinson and Pyrah, 1958; McGeown, 1961; Dent, 1962; Edwards and Hodgkinson, 1965), and these authors emphasize the value of an accurate estimation of serum calcium after meticulous withdrawal of a venous specimen.

In terms of economics and practical realities we feel that, while agreeing with the indubitable evidence of accurate and repeated estimations of serum calcium levels in making the diagnosis of hyperparathyroidism in a renal stone population, the index of suspicion can be greatly increased by the scheme outlined above. In addition, such screening can act as a means whereby only those requiring more detailed study are admitted to metabolic wards. This is important to the patient and to the use of beds in the hospital concerned.

Before submitting the patient to complicated procedures such as calcium-infusion tests (Kyle, Schaaf, and Erdman, 1954; Pronove and Bartter, 1961), steroid suppression of calcium (Dent, 1962), ^{45}Ca uptake studies (Cannigia, Genmari, and Cesari, 1965), and assay of parathyroid hormone (Buckle, 1969) some form of preliminary screening is essential if these complicated procedures are to yield the maximum information.

Examination of our figures shows that the suspicion of parathyroid overactivity in a renal stone former is greatly increased if the phosphate parameters are scrutinized, especially in those patients who are normocalcaemic or who have a mininally elevated serum calcium. We feel that repeated serum calcium estimations should inevitably reveal parathyroid overactivity but early diagnosis minimizes the urinary stone problem and also the systemic effects of parathyroid overactivity such as hypertension.

In addition, a considerable base-line knowledge of renal function is available for each individual patient and in the total management of a patient with a renal stone problem may serve as a guide in determining the surgical management of problems arising from the stone itself. It was not appreciated at the outset that the procedure could also be used to 'screen out' patients with hypercalcaemia who did not require exploration for possible parathyroid overactivity, although such patients obviously require careful supervision on a long-term basis. This group is still being carefully assessed at regular intervals.

A final difficulty in the interpretation of serum calcium levels in stone formers is that the mean value for calcium is often higher than in non-stone formers matched for age and sex (*Table VII*). This is invariably the case with males, with a progressive fall with age which is less obvious in the female population.

The clinical diagnosis of hyperparathyroidism, particularly when hypercalcaemia is minimal, causes considerable difficulties. Despite the galaxy of laboratory tests available, Strott (1968) suggested that the decision to submit a patient for operation for a possible parathyroid lesion should be dictated by the signs, symptoms, and prognosis rather than by the laboratory investigations. We disagree with this outlook. While the patient's clinical state is a very important guide to therapy, laboratory findings must not be ignored and early screening of patients with renal calculi for hyperparathyroidism should be as comprehensive as the scheme outlined here.

Acknowledgements.—We are very grateful to the resident medical staff and nursing staff of the Royal Infirmary, Glasgow, who supervised the collection of specimens. We are also deeply indebted to Mr. I. McLennan who undertook the surgical explorations. The work could not have been completed without the technical assistance of the staff of the Biochemistry Department. We are also indebted to Professor Morgan who supervised and criticized the text and also to Dr. Morgan who obtained the specimens from the Blood Transfusion Services. Lastly we are very grateful for the secretarial work undertaken by Miss Ann McKellar.

THE EFFECT OF THE FIBRINOLYTIC INHIBITOR EPSILON-AMINOCAPROIC ACID ON THE INCIDENCE OF DEEP-VEIN THROMBOSIS AFTER PROSTATECTOMY

By I. C. GORDON-SMITH, J. A. HICKMAN, and S. H. EL MASRI
THE DEPARTMENT OF SURGICAL STUDIES, THE MIDDLESEX HOSPITAL, LONDON

SUMMARY

Sixty-two patients undergoing retropubic prostatectomy were examined for evidence of deep-vein thrombosis using the ^{125}I-fibrinogen technique. Patients were allocated randomly into two groups. The first group was given the fibrinolytic inhibitor epsilon-aminocaproic acid (EACA) during the perioperative period, while the second group of patients acted as a control. The administration of EACA did not increase the incidence of deep-vein thrombosis after prostatectomy. This finding is discussed together with the possible role of the fibrinolytic system in postoperative venous thrombo-embolic disease.

It has been demonstrated that the synthetic inhibitor of fibrinolytic activity epsilon-aminocaproic acid (EACA) reduces blood-loss following prostatectomy (McNicol, Fletcher, Alkjaersig, and Sherry, 1961a; Andersson, 1962; Sack, Spaet, Gentile, and Hudson, 1962; Vinnicombe and Shuttleworth, 1966a). This effect is considered to be a result of the inhibition of the urinary fibrinolytic enzyme urokinase which, after prostatectomy, digests clot forming in the prostatic bed, thus promoting haemorrhage. If given in larger doses EACA also inhibits systemic fibrinolysis and it has been claimed that this may reduce blood-loss further (Ladehof and Otte, 1963). In fact, many published studies employed EACA in larger doses. It has been suggested, however, that the administration of EACA carries the risk of inducing intravascular thrombosis. McNicol and Douglas (1964) have recommended that this drug should not be used as routine prophylactic treatment after prostatectomy, but should be reserved for patients in whom protracted haematuria is presenting a major problem.

Although a number of studies have failed to demonstrate an increased risk of deep-vein thrombosis in association with EACA, these were based on clinical evidence (Andersson, 1962; Vinnicombe and Shuttleworth, 1966b), which is now known to be inaccurate, or on isolated phlebography 2 weeks after operation (Becker, Borgstrom, and Saltzman, 1970). With the introduction of the ^{125}I-fibrinogen technique for the accurate detection of deep-vein thrombi it was decided to reinvestigate the risk of using EACA routinely at prostatectomy.

MATERIALS AND METHODS

Sixty-two patients, all aged over 50 years, undergoing retropubic prostatectomy with general anaesthesia were studied. Patients were allocated randomly to one of two groups. Thirty patients with even ages received EACA (treated group), while the remaining 32 acted as controls (control group). The age and weight distribution of the two groups was similar. The mean age of the treated group was 66·5 years (S.D. ± 6·7) and the mean weight was 72·7 kg. (S.D. ± 11·4). In the control group the mean age was 67·6 years (S.D. ± 7·7) and the mean weight was 70·9 kg. (S.D. ± 10·6).

EACA Régime.—Patients in the treated group were given 6 g. of EACA orally 5 hours before operation, followed by the intravenous infusion of 6 g. during operation, and a further 6 g. commencing 5 hours after the end of operation and continuing for 6 hours. Thus, a total of 18 g. was given over an 18-hour perioperative period.

Table I.—INCIDENCE OF THROMBO-EMBOLISM IN THE EACA-TREATED AND IN THE CONTROL GROUPS

GROUP	NO OF PATIENTS	DEEP-VEIN THROMBOSIS		PULMONARY EMBOLISM	
		No.	Per cent	No.	Per cent
Control	32	9	28	1	3
Treated	30	9	30	2	6

Detection of Deep-vein Thrombosis.—Patients were examined for evidence of deep-vein thrombosis using the ^{125}I-fibrinogen technique (Atkins and Hawkins, 1965). After operation each patient received intravenously 0·7 mg. fibrinogen containing approximately 100 µc. ^{125}I. This material was prepared by the Lister Institute from a pool of five donors who were accredited as free of the hepatitis carrier state by Regional Blood Transfusion Centres. This was based on follow-up of recipients of their previous donations of plasma or whole blood and by examination for the presence of the Australia antigen. Iodination was carried out at the Radiochemical Centre, Amersham, Bucks.

Counting was performed on the first, second, fourth, and sixth postoperative days, and beyond this period if there was any evidence of deep-vein thrombosis. A Pitman Isotope Localization Counter, Model 235, was used to count the medial surface of each thigh and calf at 10-cm. intervals with the legs elevated to 15° to obviate venous pooling.

The criteria for diagnosis of a deep-vein thrombus were those suggested by Negus, Pinto, Le Quesne, Brown, and Chapman (1968).

Measurement of Fibrinolytic Activity.—Blood-samples were taken from 27 patients, employing minimal haemostasis, within 30 minutes of the end of the operation. A second sample was taken from 25 patients on the first postoperative day. Fibrinolytic activity was measured by the whole-blood lysis time (WBLT) (Fearnley, Balmforth, and Fearnley, 1957), modified in that an acetate citrate diluent was used (Gallimore and Shaw, 1968), and each component of the test was increased by a factor of 2·5. Thus, each sample contained 0·5 ml. of blood diluted in 4·25 ml. of buffer and 0·25 ml. of thrombin solution. An acetate citrate diluent was used since it has been shown to increase the rate of *in vitro* fibrinolysis and is considered to enable greater accuracy in end-point determination (Gallimore, 1967). Individual samples were set up in triplicate and the mean lysis time was recorded.

RESULTS

Incidence of Deep-vein Thrombosis.—There was no significant difference between the two groups in the incidence of thrombo-embolic episodes (*Table I*). Of the 18 patients diagnosed as having deep-vein thrombosis, 16 had isotopic evidence of their thrombosis within 48 hours of operation and no thrombus was detected later than the fourth postoperative day. Two patients died: 1 in the treated group from massive pulmonary embolism, and 1 in the control group from myocardial infarction. The cause of death in each case was confirmed at post-mortem examination.

Fibrinolytic Activity.—The results of lysis-time estimations were plotted on a logarithmic scale (*Fig.* 1), in view of the known exponential relationship of the WBLT to fibrinolytic activity (Sherry and Alkjaersig, 1957; McNicol, Fletcher, Alkjaersig, and Sherry, 1961b). There was a relative inhibition of fibrinolytic activity within 30 minutes of operation in the treated group when compared with the control group and this was significant ($P<0{\cdot}005$). Even so, in the treated group the fibrinolytic activity was still significantly enhanced as compared with preoperative levels in resting patients of similar age (mean, 63·4 years, S.D. ± 7·3) and weight (mean, 65·4 kg., S.D. ± 15·4) ($P<0{\cdot}05$).

DISCUSSION

Various régimes have been suggested for the administration of EACA to patients undergoing prostatectomy (McNicol and others, 1961b; Andersson, 1962; Vinnicombe and Shuttleworth, 1966a; Kirkman, 1967). It has been demonstrated (McNicol and others, 1961b) that EACA is concentrated in the urine to levels up to a hundred times the concentration in the plasma. It is therefore theoretically possible to give a dose sufficient to inhibit urinary urokinase without inhibiting the fibrinolytic activity of

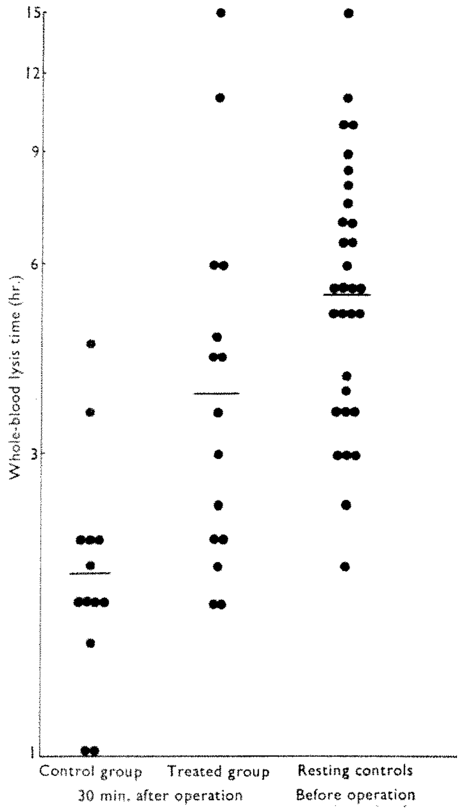

FIG. 1.—Fibrinolytic activity in the control and in the treated groups within 30 minutes of operation compared with that in resting preoperative patients. The treated group shows significantly less activity than the control group ($P<0{\cdot}005$) and significantly more activity than the preoperative levels ($P<0{\cdot}05$).

Table II.—RÉGIMES OF EACA ADMINISTRATION REPORTED IN THE LITERATURE

AUTHORS	EACA DOSE				
	Preoperative	During Operation	Postoperative	Perioperative*	Total Dose
Ladehof and others (1963)	6 g. i.v. in 30 min.	Nil	6 g. i.v. then 6 g. orally 6-hourly	18 g.	96 g.
Kirkman (1967)	5 g. orally then 6-hourly for 24 hours	Nil	5 g. orally 6-hourly	15 g.	80 g.
Vinnicombe and Shuttleworth (1966a)	Nil	0·5 g. i.v. per hour	0·5 g. i.v. hourly	6 g.	6 g.
Becker and others (1970)	Nil	5 g. i.v.	5 g. i.v. 6-hourly, then 3 g. orally 6-hourly	15 g.	148 g. (mean)
Andersson (1962)	Nil	0·1 g. per kg. i.v.	0·1 g. per kg. i.v. 6-hourly	21 g.	51 g. (mean)
McNicol and Douglas (1964)	Nil	Nil	1 g. per hr. for 4 hr, then 0·5 g. per hr. for 4 hr.	8 g.	8 g.
Present study	6 g. orally	6 g. i.v.	6 g. i.v.	18 g.	18 g.

* Total dose over 24 hours period commencing 6 hours before operation.

the blood. In fact many of the suggested régimes (Andersson, 1962; Ladehof and Otte, 1963; Kirkman, 1967) employ doses higher than is necessary solely to inhibit fibrinolysis in the urine. The aim of these régimes is to maintain a high urinary excretion of EACA and in some instances, actually to inhibit blood fibrinolytic activity as well (Ladehof and Otte, 1963). A review of some of the published dose régimes is given in *Table II*. The régime chosen in this study was of intermediate dosage, and administration was confined to the perioperative period, as it is during this time that the majority of deep-vein thrombi develop (Kakkar, 1969; Lambie, Mahaffy, Barber, Karmody, Scott, and Mathieson, 1970).

No significant increase in the incidence of deep-vein thrombosis was demonstrated in the group of patients which received EACA. This is in agreement with previous studies (Andersson, 1962; Vinnicombe and Shuttleworth, 1966b; Becker and others, 1970) in which the diagnosis of deep-vein thrombosis was based on less satisfactory criteria than the ^{125}I-fibrinogen technique employed here. This result does not support the argument that EACA should be withheld from routine use because of the risk of inducing intravascular thrombosis. However, it is possible that thrombi forming in the presence of circulating EACA would prove subsequently to be more resistant to lysis, and prone to propagation, than thrombi developing in untreated patients.

The effect of EACA on the fibrinolytic activity of blood is of interest in view of the possible relationship between the fibrinolytic system and venous thrombo-embolic disease. In the dosage used in this study EACA reduced significantly the marked enhancement of blood fibrinolytic activity which is the usual response to operation. Moreover this reduction in activity, which was demonstrated in samples taken within 30 minutes of operation, was present at a time when the majority of deep-vein thrombi are known to form. Despite this there was no increase in the incidence of deep-vein thrombosis, although it is true that the fibrinolytic activity of the treated group immediately after operation was still greater than that of preoperative resting patients. Therefore, having shown only a reduction in the enhanced activity induced by operation, it cannot necessarily be inferred that the fibrinolytic system is not involved in the pathogenesis of postoperative venous thrombosis. The precise relationship between fibrinolytic activity and venous thrombosis requires further evaluation by a specific study.

REPAIR OF THE LARYNGOPHARYNX AND CERVICAL OESOPHAGUS AFTER IRRADIATION

BY H. J. SHAW
HEAD AND NECK UNIT, THE ROYAL MARSDEN HOSPITAL, LONDON

SUMMARY

The present situation regarding the nature and treatment of cancer in this area is given. Types of defect and methods of repair, their complications, and the choice of methods are described. Emphasis is laid on the increased hazards of surgery for the patient after full dosage of irradiation. Treatment should be based on surgical resection, usually preceded by a modified plan of irradiation often completed after surgery.

In conclusion the most valuable recent advances in the techniques of surgical repair of the laryngopharynx and cervical oesophagus after irradiation and resection for cancer are the use of large regional skin-flaps from outside irradiated areas, and total pharyngo-oesophageal replacement by means of vascular pedicled gut segments.

ABOUT 98 per cent of malignant tumours of the laryngopharynx and cervical oesophagus are squamous carcinomas and 90 per cent are locally advanced when first diagnosed. In addition about 50 per cent of patients have regional metastases to the neck lymph-nodes on first attendance at hospital. It follows that cure rates by conventional means are unlikely to be high and therefore treatment should interfere with essential function as little as possible.

After many years of reliance on external irradiation as a principal means of attempting a cure it is now mainly acknowledged that radical resection of the primary lesion must form the basis of curative therapy though often combined with irradiation. Coupled with this are the proved policy of in-continuity resection of the regional lymphatics which are palpably or probably involved by disease and the concept of rapid restoration of function made possible by modern reconstructive surgery.

The roles of radiotherapy and sometimes chemotherapy are now felt to be as adjuncts to surgery usually by means of preoperative treatment with a carefully planned dosage régime. It has lately been shown that such combined treatment can certainly decrease local recurrences and modestly increase the cure rates in cancer of the mouth, pharynx, and larynx (Strong, Henschke, Nickson, Frazell, Tollefsen, and Hilaris, 1966; Ogura and Biller, 1970). The surgeon practising in this field will be constantly faced with the hazard of tissue devitalization added to the inevitable problems of healing of potentially infected wounds, the situation being frequently aggravated by the poor general medical status of these patients.

In fairness it must now be added that modern supervoltage or telecobalt irradiation does not damage normal tissues in the neck to anything like the degree that has been a constant feature with older methods and higher total doses, often through incorrectly planned fields. It should also be remembered that a properly modified preoperative course of about 4000 rad telecobalt therapy usually has little damaging effect on healing potential by itself, although the individual effects are often quite variable. However, the time interval is important; the greater the time between irradiation and surgery the greater are the probable healing difficulties.

Because of these factors weighing against the rapid healing of neck tissues undergoing surgery, the use of local flaps is restricted and the whole basis of repair is of necessity conservative and greatly dependent upon a good blood-supply imported with distant flaps or pedicled gut segments.

Despite such problems, the aim of repair for the cervical gullet remains early restoration of function with minimum of risk and hospitalization. Today the patient should be given this assurance.

TYPES OF DEFECT

Both primary and secondary defects must be considered; the majority are in the first group and quite simply may be small or large. Examples of the former include defects following lateral pharyngotomy for the uncommon small cancer of the lateral or posterior wall or the epilaryngeal region. Larger primary defects are usually created by total removal of the larynx with or without part of the pharyngeal wall. The largest defects are created by the total excision of the larynx, laryngopharynx, and part or all of the oesophagus. They are treated by immediate closure when possible; otherwise by secondary closure at an interval.

Most secondary defects are not inevitably caused by surgery but occur as a result of poor healing, usually with fistula formation and generally in the second or third week after resection with primary closure. They may be large or small and occur most frequently following a previous course of irradiation. Later secondary defects are generally due to the growth of residual primary tumour causing fistulous breakdown.

METHODS OF REPAIR

There are four main types of lining repair:—

1. Primary closure using local mucosa.
2. Reconstruction with pedicled skin-flaps.
3. Replacement with free skin-grafts or free gut transplants.
4. Replacement with vascular pedicled gut segments.

Primary Closure.—The majority of primary surgical defects in the wall of the pharynx or cervical oesophagus can be repaired satisfactorily by immediate suture at the time of resection. This method can be used successfully with all such defects, provided at least one-third of the circumference of the pharyngeal mucosa remains available for tubing. Where a defect exceeds this size or where it is judged that the tissues have been greatly devitalized by irradiation it will be necessary to create a temporary skin mucosal stoma for secondary closure.

Pedicled Skin-flaps.—Three tissue components are needed for secure closure of all fistulous defects in the gullet wall: lining, support, and cover. These can easily be provided by the use of pedicled flaps of local or distant skin. Sometimes the latter are backed on their deep surface with split-skin grafts as a lining to save time, or a local flap may be turned inwards to provide a lining and then receives split skin on the raw outer surface for cover. However, pedicled skin of local origin is more often used to provide a lining and cover, as in the Marion-Duplay technique adapted by Lewis (1965) or in the original method of Wookey (1942). Still more frequently used today if the local skin is in good condition are inturned adjacent 'trap-door' flaps for lining, while support and cover importing a good blood-supply are provided by means of large pectoral or shoulder transposition flaps (Gillies, 1957; Conley, 1960). Such a technique is certainly wiser and more effective after full therapeutic courses of irradiation. When correctly planned it does not require any delay and can give excellent functional results with rapid healing in two or three stages (Shaw, 1962). Any raw donor areas are immediately covered with split-skin grafts if the defect cannot be closed by direct suture (*Figs.* 1, 2).

Where the neck tissues are scarred and grossly devitalized it may be impossible to rely upon local skin as a 'trap-door' turnover for lining. In such a case distant pedicle skin, usually tubed, will be needed to provide all the anterior components (*Fig.* 3). Alternatively, with only slight risk, the damaged neck skin can be used for cover and a large deltopectoral skin-flap is then used for the lining, as in the two-stage Bakamjian (1965) technique (*Fig.* 4). However, in the former case, where complete resurfacing and anterior lining with distant skin and subcutaneous tissue is essential, one or two fully tubed acromiothoracic chest pedicles may be used. This is a lengthy procedure requiring four stages, though it can give excellent results for large defects (*Fig.* 5).

Free Skin-grafts.—Following Rob and Bateman's (1949) original report on the use of free split-skin grafting for the reconstruction of the trachea, a number of workers (Edgerton, 1952; Conley, 1953; Negus, 1953) developed a similar method using a primary split-thickness skin-graft carefully positioned around a hollow latex or wire mesh stent to replace the pharynx and cervical oesophagus (*Fig.* 6 A).

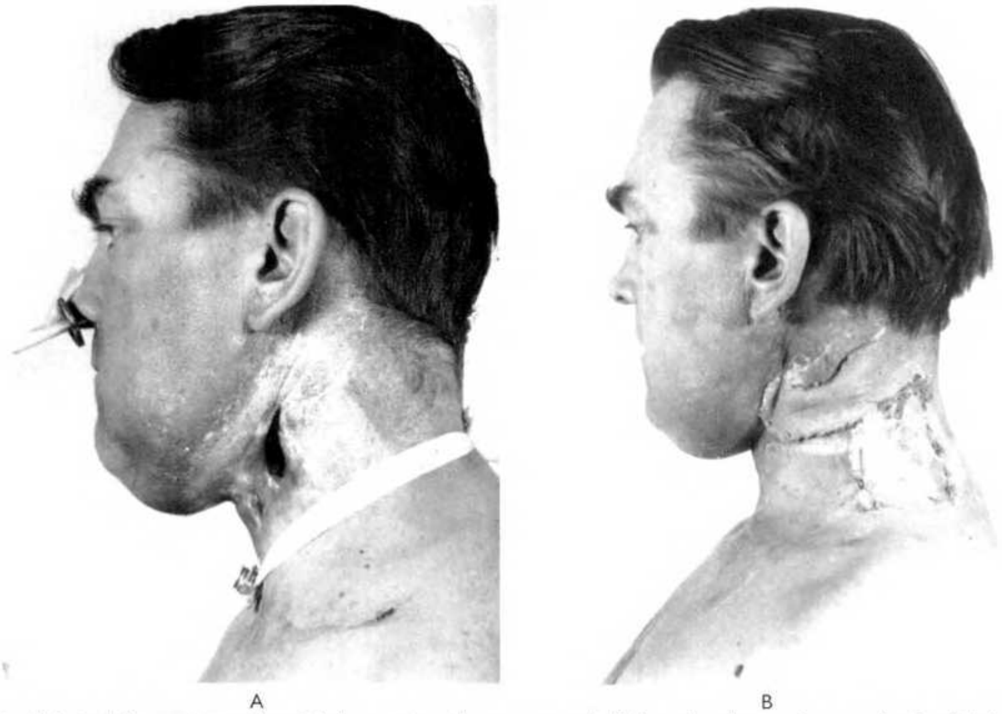

FIG. 1.—A, Lateral pharyngotomy with partial pharyngectomy (larynx conserved). B, Secondary closure using nape of neck pedicle for cover

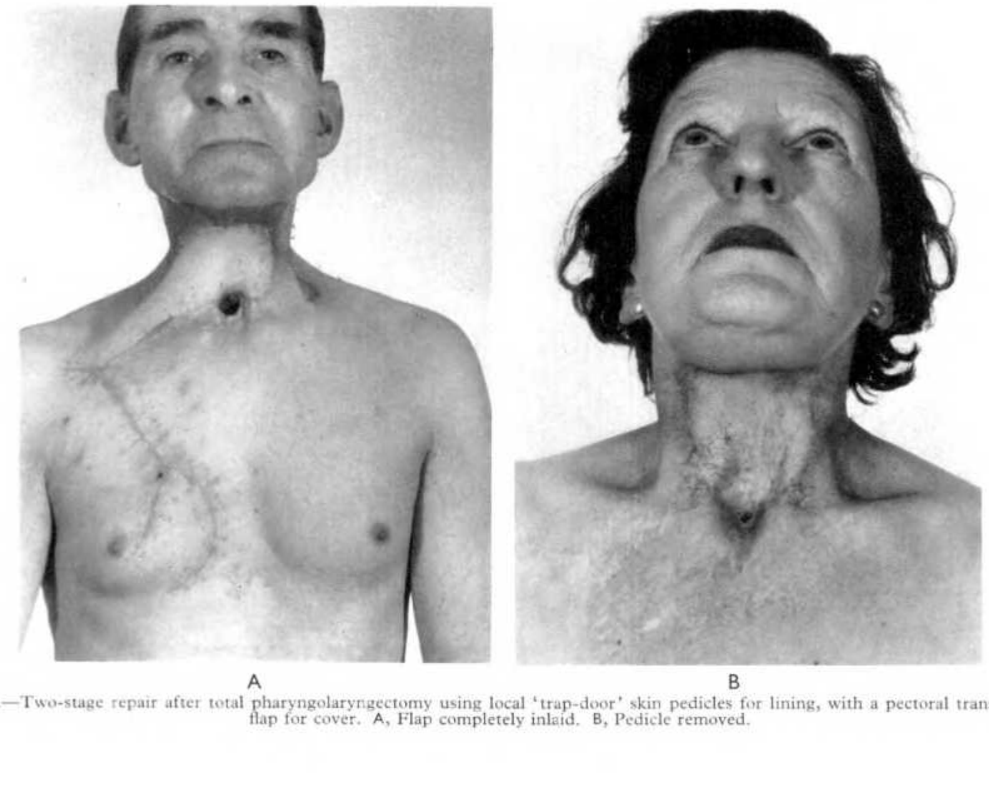

FIG. 2.—Two-stage repair after total pharyngolaryngectomy using local 'trap-door' skin pedicles for lining, with a pectoral transposition flap for cover. A, Flap completely inlaid. B, Pedicle removed.

Neck skin-flaps were used for cover and the stent was withdrawn through the mouth about 3 months later. The writer had personal experience of using this technique when it was first introduced. Providing the free skin-graft is carefully taken, followed by meticulous placement and suturing around the stent, it is possible to get good early functional results, the patients being permitted to swallow through the stent within 2 weeks of operation and often being out of hospital within 3 weeks. Despite such care, poor initial healing may occur and cause serious early complications in a small proportion of cases.

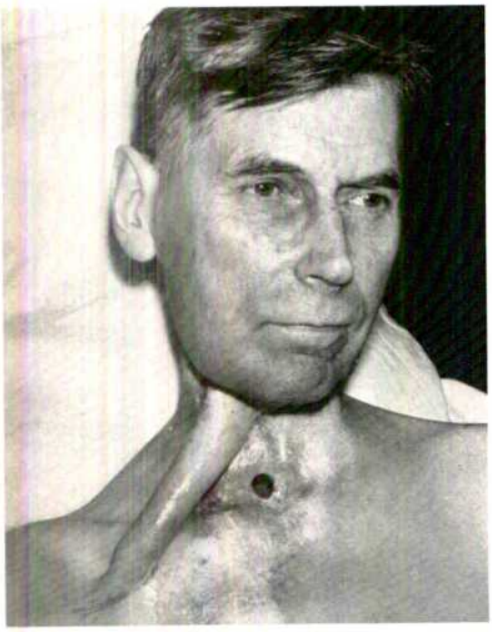
C



B

FIG. 3.—Partial pharyngectomy with total laryngectomy. Secondary closure using pectoral tubed pedicle flap for lining and cover.

However, the worse problem of intractable late stenosis of the graft usually at or close to the lower skin–mucosa junction in about one-half of the patients has caused the method to be abandoned (Shaw and Ormerod, 1957) (*Fig.* 6 B).

Kaplan and Markowicz (1964) and others have described the successful use in a few cases of a tube of whole-thickness penile skin, raw surface outwards, inserted as a free graft. Although intriguing, this has obvious sexual limitations and postoperatively is perhaps more hazardous than a split-thickness graft.

Free Gut Transplants.—The Nakayama technique of stapling small blood-vessels which was introduced in 1962 (Nakayama, Tamiya, Yamamoto, and Akimoto, 1962) has greatly aided the experimental work devoted to establishing a reliable means of grafting a completely excised segment of large or small bowel into the neck to replace a pharyngo-oesophageal defect (Seidenberg, Rosenak, Hurwitt, and Som, 1959; McKelvie, 1964; Jurkiewicz, 1965). Although some successful results have been reported in dogs and sheep, it has nevertheless proved extremely difficult to translate the method using the blood-vessels of middle-aged and elderly humans. Many practical problems have been reported; also it still involves anastomoses within the abdomen as well as in the neck.

Vascular Pedicled Gut Segments.—For the past 10 years adaptations of essentially old techniques (Kelling, 1911; Turner, 1936), using a fully vascularized pedicle to carry a segment of colon or stomach through the mediastinum and up into the neck, have been used with increasing success by a number of centres (Fairman, Hadley, and John, 1964; Le Quesne and Ranger, 1966; Harrison, 1969). The main reason for their revival has been dissatisfaction with the functional problems resulting from the delayed completion of skin-flap procedures coupled with new skill and knowledge in the use of transthoracic routes for the gut segments and vascular pedicles. Despite the fact that this is a serious operation by any standards, carrying at times a high, though falling, mortality, it has now become an

established method of treatment for extensive tumours of the cervical oesophagus, and gives good results if used in selected cases by a skilled team. Debate continues regarding the precise indications for its use; whether it is preferable to use stomach or colon, and which route should be used (anterior or posterior mediastinal or presternal subcutaneous). Patients are generally able to leave hospital 3–4 weeks following successful surgery, with a satisfactory swallow as well as having a fair chance of regaining some useful speech (*Fig.* 7).

AIDS TO HEALING

General Condition of Patient.—The majority are in middle age and are often in poor general health for a variety of reasons some of which it is not possible to improve in the short time available before surgery. However, in consultation with a physician or the anaesthetist in charge a vigorous attempt should be made to overcome any chest infection, circulatory defect, or anaemia that is present. Diabetes must be corrected and sinusitis or dental sepsis must be cleared. The patient should be started on regular physiotherapy and introduced early to the speech therapist. It is also essential to carry out detailed preoperative nutritional studies on patients likely to undergo gut-transplant repairs together with routine checks of liver and renal function. Any drug sensitivities, especially to antibiotics, must be known. Chronological age is certainly no bar to surgery unless extreme, but physical condition and psychology must be taken into account when deciding the type of operation. These points again have much greater significance in the irradiated patient.

Planning and Technique.—Ideally all planning must be experienced, sometimes requiring consultation with other colleagues or the collaboration of two or more surgeons. The technique of repair must be meticulous with after-care by a skilled team of nurses and medical staff, preferably in special units.

Some years ago it was often said that tumour surgery in the head and neck required two teams: one to resect and the other to reconstruct—the Halstead concept Another cliché of the time supporting this argument was that if resection is carried out by the surgeon responsible for reconstruction inevitably there is a risk that the resection will be inadequate. Certainly this is no longer true today, the main reasons being, first, that reconstructive techniques are much more effective for all situations both in restoration of function, and in regaining the ability to speak, and, secondly, it has been clearly recognized that surgeons working in this field must themselves have experience in modern reconstructive surgery. In fact the reverse may therefore now hold more truth; that the surgeon trained in reconstructive techniques is best able to cope with any type of resectional defect that he may create.

Haemostasis, Sutures, Drains, and Dressings.—In recent years a wide variety of suture material has become available and it is felt that the less chromic catgut and diathermy are used the better is the result especially when working with irradiated tissues. Linen thread or silk for the largest vessels and 00 or 000 monofilament nylon on atraumatic needles for backing up defects closed with a single continuous extramucosal 00 atraumatic chromic catgut suture for the inner layer appear to give the best results.

Care in achieving haemostasis before closure together with the elimination of as much dead space as possible by the incorporation of muscle and connective tissue in mucosal suture lines and accurate tacking down of flaps will greatly help to reduce the amount of drainage required and will promote early healing.

The use of Haemovac-type continuous underflap suction drainage is certainly valuable and more comfortable for the patient, but in the heavily irradiated neck it is felt that there is still a good case for the use of additional bulky neck dressings as they do achieve an important and useful degree of immobility with adherence of the tissues during the first 3–4 days after surgery.

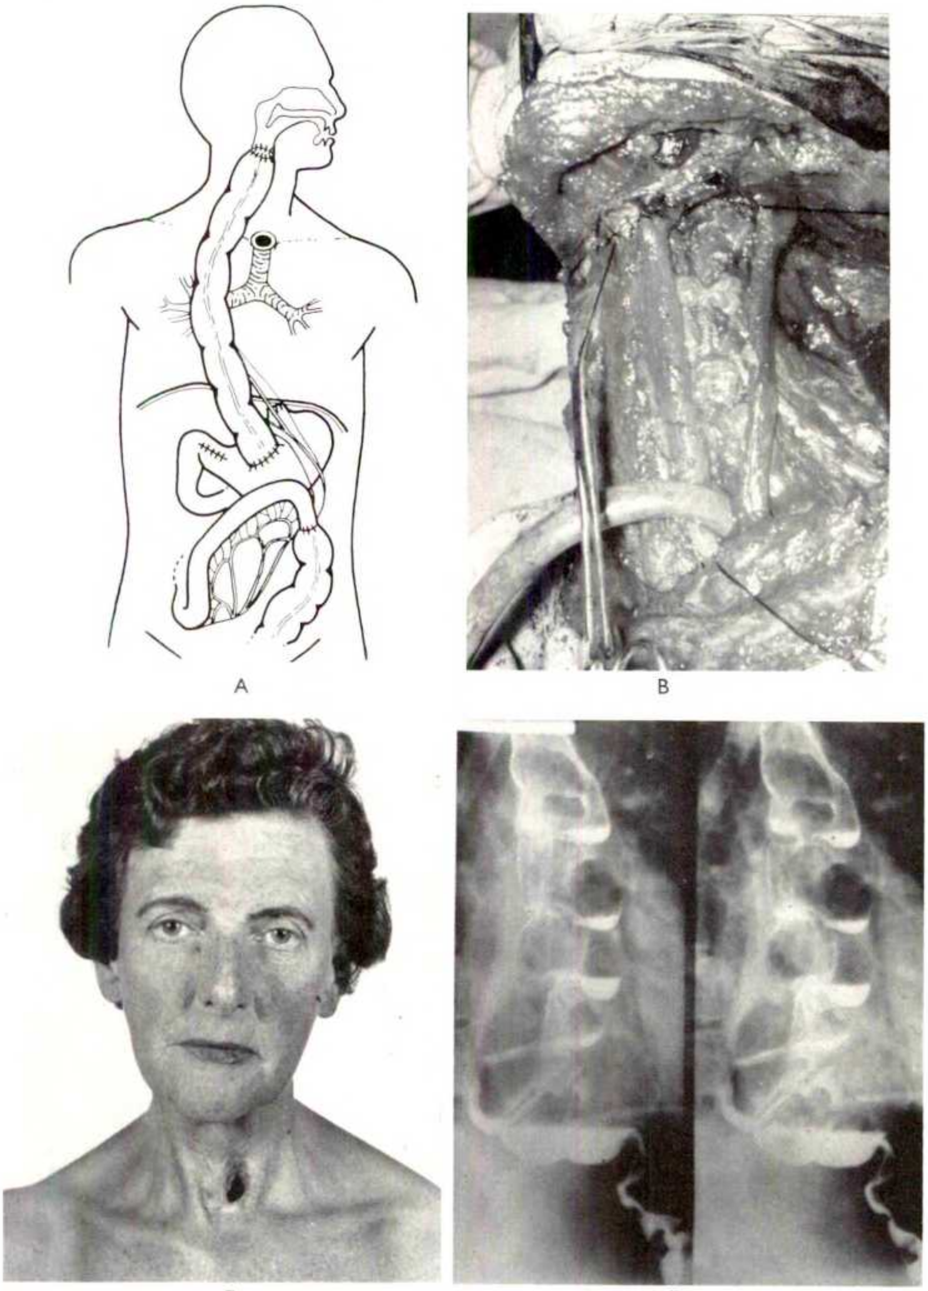

FIG. 7.—Total pharyngolaryngo-oesophagectomy with immediate reconstruction using a vascular pedicled segment of colon brought through the anterior mediastinum. A, Diagrammatic representation. B, Cervical anastomosis. C, Patient and D, barium-meal films 3 years after operation.

Feeding, Fluid, and Electrolytes.—Accurate maintenance of fluid and electrolyte balance is essential after all major surgical operations and is no less important in these patients, especially in view of their frequently complex medical problems.

Adequate nutritional intake when swallowing is in abeyance can certainly be maintained for several weeks by intravenous dextrose, aminosol, and lipid therapy, but over a long period this has obvious problems and reliance on nasogastric tube feeding, gastrostomy, or jejunostomy is both more effective and convenient, especially for protein supplements.

After reconstructive techniques likely to exceed 4 weeks to completion or where the abdomen must be opened as part of the procedure, experience shows that a feeding gastrostomy or jejunostomy is usually preferable to nasal tube feeding.

Antibiotics, Vitamins, and Hormone Replacement.—The use of a suitable wide-spectrum systemic antibiotic such as ampicillin or tetracycline is mandatory and must be continued in large doses throughout the period of initial healing after any reconstructive procedure—usually at least 2 weeks and often 3 weeks in irradiated patients. Vigilance to detect any overgrowth of pathogenic Gram-negative or other resistant organisms is always required.

The addition of vitamin supplements, especially vitamins B, C, and D, to the diet is helpful and the use of adequate hormone and calcium replacement after the total or even partial removal of the thyroid or parathyroid glands is essential.

COMPLICATIONS

There would seem to be little need to describe in detail the many possible complications relevant to the procedures described. However, certain problems are likely to be encountered more frequently after surgery in irradiated subjects. Fistula formation with a tissue defect following primary mucosal closure or secondary skin closure is common. The fistula is usually small in size and has been estimated to occur in 30–40 per cent of all suture lines following total laryngectomy. About 90 per cent of these close in a few weeks with simple measures to reduce infection. A small number will require plastic closure if no great improvement is noted after 8–10 weeks. If drainage from the fistula directly involves an exposed main vessel such as the common carotid artery, early intervention will be required at least to cover and protect the vessel with a suitable skin-flap.

There is no certain way to avoid fistula formation, which is often quite unpredictable in its occurrence, but a strict observance of surgical principles, meticulous technique at operation, and expert post-operative attention to drainage and dressings are essential. It is also very important to ensure the best possible local blood-supply without tension on the tissues in the design of the flaps and suture lines and to see that the normal circulating blood-volume and a normal haemoglobin level are well maintained after surgery. The use of some form of tube feeding is essential, preferably nasogastric, during the main healing period. Dressings bulky enough to secure some reduced mobility of the head and neck have a distinct advantage whether or not underflap suction drainage is employed. The value of systemic antibiotics has also been mentioned and is a practical necessity for at least 2 weeks following surgery.

Necrosis of the flap margins may occur unpredictably after irradiation despite good planning of the incisions. Usually the necrosis is small and of little consequence, but if major blood-vessels are exposed early cover by a well-vascularized skin-flap is again necessary.

With regard to pedicled gut transplants, most complications concern the anastomotic suture line to the pharynx and also may result from the surgical interventions within the mediastinum. The intra-abdominal anastomoses usually give little trouble. The most serious problem is partial or complete necrosis of the transplant. This, fortunately, is a rare event with proper planning and technique. Secondly, severe haemorrhage at operation within the thorax or later haemorrhage from the neck or thoracic vessels is often a serious risk. Gross superior mediastinal infection and necrosis can also follow this type of surgery in irradiated cases, particularly where there is pre- or postoperative chest infection. It is especially important in all these patients to spend at least 2 weeks preceding surgery in improving their general medical state and making good any nutritional defects, in addition to thorough bowel preparation.

Stenosis at anastomotic suture lines in the neck is not uncommon at skin–mucosa junctions, especially at the oesophageal end of a skin-tube repair if the technique has not been meticulous or if any local necrosis or infection has occurred. It seldom leads to severe dysphagia and can usually be overcome by repeated dilatation. Occasionally reoperation is necessary. When reconstruction has been by means of a free split-skin graft a complete stenosis of the graft may occur, requiring its total removal and a fresh reconstruction. In the author's experience mucosa–mucosa junctions have not given rise to any serious degree of stenosis requiring additional treatment.

Local recurrence of the tumour at or adjacent to the site of reconstruction is always an anxiety, especially if the repair is in any way difficult or prolonged. It is generally evidence of incomplete resection due to lymphatic permeation and by the time it becomes clinically apparent there is little chance of eradication by further surgery. Patients must then be treated by other means and are unlikely to be cured. A virtue of complete oesophagectomy followed by a pedicled gut transplant is that local lymphatic recurrence will be extramural and will not therefore cause undue dysphagia until a late stage, if at all.

CHOICE OF METHOD

The choice of the method of repair will depend chiefly on (*a*) the extent of the defect, (*b*) the details of previous irradiation or other treatment, (*c*) the general health of the patient, and (*d*) the surgical and nursing facilities available.

Although plans for repair should always be ready to meet unexpected contingencies at operation, it is preferable to obtain a precise knowledge of the extent of the lesion and thereby of the resection and defect created, as well as the other factors outlined earlier, before surgery. A suitable plan can then be prepared, followed through, and any required assistance anticipated.

In general, where the defect is small and can be closed without tension and with adequate cover, or where at least one-third of the mucosal circumference is intact, primary closure should be carried out unless the normal tissues have been excessively damaged by irradiation. In the latter case a simple stoma must be created by accurate skin/mucosa suturing, allowed to heal, and then closed secondarily with a transposed non-irradiated pedicle skin-flap.

When less than one-third of the mucosal circumference remains at any point so that tubing it and primary closure is impossible, either a stoma must be created again with secondary closure or a total excision completed and one of the described procedures used.

A special situation arises with the uncommon tumours arising on the posterior pharyngeal wall. If the bare area remaining after resection is less than 2 cm. in its greatest diameter either it may be left to heal by granulation and epithelial overgrowth or a local mucosal flap may be used to reduce or close the defect. If the area to be repaired is greater than 2 cm. in diameter it is best to restore the defect using an inlay pedicle skin-flap previously planned and inserted via a lateral pharyngotomy approach. When prior irradiation has been given the creation of a temporary small lateral pharyngeal stoma is advisable together with the use of such a pedicle. This stoma can easily be closed using local skin or a transposed pectoral flap at a second stage.

It has already been stated that the great majority of these tumours are advanced when first diagnosed. This applies particularly to the cervical oesophagus and here two situations often arise. The first is where a post-cricoid or pyriform fossa tumour is extensive enough to require a complete segmental excision of the larynx and pharynx in the immediate vicinity but does not extend far down, if at all, into the cervical oesophagus. In this situation most of the cervical oesophagus can be safely retained and several choices are available for reconstruction. Many such cases can be repaired well with only slight risk by using a skin-pedicle method, and of these, the long deltopectoral flap method developed by Bakamjian (1965) is perhaps the most suitable. It has a number of virtues, possibly the greatest being the use of non-irradiated skin for the lining of the new gullet together with the importation of a good blood-supply from branches of the internal mammary vessels. An effective and well-tried alternative where the neck skin has not been seriously damaged by irradiation is to use the local skin for lining as inturned 'trap-door' flaps and to bring up a pectoral transposition skin-pedicle flap for cover, as has already been described.

In the second situation, regrettably the more common, the cervical oesophagus is widely involved, the disease perhaps extending into the upper thoracic oesophagus. Here there is little alternative but to carry out a total pharyngolaryngo-oesophagectomy with replacement by a transposed vascular pedicled gut segment, the author's choice being to use an isoperistaltic segment of ascending and transverse colon. This is now an operation of proved effectiveness and advantages. However, it is still an extensive and serious procedure carrying at all times a considerable risk of postoperative mortality—especially relevant in view of the poor general nutrition of many patients with oesophageal cancer. Because of this and considering the comparatively low risks of skin-pedicle operations it is felt that the latter type of repair, carefully planned for suitable defects, must still be performed when possible in cases which are bad surgical risks.

CONCLUSIONS

Although it is correct to say that there has been little further improvement in curative treatment for tumours of the laryngopharynx and cervical oesophagus over the past 10 years, except for a better use of combined methods, there has been a more complete understanding of their surgical pathology (Harrison, 1970) and a great improvement in the techniques of repair of surgical defects, with early restoration of function. The most notable of these new techniques are the more sophisticated use of large regional skin-flaps from outside the irradiated areas and the employment of vascular pedicled gut replacements. These have resulted in less morbidity, reducing the time spent in hospital, allowing a faster return of the normal swallow, and enabling speech therapy to be begun earlier. The choice of technique remains important and much work must continue to be done on diminishing the hazards of gut transposition, especially in irradiated and undernourished patients.

Acknowledgements.—My thanks are due to Miss Pegus and Miss Scott-Ellis of the Medical Art and Photographic Departments of the Royal Marsden Hospital for their valuable help in the preparation of the illustrations.

I am indebted to my colleague Mr. J. D. Griffiths for the skilful planning and technique of vascularized colon transposition.

Open weave gauze support backing.
Cotton/acrylic pad. Three times more absorbent than cotton wool.
Non-adherent film to protect wound. Perforated to allow exudate through.

Melolin. One dressing idea that really comes off.

Most dressings stick. And a pretty painful business it can be. But with Melolin the wound is protected by a non-adherent perforated film.

Exudate is taken through the perforations into an extra absorbent pad.

When you change the dressing it peels off. If you prefer, you can peel away the pad, leaving the film only on the wound.

Melolin comes individually wrapped (sterile) or in bulk.

Write for full information or ring Mrs E. Arthur, Welwyn Garden 25151.

Melolin is a registered trade mark of T. J. Smith & Nephew Limited.

Smith & Nephew Limited,

THE ROLE OF RADIOTHERAPY IN THE MANAGEMENT OF MALIGNANT THYMOMA

By C. R. H. PENN and H. F. HOPE-STONE
DEPARTMENT OF RADIOTHERAPY, THE LONDON HOSPITAL, LONDON

SUMMARY

A series of 18 cases of malignant thymoma referred for radiotherapy during a 21-year period is reviewed. The presentation, treatment policy, and results are examined. Of the 7 cases treated with a full radical dose all were alive at 3 years, all 4 cases followed for 5 years survived that period, and 3 of the 4 cases followed for 10 years were alive at that time. Of these, only 3 cases had had macroscopically complete excision of the tumour at thoracotomy. These findings suggest that postoperative radiotherapy should be of benefit in all cases of invasive thymoma whether operable or otherwise.

THE place of radiotherapy in the management of malignant thymoma is still a matter of some dispute. An editorial in the *British Medical Journal* (1969) on Hodgkin's disease of the thymus states: 'the lesion responded to radiotherapy, in contrast to those of true thymoma'. This would appear to imply that radiotherapy is not effective in the treatment of the latter condition. Holmes Sellors, Thackray, and Thomson (1967), however, state that radiotherapy plays an important part in the management of invasive thymoma, although they believe radiotherapy alone to be less effective than a combination of surgery and radiotherapy. Others, including Legg and Brady (1965), Piercy (1966), Wilkins, Edmunds, and Castleman (1966), and Hatcher, Exarhos, Logan, and Abbott (1967), also advocate a combination of surgery and radiotherapy. Sawyers (1968), however, suggests that postoperative radiotherapy is not needed if complete excision has been achieved.

The majority of these authors advocate postoperative rather than preoperative radiotherapy, although Holmes Sellors and others (1967) are of the opinion that the results of both approaches are equally satisfactory. One of the earliest advocates of combined surgery and radiotherapy was Keynes (1949), who suggested preoperative radiotherapy for thymomas with myasthenia. This approach has tended to continue to be used for such cases (Piercy, 1966), but even in this situation has been attacked by Henson, Stern, and Thompson (1965), who feel that preoperative radiotherapy has no value and is a contra-indication to surgery.

In the management of malignant thymoma surgery is nearly always attempted in the first instance, as, even if the lesion is inoperable, this may be the only way to establish a histological diagnosis. If complete removal is impossible or if local recurrence is feared following apparently complete removal, irradiation is usually given.

The use of radiotherapy alone meets with little support in the literature. However, many cases are inoperable (8 out of 15 cases in the present series) and it has been our policy to irradiate these patients unless they are hopelessly ill.

In this article we report the outcome of all the cases of malignant invasive thymoma receiving radiotherapy at the London Hospital from 1948 to 1968 inclusive.

MATERIAL

Eighteen cases were available for study, all of whom had histologically proved diagnoses of malignant thymoma, and all of whom had received radiotherapy.

In 15 cases radiotherapy was used as part of the original management of the condition. In 2 cases it was used for recurrence following surgery alone, and in 1 case the patient was watched for some years on the grounds of age and poor general condition before being referred for palliative irradiation.

Of the 15 patients who received radiotherapy as part of the primary management, all have been followed for 3 or more years, and 9 for 5 years or more.

Age at presentation ranged from 19 to 69 years, with an overall mean of 43 years. The population, however, fell into two age-groups: those below 30 years (6 patients, with an average age of 25 years) and those over 40 years (12 patients, with an average age of 52 years). The sexes were evenly distributed.

Three cases were asymptomatic, being detected on mass miniature radiography or 'routine' radiographs. The mean length of history for those with symptoms was 5½ months. The commonest thoracic symptom was left-sided chest and arm pain, although pain also occurred at other sites in the chest, arms, and neck. The association between myasthenia gravis and thymoma has long been established and 4 cases in the present series—2 lymphocytic thymomas and 2 'mixed' tumours—had symptoms of myasthenia at presentation. Other symptoms, each noted once only, were anorexia, vomiting, tiredness, chest-wall swelling, and hoarseness of voice.

In our series all the cases had lesions detectable on plain radiographs (*Figs.* 1 A, B). The commonest radiographic appearance was an anterior mediastinal mass. Four of the cases had palpable lymph-nodes. Three of these had small nodes in one or both axillae which were felt not to be significant and gave no rise to further trouble when left untreated. The fourth patient had a granulomatous lesion with involved nodes in both supraclavicular fossae.

Distant pulmonary metastases occurred in 1 patient, and a further patient developed multiple bony metastases 7½ years after presentation (*Fig.* 2). He was treated with preoperative radiotherapy, following which macroscopically complete excision of the tumour remnant was achieved, the histological appearance being that of a thymoma of mixed pathology with none of the features of a granulomatous lesion. At the time of the development of the bony metastases there was no clinical evidence of a new primary neoplasm elsewhere. A further patient with a proved lymphocytic lesion developed pelvic bone pain and tenderness 9 months after presentation, by which time pulmonary metastases had also developed. This pain responded well to radiotherapy and was felt to be due to metastases, although there were no conclusive changes on the radiographs.

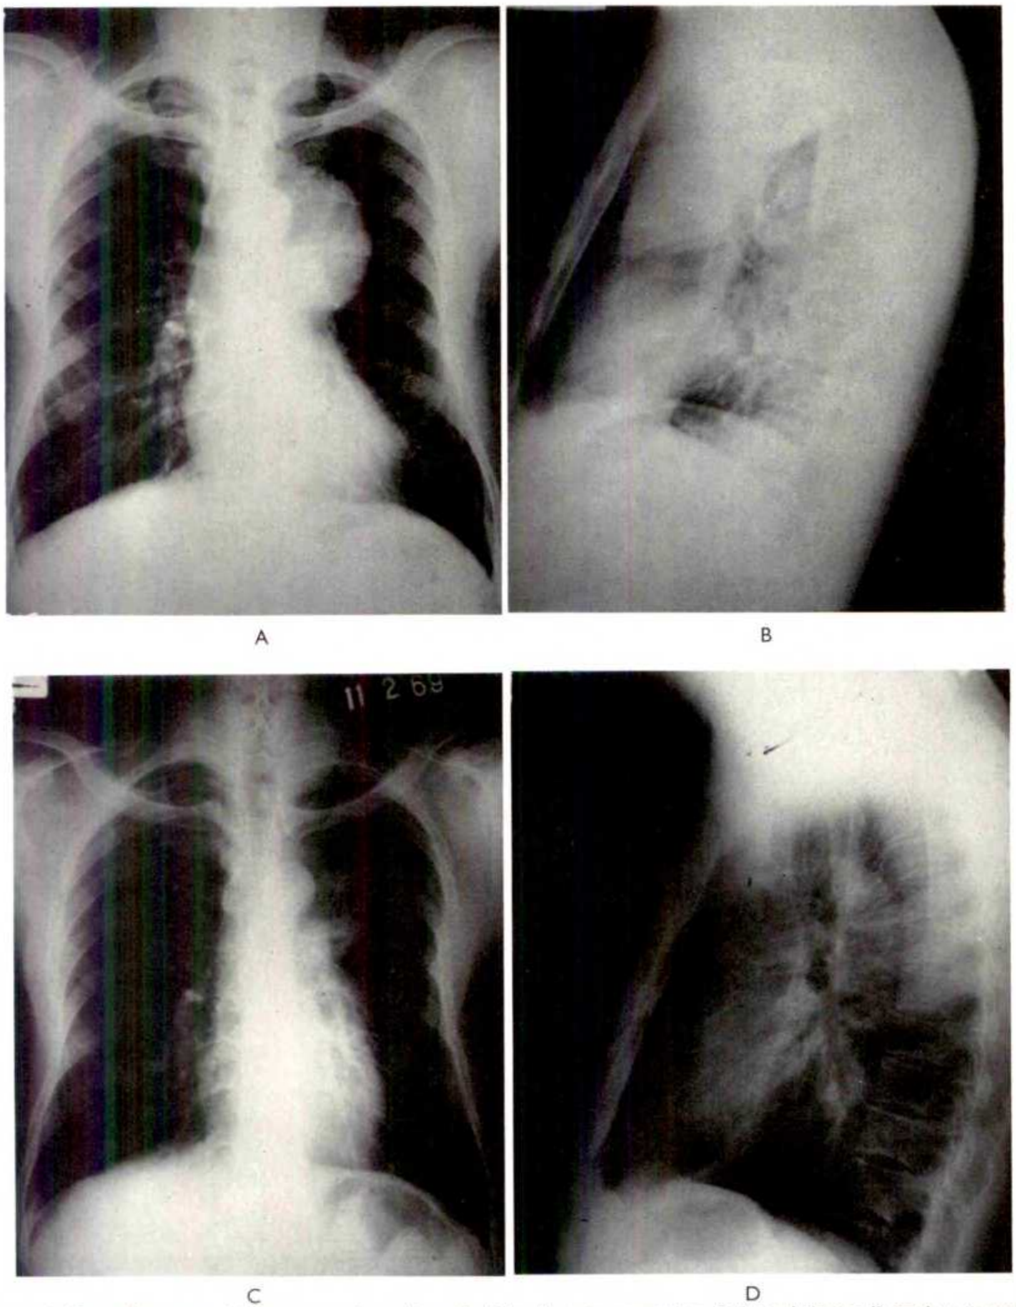

FIG. 1.—A. B., aged 50 years. A, Postero-anterior radiograph of the chest at presentation. B, Lateral chest radiograph at presentation. C, Postero-anterior chest radiograph 10 months after sternal split thoracotomy, biopsy, and radical radiotherapy. D, Lateral radiograph of the chest 10 months following treatment.

HISTOLOGY

Thomson and Thackray (1957) have suggested a basic classification in three groups: epithelial, lymphocytic, and teratomatous. The epithelial group, however, includes amongst others the lympho-epithelioma and the granulomatous thymoma, which are tumours of widely differing natural history. We have therefore used a slightly different classification in reviewing our cases, all of which have been histologically confirmed (*Table I*).

The 'benign' lympho-epithelioma is a small, well-circumscribed, well-differentiated lesion, most commonly associated with myasthenia. None of these has been referred to us for radiotherapy.

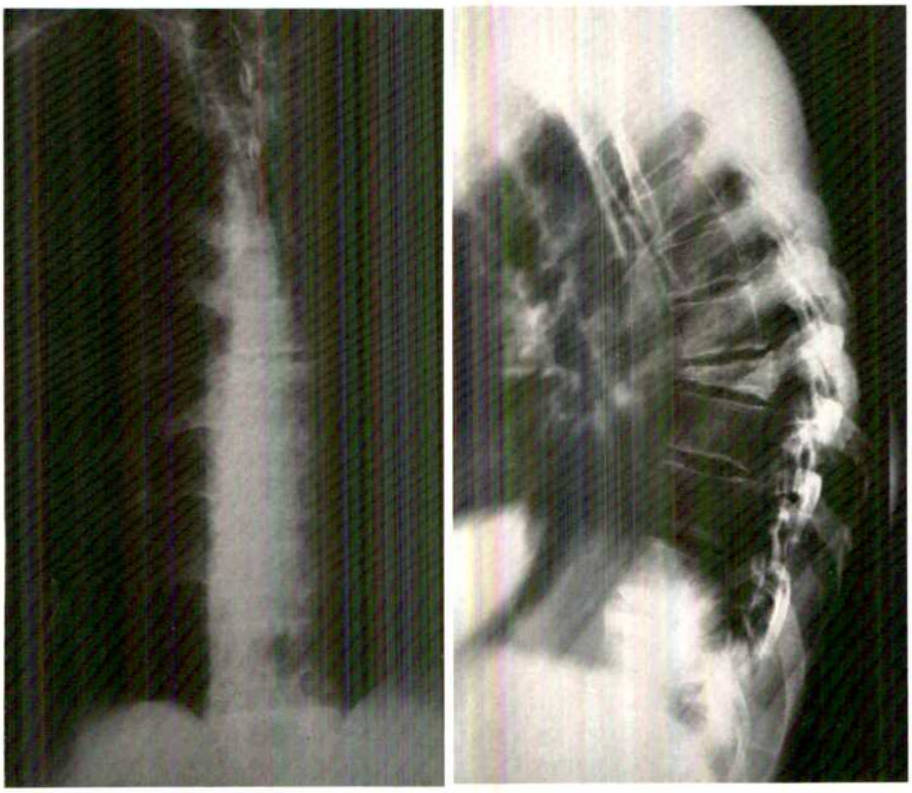

FIG. 2.—O. S., aged 51 years. A, View showing metastases in the dorsal spine. B, Lateral radiograph of the dorsal spine showing metastases. There were additional deposits in the cervical and lumbar spines, pelvis, and skull.

Table I

Classification	*No. of Cases*
'Benign' lympho-epithelioma	0 (in our series)
Invasive thymoma	
Epithelial	1 (no myasthenia)
Lymphocytic	6 (2 with myasthenia)
Mixed	6 (2 with myasthenia)
Granulomatous thymoma	2 (no myasthenia)
Teratoma	0 (in our series)

The invasive thymoma is a malignant lesion arising from the thymus. Since two elements—lymphoid and epithelial—occur in the thymus these are able to occur in varying proportions in the thymoma, providing a simple classification based on the predominating tissue type. A mixed lesion implies roughly equal proportions of epithelial and lymphocytic elements.

The granulomatous thymoma also contains mixed lymphoid and epithelial cells, but in addition it contains mononuclear cells, giant cells, and a fibrous stroma.

Teratoma is rare but does occur arising primarily in the thymus, although none was found in this series. Tissues representing all three germ layers are present.

SURGERY

Fifteen cases were submitted to thoracotomy, and in the majority a 'sternal split' approach was employed. In 8 of these cases macroscopically complete removal was achieved, and 7 of these, comprising 3 lymphocytic lesions and 4 tumours of mixed pathology, were referred for postoperative radiotherapy. The eighth was eventually irradiated for local recurrence.

In 2 of the 7 remaining cases removal was attempted but was known to be incomplete. The other 5 cases were regarded as inoperable and only a biopsy was performed.

RADIOTHERAPY TECHNIQUE

In this department we regard 4000 rad (megavoltage) in 20 treatments over 28 days as a radical tumour dose. Fifteen patients were irradiated as part of the primary management. Of these, 4 received this dose or a greater one on megavoltage. Three further cases were treated with conventional deep X-rays to an equivalent dose. The remaining 8 patients were treated palliatively on the grounds of widespread disease or poor general condition. Here the tumour dose varied from 2000 R (250 kV.) to 3500 rad on megavoltage.

If the tumour was relatively small a technique using two large anterior oblique wedge fields was used. Field size was of the order of 15 × 8 cm., wedge angle 45°, and hinge angle 90°. Tumour regression is shown in *Fig.* 1 C and D.

Table II.—SURVIVAL OF CASES RECEIVING RADICAL RADIOTHERAPY

CASES	TOTAL NO. OF CASES	3 YEARS		5 YEARS		10 YEARS	
		No. Followed	No. Alive	No. Followed	No. Alive	No. Followed	No. Alive
All cases	7	7	7	5	5	4	3
Patients under 30 years	2	2	2	1	1	1	0
Patients over 40 years	5	5	5	4	4	3	3

Table III.—EXTENT OF SURGERY AND THE SURVIVAL OF CASES RECEIVING RADICAL RADIOTHERAPY

EXTENT OF SURGERY	TOTAL NO. OF CASES	3 YEARS		5 YEARS		10 YEARS	
		No. Followed	No. Alive	No. Followed	No. Alive	No. Followed	No. Alive
All cases	7	7	7	5	5	4	3
Complete excision	3	3	3	3	3	2	2
Less than complete excision	4	4	4	2	2	2	1

Table IV.—SURVIVAL OF THE CASES RECEIVING RADIOTHERAPY IN THE PRIMARY MANAGEMENT OF MALIGNANT THYMOMA

CASES	TOTAL NO. OF CASES	3 YEARS		5 YEARS		10 YEARS	
		No. Followed	No. Alive	No. Followed	No. Alive	No. Followed	No. Alive
All cases	15	15*	10	9	6	9†	3
Patients under 30 years	6	6	2	4	1	4	0
Patients over 40 years	9	9*	8	5	5	5†	3

* Includes 1 case dying of myasthenia and lung abscess at 3 months. No evidence of recurrence.

† Includes 1 case dying of bronchopneumonia at 9 years. No evidence of recurrence.

More extensive lesions were treated with large parallel opposed fields or with parallel opposed fields supplemented with a wedge pair or additional direct anterior field. Field sizes were up to 20 × 15 cm. for the parallel opposed fields, and up to 20 × 8 cm. for the wedge fields. We believe these techniques yield an adequate dose to the anterior mediastinum without excessive exposure to the spinal cord. With conventional deep X-rays (250 kV.) parallel opposed fields and wedge pairs have been used.

SIDE-EFFECTS

In the present series 4 out of 10 cases treated with tumour doses ranging from 3500 rad in 20 treatments to 4500 rad over the same period showed evidence of pneumonitis. The classic presentation of this complication was a dry cough progressing to dyspnoea. There were low-grade fever and scattered coarse crepitations. Chest radiographs showed patchy mottling spreading from the treated area.

Although this problem reached serious proportions in 1 case, most patients were not badly affected and they responded to low doses of prednisone with the addition of antibiotics where there was evidence of superadded infection (Hope-Stone, 1967). In the severe case on such a régime immediate symptoms usually subside in 3 or 4 days, and complete resolution occurs within a month. If, however, fibrosis has developed steroids are less effective.

Mediastinitis, as shown by central chest pain and a rising pulse-rate, has not been observed in this series. Pericarditis has not occurred.

Meningitis was not seen but possible temporary spinal cord damage occurred in 1 case, who received a cord dose of 3000 rad with a 20-cm.-long field. This patient developed a transient radiation myelopathy associated with large-field irradiation to the thorax, which has been described by Jones (1964). This occurred 4 months after treatment and settled after 2 months with no residual neurological deficit. The highest dose received on the spinal cord in our series was 4000 rad in 20 treatments over 27 days. This is within the tolerance level suggested by Boden (1948) of 4000 rad in 15 treatments over 21 days for lengths of cord less than 15 cm.

RESULTS

Fifteen cases received radiotherapy as part of the primary treatment. Of these, 7 were treated with what we now regard as a radical dose, and the remaining 8 received palliative treatment only.

Table II shows survival figures for those treated radically, both for all the cases and for the two age-groups. These show satisfactory survival figures for up to 5 years after treatment. One patient, however, died of his disease at 6½ years. All the 10-year survivors are recurrence-free and no patient who was treated with a full radical dose and who was recurrence-free at 5 years has died.

Table V.—THE HISTOLOGY OF THE LESION AND THE SURVIVAL OF THE CASES RECEIVING RADIOTHERAPY IN THE PRIMARY MANAGEMENT OF MALIGNANT THYMOMA

HISTOLOGY	TOTAL NO. OF CASES	3 YEARS		5 YEARS		10 YEARS	
		No. Followed	No. Alive	No. Followed	No. Alive	No. Followed	No. Alive
All cases	15	15*	10	9	6	9†	3
Lymphocytic	6	6	4	3	1	3†	0
Epithelial	1	1	1	0	0	0	0
Mixed	6	6*	5	5	5	5	3
Granulomatous	2	2	0	1	0	1	0

* Includes 1 case dying of myasthenia and lung abscess at 3 months. No evidence of recurrence.

† Includes 1 case dying of bronchopneumonia at 9 years. No evidence of recurrence.

Table VI.—EXTENT OF SURGERY AND THE SURVIVAL OF CASES RECEIVING RADIOTHERAPY IN THE PRIMARY MANAGEMENT OF MALIGNANT THYMOMA

EXTENT OF SURGERY	TOTAL NO. OF CASES	3 YEARS		5 YEARS		10 YEARS	
		No. Followed	No. Alive	No. Followed	No. Alive	No. Followed	No. Alive
All cases	15	15*	10	9	6	9†	3
Complete excision	7	7*	6	4	4	4†	2
Less than complete excision	8	8	4	5	2	5	1

* Includes 1 case dying of myasthenia and lung abscess at 3 months. No evidence of recurrence.

† Includes 1 case dying of bronchopneumonia at 9 years. No evidence of recurrence.

Table III compares the results of those cases receiving a radical dose and complete surgical excision of the tumour with those who received similar radiotherapy but for whom the surgery was less than complete. These small numbers are not statistically significant but they do not demonstrate any great advantage of complete surgical excision in those cases who were subsequently irradiated radically.

Table IV shows the survival figures for all the cases receiving radiotherapy as part of their primary management. This series includes cases with extensive primary tumours, those with distant metastases, and those felt to be too frail for radical radiotherapy. *Table IV* shows how the overall figures are affected by the highly aggressive nature of the disease in the younger age-group. Only 2 out of the 6 cases in this age-group had sufficiently localized lesions to be treated radically, and these were the only survivors at 3 years. The only death occurring within 10 years among those receiving a full course of treatment was also in this age-group.

Table V attempts to show the effect of histology on the prognosis, but this is difficult in a small series. The apparently better prognosis for the 'mixed' tumours is more probably due to the earlier presentation in 4 out of 5 of these cases and the associated radical treatment. In the present series there was no demonstrable improvement in the response to radiotherapy with the lymphocytic lesions, as described by Holmes Sellors and others (1967).

Table VII.—THE RESULTS OF TREATMENT OF 7 CASES OF RECURRENCE OF MALIGNANT THYMOMA

Time after Treatment	*No. of Cases Alive and Well*	*No. of Cases Alive with a Recurrence*
3 months	5	1
6 months	2	2
1 year	2	2
2 years	0	1

The advantages of complete surgical removal shown in *Table VI* are probably more apparent than real. *Table III* has shown the nearly equal results with and without complete excision in those tumours which were irradiated radically, and undoubtedly an element of surgical discretion has improved the results for complete excision in the series as a whole by excluding poor-risk cases.

Table VII shows the results of treatment of recurrences. This, not surprisingly, indicates a very short period of survival after treatment and, in general, a short period of remission of symptoms. However, an occasional dramatic palliative result can be obtained, as in the case described by Roberts and Hope-Stone (1972), where palliative irradiation of the mediastinum caused regression, not only of the mediastinal mass, but also of the associated red-cell aplasia and a neuropathy.

DISCUSSION

The presentation of our cases was essentially similar to that in previously reported series, although in our series the mean age at presentation was slightly lower than the 54 years reported by Legg and Brady (1965).

Our patients' symptoms were also similar, although we have not noted the 'hiccups' reported by Wilkins and others (1966). However, 58 per cent (15 out of 26 cases) of the patients in the series of Wilkins and others (1966) were asymptomatic at presentation against 36 per cent in the series of Hatcher and others (1967), 20 per cent in that of Legg and Brady (1965), and 18 per cent in our own series.

The radiology of these tumours has been widely reviewed. Holmes Sellors and others (1967), discussing the radiological diagnosis, mention the sail-like shadows seen on plain radiographs, which they state is pathognomonic. These authors also advocate apical views, lateral tomography, angiocardiography, and pneumomediastinography. The radiological diagnosis has been further discussed by Jones (1955), who regards fluoroscopy and tomography in several planes as essential.

In the present series, however, the initial diagnosis was made without special radiographic procedures, although in 3 cases tomography was later carried out to determine more fully the extent of the lesion. This would suggest that for the invasive lesion giving rise to local symptoms, special radiographs are seldom vital in diagnosis. For the smaller lesions associated with myasthenia and of the type which have not been referred to us for radiotherapy the technique of selective thymic venography described by Kreel (1967) appears attractive and is described as less distressing to the patient than the other radiological contrast procedures.

All authorities are agreed that metastases outside the thorax are excessively rare except with the granulomatous lesion. Rachmaninoff and Fentres, reviewing the world literature in 1964, reported only 10 acceptable cases of distant metastases from these tumours. In 8 cases the tumour had spread to lymph-nodes: 4 each to the kidney, liver, and bones, and 3 to the spleen. In 2 cases there were metastases to the cranial nerves and there was 1 each to the skin, choroid plexus, spinal nerve-roots, brain, and dura mater. We feel that at least 1 of our cases can definitely be added to this series.

The association between red-cell aplasia and thymic tumours has been discussed by Havard and Scott (1960). This condition is felt to represent an autoimmune phenomenon and progresses later to a pancytopenia.

Two of our cases developed refractory anaemia late in their disease and in 1 a definite red-cell aplasia was demonstrated (Roberts and Hope-Stone, 1972).

Side-effects of radiotherapy in this condition have been discussed fully by Williams (1951), Jones (1960), and Skeggs (1968). The special problems reported are pneumonitis, mediastinitis, pericarditis, and meningitis and spinal cord damage. In our series, the only one of these side-effects to occur was pneumonitis. This can be expected in 40 per cent of the cases which are treated radically and occasionally leads to lung fibrosis but it usually resolves completely. Mediastinitis, which we have not encountered, represents a greater risk to life than pneumonitis, and we have no experience of its response, if any, to steroids. Pericarditis has been avoided, and Skeggs (1968) only reports it in cases treated with tumour doses of 5000–6000 rad in 5–6 weeks. Permanent spinal cord damage was avoided by our cord dose being within the limits of tolerance.

In assessing results the rarity of malignant thymoma makes the preparation of any series from a single centre difficult, and one is forced to attempt to draw conclusions from relatively few cases. It is also difficult to compare these figures for radiotherapy with those for surgery alone, where the majority of cases will have small localized tumours, and a few will be of the infiltrating type which tends to be referred to the radiotherapist. Having recognized this, however, it seems clear that our 5-year survival figures for radical radiotherapy (100 per cent), and the 65 per cent 10-year survival in cases treated by radical irradiation, with or without complete surgical excision, are unlikely to be much improved by surgery alone.

Since the response of late recurrence after radical surgery to irradiation is so poor it would seem reasonable to suggest that all cases of infiltrating tumours could with advantage be referred for postoperative radiotherapy, even if surgery is macroscopically complete. In addition, all locally inoperable cases should perhaps be given a chance to respond to a course of radical irradiation. Palliative treatment in widespread disease is sometimes rewarding. This should also be considered where appropriate.

Acknowledgements.—We would like to thank the physicians and surgeons of the London Hospital and the London Chest Hospital, and in particular Dr. W. Brigden, Mr. G. Flavell, Dr. R. A. Henson, and Dr. M. Caplin. We would also like to thank Dr. W. Shanks, who treated many of these patients originally, and Professor I. Doniach, Dr. A. H. E. Marshall, and the staff of the Institute of Pathology at the London Hospital for their valuable help with the pathology of these patients. In addition, we would like to thank Miss S. Gibby and Miss S. Long for preparing the manuscript.

BRACHIAL PLEXUS LESIONS ASSOCIATED WITH TRAUMATIC ASPHYXIA

BY PETER LEECH AND HUGH CUTHBERT

INSTITUTE OF NEUROLOGICAL SCIENCES AND DEPARTMENT OF ORTHOPAEDIC SURGERY, SOUTHERN GENERAL HOSPITAL, GLASGOW

SUMMARY

Among 19 patients admitted to hospital following a major disaster it was noted that 15 showed evidence of traumatic asphyxia and 7 had sustained brachial plexus injury. Three such cases are presented, the possible pathogenesis of the brachial plexus lesions is discussed, and the diagnostic difficulty presented by unconscious traumatically asphyxiated patients with monoparesis is highlighted.

THE syndrome of traumatic asphyxia is well documented (Bonnin, 1941.) First described by Ollivier in 1837 when the findings in 23 patients fatally crushed in a rioting crowd in a Paris street were presented, most of the cases reported in recent years have been of single individuals crushed in road-traffic, industrial, or agricultural accidents (Fred and Chandler, 1960). The Ibrox Football Stadium disaster of 2 Jan., 1971, in which 66 people were killed on an exit stairway as the crowd left the stadium is one of the few modern disasters where loss of life has been predominantly due to traumatic asphyxia and it is noteworthy for this reason alone. That 7 of the cases involved in the incident should have sustained brachial plexus lesions is believed to be unique in the tragic history of crowd-crush disasters.

CLINICAL MATERIAL

Of the 97 patients who attended the Casualty Department of the Southern General Hospital, Glasgow, immediately after the disaster, 15 were admitted with evidence of traumatic asphyxia. Six of these 15 patients were found to have associated brachial plexus injuries (1 further case of brachial plexus injury was admitted to hospital but showed no signs of traumatic asphyxia), and 3 of these patients are reported in detail here.

CASE REPORTS

Case 1.—The patient, a 19-year-old boy, arrived at the hospital about 30 minutes after injury. He was unresponsive to spoken commands but was able to move all his limbs except his right arm. He had striking bilateral subconjunctival haemorrhages (*Fig.* 1), his upper thorax and face were covered with small petechiae, and a linear abrasion was noted on the right side of his neck (*Fig.* 2). It was felt that a significant intracranial lesion could not be excluded and he was transferred to a neurosurgical unit. Twelve hours after injury, however, when the patient was alert and fully orientated, it was confirmed that the monoparesis was due to a right brachial plexus lesion involving predominantly the upper roots, and the following muscle strengths were recorded using the M.R.C. scale (Medical Research Council, 1965): biceps, 1; deltoid, 0; supinator, 1; triceps, 4. There was sensory impairment of the 5th, 6th, and 7th cervical roots, and the biceps and supinator tendon reflexes were absent. During the ensuing 48 hours the sensory loss recovered completely and the muscle strengths improved. Two months after injury motor recovery was almost complete.

Case 2.—A 14-year-old boy, who was not responsive to spoken commands on arrival from the disaster, was noted to be unable to move his left arm. Stigmata of traumatic asphyxia were limited to scattered petechiae on the face and bilateral subconjunctival haemorrhages. He had a linear abrasion on the left side of his neck (*Fig.* 3). During the 12 hours following admission to hospital his conscious level returned to normal but he remained disorientated in time and place. His increased co-operation at this time, however, allowed a more detailed examination of his left arm which showed an upper brachial plexus lesion with sensory loss over the dermatomes of the 5th and 6th cervical roots and grade-1 power in the biceps, supinator, and deltoid muscles. The biceps and supinator tendon reflexes were absent. The patient gradually improved, both in regard to his conscious state and in muscle power in his paretic limb, but although he was completely orientated without sensory loss 3 days after the disaster the motor loss was still detectable 2 months later, at which time some wasting in the deltoid was noted. Electromyograms performed 1 week and 5 weeks after the accident confirmed lower motor neuron damage.

Case 3.—A 32-year-old man, who was seen about 1 hour after the disaster, was found to be unresponsive to painful stimuli. His face and upper trunk were deeply cyanosed and he had marked bilateral subconjunctival haemorrhages. He was bleeding from both external auditory meati and he had marked dyspnoea due to multiple fractured ribs with a flail segment on the right side. As a basal skull fracture was suspected he was transferred to the neurosurgical unit for observation but subsequent skull radiographs were normal. Examination following recovery from his respiratory distress showed a paresis of the left biceps, deltoid, and supinator muscles and of the right anterior serratus muscle with some sensory loss over the dermatome of the 5th cervical root. He made rapid progress and when examined 2 months after injury the muscle groups in the left arm had almost returned to normal although there was still considerable weakness of the right anterior serratus muscle.

Cases 4–7.—These cases, 3 of which were fully conscious on arrival at hospital, were found to have minor unilateral paresis involving the myotomes of the 5th and 6th cervical roots. All of them made a complete recovery within 2 months. One case in this group showed no signs of traumatic asphyxia.

REVIEW OF EARLIER CASES

Following a similar incident at the Ibrox Stadium on 16 Sept., 1961, 12 cases of traumatic asphyxia were admitted to the Southern General Hospital, Glasgow. The case records of these patients were examined, but no evidence of a brachial plexus lesion had been documented and of the 6 patients who responded to a request for long-term follow-up, none could remember sustaining any weakness or sensory changes in the upper limbs at the time of their injury.

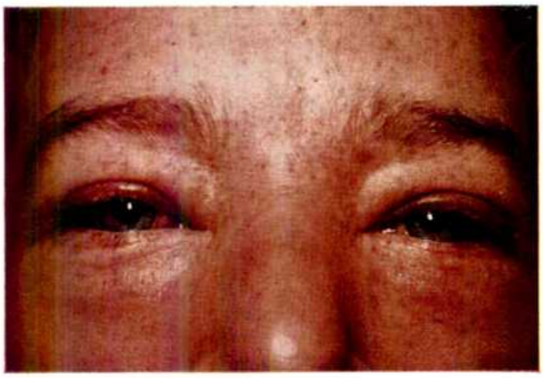

FIG. 1.—*Case* 1, showing bilateral subconjunctival haemorrhages and scattered petechiae.

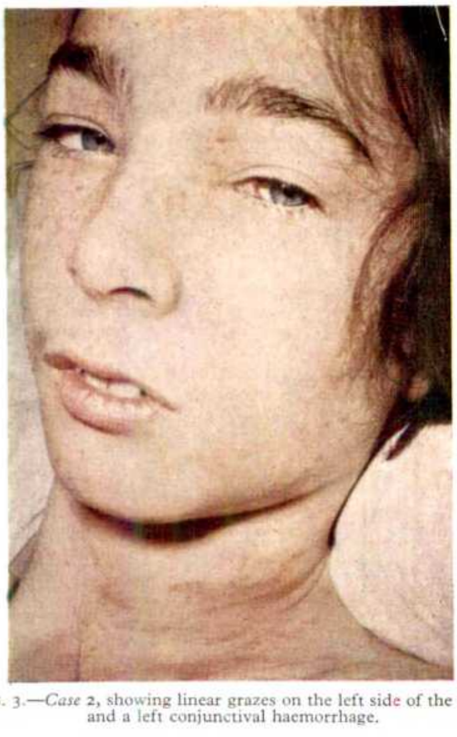

FIG. 3.—*Case* 2, showing linear grazes on the left side of the neck and a left conjunctival haemorrhage.

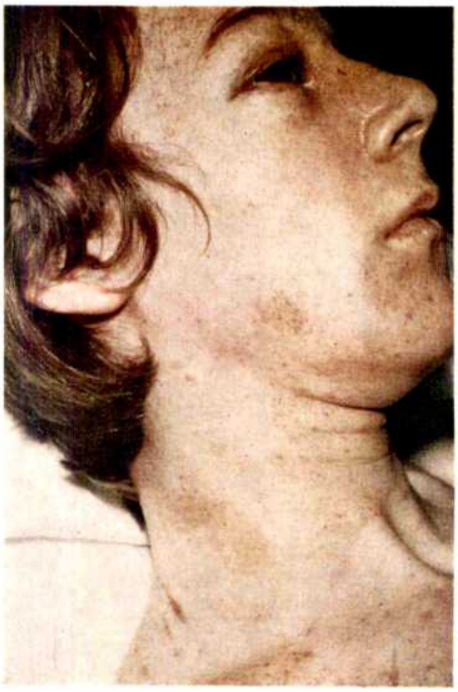

FIG. 2.—*Case* 1, showing scattered petechiae and linear abrasions on the neck.

DISCUSSION

Although many cases of traumatic asphyxia have been recorded (Shamblin and McGoon, 1963; Carveth and Mathews, 1967; Williams, Minken, and Adams, 1968; Feldman, 1969), little mention is made in the literature of the occurrence of simultaneous branchial plexus injury. That it may occur owing to direct trauma has been indicated (Fred and Chandler, 1960) but such a high incidence as occurred in this series has not been noted previously. Among 12 cases of traumatic asphyxia seen following a similar incident at the Ibrox Stadium in 1961, no cases of brachial plexus injury were noted, and in 1 case of traumatic asphyxia sustained at Ibrox in 1901 no brachial plexus injury was documented (Beatson, 1907).

Paraparesis has been recorded in 1 case of traumatic asphyxia (Heuer, 1923), and concomitant paraplegia has been reported but no obvious cause was found when the cord was explored and it was attributed to ischaemia (Reichart and Martin, 1951).

It is recognized that lesions of the upper roots of the brachial plexus may occur when the head and the ipsilateral shoulder are distracted (Barnes, 1949; Sunderland, 1968), and as the observed lesions were predominantly of the upper roots and primarily of a neuropractic nature their pathogenesis may be surmised to be as follows:—

1. During crushing by the crowd forceful lateral flexion of the neck may have occurred.

2. The patient's neck may have been pushed against the tubular steel railings which collapsed during the tragedy in the centre of the crowd. Abrasions of the lateral aspects of the necks of 2 of the cases with ipsilateral monoparesis would appear to support this view.
3. During the rescue of the trapped men it may be surmised that efforts to extricate the victims by traction on their arms while their heads were still not freed may again have resulted in extreme lateral flexion of the neck.

The high incidence of brachial plexus lesions in this tragedy prompts us to emphasize the diagnostic difficulty presented by a patient who is deeply unconscious with traumatic asphyxia and with a monoparesis; such a patient may be considered to be suffering from a serious head injury with a lateralizing sign warranting urgent neurosurgical investigation.

A COMPARISON OF PORTAL AND SYSTEMIC VENOUS DRAINAGE IN PORCINE RENAL ALLOGRAFTS*

BY G. MAZZONI, C. DI MARTINO, A. DEMOFONTI, A. VALLI, S. PELLEGRINI, B. GENTILI, AND M. MELIS

DEPARTMENT OF SURGERY, VITTORIO EMANUELE III° HOSPITAL, ROME

SUMMARY

The results obtained when both kidneys were allografted in the pig are described. The experiments were performed in two groups of animals. In one group both kidneys were transplanted with portal venous drainage and in the other group caval drainage was used. Animals with portal venous drainage of the renal grafts survived for more than 4 months whereas those with caval drainage died within 15 days.

THE prolonged survival of an allogenic tissue in a 'privileged' zone is probably due to a barrier to the transport of transplantation antigens from the transplant into the lymphatic system of the host (May, Bauer, Leddy, Parmer, Vaugham, and Russel, 1969). The routes by which the antigens reach the host tissue from the transplanted organ have not been defined. The venous blood may be the main transport system for transplantation antigens. After transplantation in man and in experimental animals the caval and the portal venous systems are both potential routes for venous drainage; the latter offers the possible advantage of antigens passing directly into the liver. If this organ modifies transplantation antigens then the response of the host to the transplant should be altered. In the pig a kidney allograft with portal venous drainage is tolerated for several months with a mild rejection reaction (Mazzoni, Melis, Demofonti, Valli, Constantini, Francesconi, and Armisi, 1968). The pig liver can modify transplantation antigens coming directly into it through the portal vein. This effect undoubtedly depends on either the quantity of transplantation antigens or the length of time they remain in the liver (May and others, 1969). In order to clarify the influence of one of these factors (quantity of antigens) on the capacity of the pig liver to metabolize such antigens both kidneys (from the same donor) were allografted and anastomosed with portal venous drainage.

MATERIALS AND METHODS

Unselected pigs of different races and of either sex but with erythrocyte compatibility, weighing between 12 and 25 kg., were used. No food was given for 24 hours before the operation. The animals were premedicated with atropine and anaesthetized with halothane. Each pig received 500 ml. of normal saline intravenously. No immunosuppressive therapy or antibiotics were used and blood transfusion was avoided. The animals were given a routine diet 24 hours after receiving the allografts.

The left and right kidneys of the donor animals were isolated. The renal artery was prepared to its origin from the aorta, which was exposed above and below the renal artery. The inferior vena cava was exposed above and below the origins of the renal veins. The ureters were mobilized, paying attention to the arterial blood-supply. Heparin was given during the procedure (2000–3000 U.) Double renal allografts were performed in unselected pigs divided into two groups:—

---

* Based on a paper read to the Surgical Research Society, in January, 1971.

1. **Allografts with Portal Venous Drainage.**— Both kidneys were removed from the recipient and the aorta was prepared from just above the renal arteries. The portal vein was dissected clear, removing any surrounding lymph-nodes. An end-to-side anastomosis was made between the portion of aorta removed with the allograft and the aorta of the recipient. An end-to-side anastomosis was made between the vena cava of the allograft and the recipient's portal vein. The average ischaemic time was 22 minutes. The kidneys were not perfused prior to reimplantation. The corresponding allograft and recipient ureters were anastomosed end to end, bringing the left ureter under the sigmoid colon (*Fig.* 1).

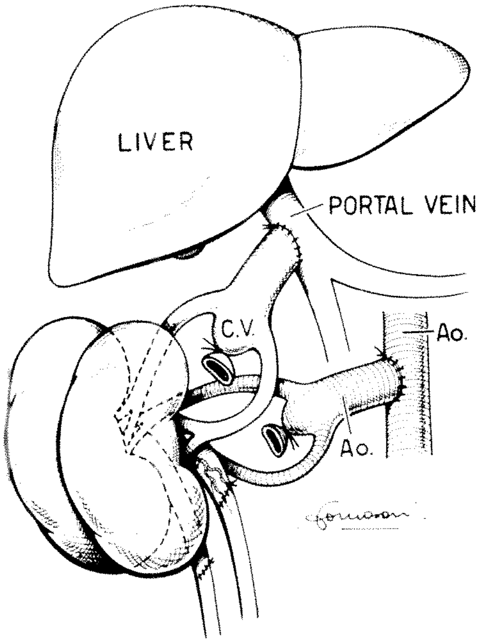

FIG. 1.—Bilateral renal allograft with portal venous drainage.

2. **Allografts with Caval Venous Drainage.**— A similar technique was used, differing only in that the venous anastomosis was made between the vena cava of the allograft and the vena cava of the recipient.

RESULTS

Animals which survived less than 5 days after the operation, dying because of anaesthetic or technical problems, were excluded.

1. **Allografts with Portal Venous Drainage** (10 animals).—Six animals survived more than 30 days and 4 were still alive at 120, 72, 105, 56 days, respectively, after transplantation (*Table I*). Intravenous pyelograms were performed in 4 animals and in 1 (No. 705) an intravenous pyelogram on the fifteenth day showed hydronephrosis in both kidneys. The picture was similar on the thirtieth day. The following day the animal died with a ureteral fistula and peritonitis. In a second animal (No. 706) intravenous pyelograms 15 and 60 days after transplantation showed that one kidney was not functioning while the other appeared to be quite normal. The kidney was explored and found to have a poor blood-supply, probably due to a spasm or torsion of the renal artery. In the other 2 animals (Nos. 707 and 709), which are still alive, intravenous pyelograms carried out 15 and 52 days after transplantation showed both kidneys to be functioning normally. Histological examination was performed in 6 animals. A glomerulitis of an inflammatory type was evident in 1 pig (No. 705) with no signs of rejection. In 4 animals (Nos. 706, 708, 715, and 718) the histological responses were similar, consisting of a very mild mononuclear cell infiltrate with a typical constant distribution around

the small vessels. There was no tubular necrosis or glomerular lesions. In 1 animal (No. 709) a biopsy taken on the sixtieth day showed only a partial and mild perivascular mononuclear cell infiltrate (*Fig.* 2). This animal was still alive 200 days after transplantation.

2. Allografts with Caval Venous Drainage (10 animals).—All the animals in this group died within 15 days of allografting with the exception of 1 which survived for 35 days (*Table II*). Histological examination of the kidneys of these animals showed a massive mononuclear cell infiltrate in the interstitial connective tissue with tubular necrosis. In the single long-term survivor (No. 711) there was a mononuclear cell perivascular infiltrate and glomerular lesions with periglomerular fibrin deposition (*Fig.* 3).

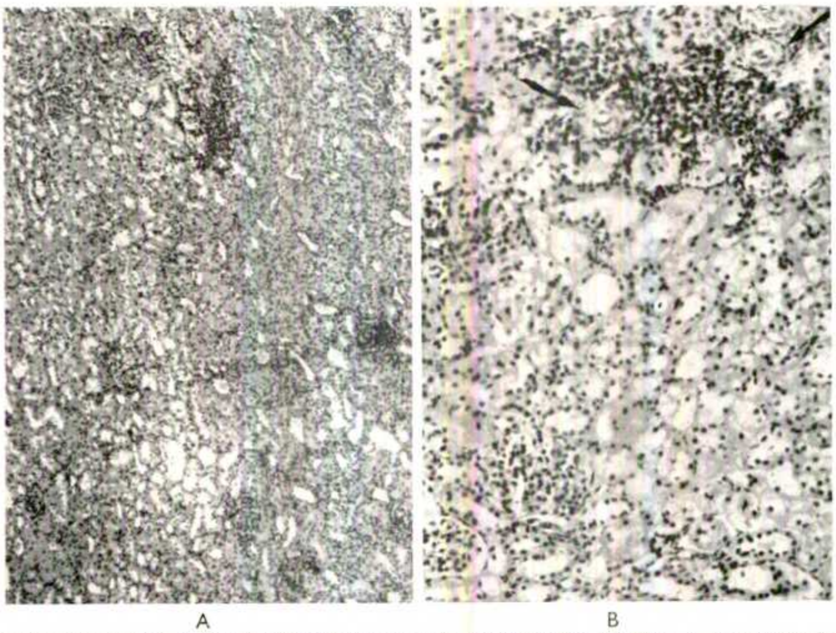

FIG. 2.—Bilateral renal allograft in the pig with portal venous drainage. Kidney biopsy at 60 days. A, Low-power view shows partial mild mononuclear cell infiltration. B, High-power view shows the typical disposition of the infiltration around the vessels. This animal was alive 200 days after transplantation.

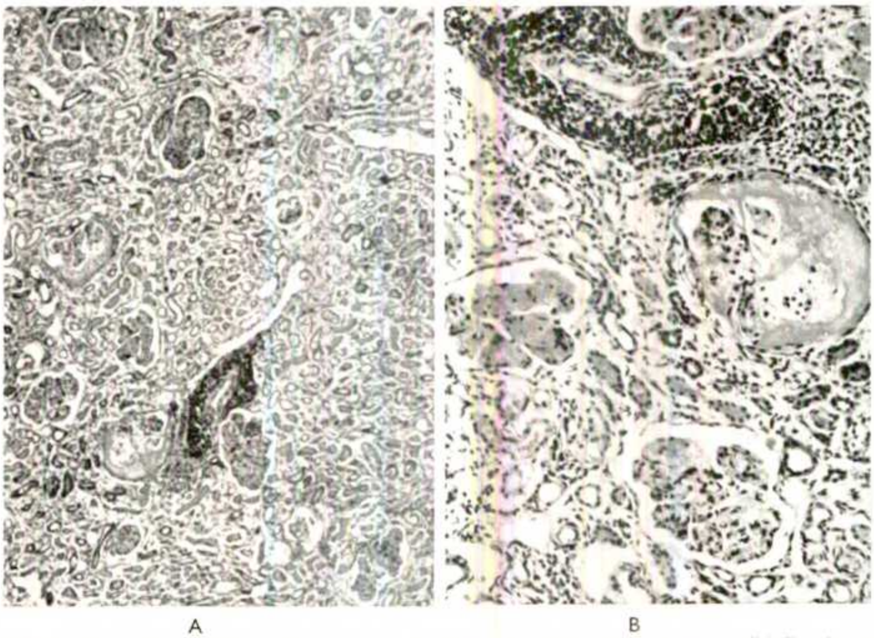

FIG. 3.—Bilateral renal allograft in the pig with caval venous drainage. A, Low-power view showing cell infiltration and glomerular lesions with intracapsular fibrin deposition. B, High-power view. This animal survived for 35 days.

DISCUSSION

The results demonstrate that tolerance is much more prolonged, not only in the case of a single-kidney allograft (Mazzoni and others, 1968; Mazzoni and Melis, 1969; Mazzoni, Di Martino, Melis, Demofonti, Valli, Francesconi, and Pellegrini, 1971), but also when both kidneys are allografted, with portal venous drainage. The average survival time of pigs with portal venous drainage of the renal allograft was 50·9 days, compared with an average survival time with caval drainage of 10 days. This suggests that even a double quantity of transplantation antigens carried directly into the portal vein is degraded so that rejection appears to be prolonged and perhaps abolished. Moreover, histological examination showed the presence of a partial lymphocyte infiltrate in most animals; even in those which survived with good renal function. Some of these animals are still living with no signs of rejection. These results were achieved with no immunosuppressive therapy. It is suggested that such histological responses may be due to processes of a different nature or to quite temporary and reversible immunological processes. This applies only to organs transplanted with portal venous drainage. As far as allografts with caval drainage are concerned, similar but more intensive histological lesions were evident in the grafts and were sufficient to explain death due to rejection. Kidneys allografted with portal venous drainage are tolerated for a long time in the pig but not in other animals. In the mouse and in the dog the same experiment does not prolong the survival time and rejection occurs in a few days (Barker and Corrier, 1967; Fukuda, Hanaoka, Solowey, and Rapaport, 1969; May and others, 1969). The pig is unique in its immunological reactions; for instance, it is the only animal (among those used in experimental surgery) that does not reject the liver allograft, though it does reject other organs (Calne, Davis, Hebertson, Millard, Pena, Salaman, and Sells, 1969). The porcine liver allograft even protects other organs, such as the kidney or the skin, when they are transplanted simultaneously (Calne, Sells, Pena, Davis, Millard, Hebertson, Binns, and Davis, 1969; Calne, Davis, Hadjiyannakis, Sells, Wite, Hebertson, Millard, Joysey, Davis, Binns, and Festenstein, 1970). It has been suggested that the pig may be different from other species and may share similar histocompatibility antigens due to the effect of controlled breeding. Certain strong transplantation antigens present in some strains of pigs are absent in the breeds normally used for transplantation experiments (Calne, Sells, and others, 1969). It has been shown that, using different breeds, and in animals with positive mixed lymphocyte culture reactions, similar results are obtained (Calne, Sells, and others, 1969). Nevertheless, the pig rejects the kidney in the same way and at the same time as other animals (Calne, Davis, and others, 1969; Mazzoni and Melis, 1969; Perper, Gorder, and Bowersox, 1970; Mazzoni and others, 1971). Perper and others (1970) have demonstrated recently that vascularized grafts can survive long periods in moderately immunosuppressed pigs, suggesting that survival of the grafts is not due to enhancement of tolerance but to a low threshold for suppression of the thymus-dependent immune response. Studies on tissue typing are in progress and may give an answer to this question (Vainan, Renard, LaFage, Ameteau, and Nizza, 1970). Other studies on pigs in this laboratory indicate a different lymph-node structure, lack of lymphocytes in the thoracic duct in comparison with the peripheral blood (Binns and Hall, 1966), and a very abundant diuresis. These characteristics, we believe, may explain the results obtained in the present series of experiments.

THE SINGLE THYROID NODULE

By A. PSARRAS, S. N. PAPADOPOULOS, D. LIVADAS, A. D. PHARMAKIOTIS, and D. A. KOUTRAS
ATHENS UNIVERSITY DEPARTMENT OF CLINICAL THERAPEUTICS, AND THYROID SECTION, ALEXANDRA HOSPITAL, ATHENS

SUMMARY

Between November, 1966, and March, 1970, 2736 patients with single thyroid nodules were investigated at the Alexandra Hospital. Females were more frequently affected than males, with a ratio of females to males of about 7 : 1. The right lobe was one and a half times more frequently involved than the left. In both lobes the lower pole was six to eight times more commonly involved than the upper pole. Pathological data after surgical excision were available in 692 of these patients. Malignancy was proved in 81 cases. The overall incidence of carcinoma was 11·7 per cent. Malignant nodules were two to three times more frequent in persons aged below 20 and over 60 and in males than in females. The incidence of carcinoma in cold and warm nodules was 12·8 and 6·6 per cent respectively. No malignancy was found in a hot nodule or in a toxic adenoma. The location of the nodule was not helpful in predicting malignancy. It is concluded that the incidence of malignancy in cold and warm single thyroid nodules is high, and for this reason surgical removal supplemented with replacement therapy is recommended.

THE single thyroid nodule is of special interest to both physicians and surgeons responsible for the clinical management of patients with thyroid disease. This interest arises from the now well-documented risk of malignancy in such cases (Miller, Hamburger, and Mellinger, 1965; Taylor and Psarras, 1967; Koutras, Livadas, Sfontouris, Messaris, and Statherou, 1968).

In the present paper the clinical and isotopic findings in 2736 patients with single thyroid nodules are described. Pathological results are also included when available. It is hoped that this may be helpful in planning the management of patients with single thyroid nodules.

MATERIALS AND METHODS

The case material of the present study consists of 2736 patients with single thyroid nodules who were investigated at the Thyroid Clinic of the Alexandra Hospital in the period between November, 1966, and March, 1970. These cases have been selected from a total of 12,000 patients who were studied with ^{131}I for possible thyroid disease in the same period. A single thyroid nodule was accepted as being any localized enlargement of the gland without an obvious increase in the size of the remaining thyroid tissue.

All the patients were assessed clinically by the criteria of Crooks, Murray, and Wayne (1959), and in all of them the radio-isotope tests previously described by Malamos, Daikos, Samara, and Koutras (1959) were performed. These tests include measurement of the uptake of ^{131}I by the thyroid at 2, 4, 10, and 24 hours, of the $PB^{131}I$ at 48 hours and the performance simultaneously of a dot scan and a photoscan by a Baird Atomic, type 500, apparatus. The position of the nodule on examination and on the scan was recorded. The single thyroid nodules were described as 'hot', 'warm', or 'cold' according to whether the concentration of dots and/or the density in the photoscan showed a higher, an equal, or a lower concentration of radio-iodide compared with the surrounding parenchyma (Koutras and others, 1968). Of these 2736 patients with single thyroid nodules, pathological data after surgical excision were available in 692. The remaining 2044 patients

have not been operated on or have been lost to follow-up.

RESULTS

Patients with a single thyroid nodule constituted 22·8 per cent of the total number of patients investigated for thyroid disease during the period from November, 1966, to March, 1970. This percentage is higher than that obtained in areas of the United States where thyroid disease is not endemic (Vander, Gaston, and Dawber, 1953; Slater, 1956).

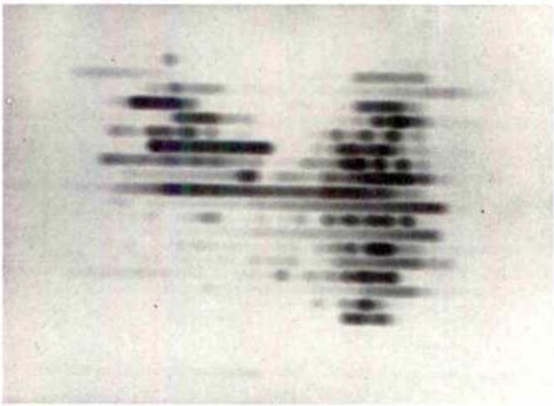

FIG. 1.—Scintiscan showing a cold nodule in the right lower lobe. Histology: nodular colloid goitre.

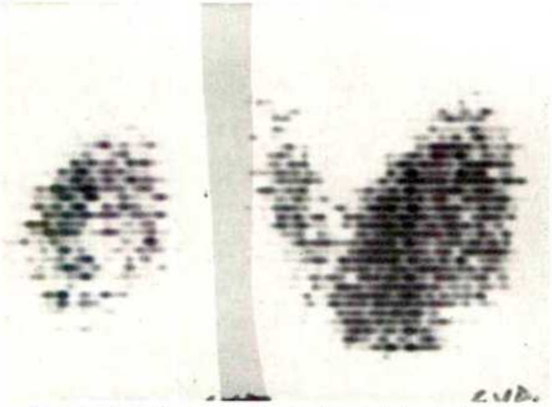

FIG. 3.—*Left*, Scintiscan of a single nodule in the left lobe. Only the nodule takes up iodine whereas the surrounding parenchyma is functionally inert (toxic adenoma). A cold area within the nodule should be noted and was probably due to colloid degeneration. *Right*, After the administration of thyroid-stimulating hormone to the hot nodule, the right lobe and the 'healthy' parts of the left lobe are shown. This confirms the diagnosis of toxic adenoma of the thyroid.

The distribution of the nodules according to the age and sex of the patients is shown in *Table I*, while the distribution according to the location in the thyroid is given in *Table II*.

It can be seen from *Table I* that single thyroid nodules are more frequent in the age-group of 21–40 years, while they are less common at the extreme ages. A high preponderance of females over males in a ratio of about 7 : 1 is evident. The higher incidence of single nodules in females is more or less constant for all age-groups. On the other hand, endemic diffuse goitre affects equally male and female prepubertal children, and it is only after puberty that the female preponderance appears (Malamos, Koutras, Kostamis, Kralios, Rigopoulos, and Zerefos, 1966).

From *Table II* it is clear that the right lobe is more frequently affected than the left one or the isthmus. In both lobes the lower pole is much more commonly involved than the upper pole, which is in agreement with a previous report by Kamba (1970).

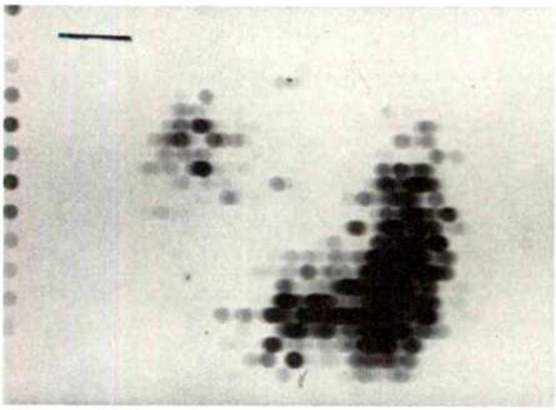

FIG. 2.—Scintiscan showing a cold nodule in the middle of the right lobe. Histology: papillary carcinoma.

Table IV.—HISTOLOGY RESULTS IN 692 SINGLE NODULES IN RELATION TO AGE AND SEX

AGE (years)	BENIGN		MALIGNANT		TOTAL
	No.	Per cent	No.	Per cent	
Below 20	29	76·3	9	23·7	38
21–40	294	90·5	31	9·5	325
41–60	250	90·3	27	9·7	277
61+	38	73·1	14	26·9	52
Total	611	88·3	81	11·7	692
SEX					
Male	78	74·3	27	25·7	105
Female	533	90·8	54	9·2	587

Table V.—HISTOLOGY RESULTS IN 692 SINGLE NODULES IN RELATION TO LOCATION

CLASSIFICATION	RIGHT LOBE		LEFT LOBE		ISTHMUS		BILATERAL		TOTAL
	No.	Per cent	No.	Per cent	No.	Per cent	No.	Per cent	
Benign	313	87·9	236	88·7	57	90·5	5	71·4	611
Malignant	43	12·1	30	11·3	6	9·5	2	28·6	81
Total	356		266		63		7		692

The scintiscan results are shown in *Table III*, and representative examples are illustrated in *Figs*. 1–3. Cold nodules are about eight times more frequent than either warm, hot, or toxic adenomas. Cold and warm nodules together make up 80·4 per cent of the total. Analysis of these results according to the age of the patients shows the great preponderance of cold nodules in all age-groups and particularly between the ages of 21 and 60. Warm nodules are more frequent in patients in the 21–40 age-group, while hot nodules and toxic adenomas are more common in patients aged between 40 and 60.

The overall incidence of carcinoma was 11·7 per cent, i.e., 81 cases proved histologically out of 692 patients. The histology results in relation to age and sex, and location and function of the single nodules are shown in *Tables IV–VI*. Malignant nodules are two to three times more frequent in persons aged below 20 and over 60 and in males than in females. Fifty-four of the 81 patients with malignant disease were women and 27 were men, giving a sex ratio of 2 : 1 compared with more than 7 : 1 in the series as a whole. Forty-three (12·1 per cent) of the nodules in the right lobe were malignant compared with 30 (11·3 per cent) of those in the left lobe and 6 (9·5 per cent) of those in the isthmus. Seventy-eight of the 607 cold nodules and 3 of the 45 warm nodules were proved to be carcinomas, an incidence of 12·8 and 6·6 per cent respectively. No malignancy was found in a hot nodule or in a toxic adenoma.

DISCUSSION

A survey such as the present one would be of little use if it did not help in planning the management of the patient with the disease under discussion. The overall incidence of cancer of the thyroid found is high enough to justify a radical therapeutic approach. Looking through the figures of the present series, the high preponderance of cold nodules is impressive. Furthermore, 12·8 per cent of them were malignant. This figure agrees with previous results in a smaller series from this unit (Koutras and others, 1968). Although this percentage is not as high as in other selected series where figures between 20 and 58 per cent have been found (Saenger, Barrett, Passino, Seltzer, and Dooley, 1964; Miller and others, 1965), it is still considerable. In another large series of 607 cold nodules, Mellière, Massin, Calmettes, Chigot, Savoie, and Garnier (1970) found malignancy in 115, an overall incidence of 19 per cent. The incidence of malignancy in warm nodules in the present series was 6·6 per cent, and this figure questions the advisability of conservative treatment for such nodules which is advocated by some thyroidologists (Astwood, Cassidy, and Aurbach, 1960). No case of malignancy was detected histologically in 27 cases of toxic adenomas, in agreement with the results of others (Taylor and Psarras, 1967).

The preferential location of lesions in the right lobe is probably due to the fact that this lobe is a little larger than the left in 80 per cent of cases (Börner, Moll, and Heller, 1963; Keynes, 1966; Thompson and Jackson, 1969). Kamba (1970) also observed a greater incidence of nodules in the right lobe, but in his case material the difference from the left lobe was not as striking as in the present series. Regarding the isthmus, nodules in this part of the gland may well have arisen in one or other lobe and been forced to the midline by the action of the strap muscles. The slightly greater incidence of cancer in the right lobe does not seem, however, to be statistically significant. There is a slight discrepancy between the numbers of patients with single thyroid nodules who were investigated and those who were operated on, which is probably due to the fact that many of the patients treated surgically elsewhere were lost to follow-up. Since both groups seem to be identical, the results of the analysis of one group should also be applicable to the other.

It may be argued that the groups investigated are highly selected and do not represent the population as a whole. Although the figures of Sokal (1959) and Tellem, Shahl, and Meranze (1961) give a very low incidence of thyroid cancer in the general population, the more exhaustive study of excised thyroid glands such as that carried out at the Mayo Clinic by Mortensen, Bennett, and Woolner (1955) found many tumours which had not been detected during life. On the other hand, it is generally accepted that there has been an increase in the incidence of thyroid cancer in recent years (Colcock and Cattell, 1962; Veith, Brooks, Grigsby, and Selenkow, 1964; Wahner, Cuello, Correa, Uribe, and Gaitan, 1966; Weaver, Nishiyama, Burton, and Bitsakis, 1966). It is possible that many of the thyroid carcinomas which are removed surgically would, if they were not excised, remain clinically silent for the entire life-span of the patient. However, although thyroid cancer has a good prognosis in most of the cases which are treated, it still remains a potentially lethal disease if left untreated (Hirabayashi and Lindsay, 1961). It is generally accepted that the prognosis is closely related to early diagnosis (Woolner, Beahrs, Black, McConahey, and Keating, 1967, 1969). Thus, the problem is, when one is confronted with a patient with a single thyroid nodule, what is the best treatment for this particular case (Meachim and Stainsby, 1966; Taylor, 1968). Unfortunately, there is at present no practical technique for differentiating malignant nodules from benign ones before operation (Groesbeck, 1959; Attie, 1960; Greene, Piercy, and Singer, 1964). Radioactive iodine and scintiscanning give useful information and may make the clinician suspicious of malignancy, particularly in the case of cold and warm nodules, but they are in no way definitely diagnostic. There are a great many other lesions of the thyroid gland which do not take up radio-iodine or take it up to the same extent as the surrounding tissue. Hopefully, thyroid scans with isotopes other than iodine may provide in the future a simple technique for distinguishing between malignant tumours and benign structures, which are both 'cold' in the usual radio-iodine scans, but these techniques require further improvement before becoming generally applicable. Hot nodules and toxic adenomas are practically always benign, but they constitute only a small minority of the thyroid nodules.

Most surgeons prefer to avoid a needle biopsy since there is the real possibility that the tumour may be spread down the needle tract and the subsequent excision of the tumour made more difficult. Mellière and others (1970), however, stress that if aspiration in cystic nodules results in a complete disappearance of the nodule, then malignancy may be excluded, but if the nodule does not disappear completely after aspiration there is a 10 per cent chance of the lesion being malignant. In any case, the policy of this thyroid unit of the Alexandra Hospital, Athens, is to advise every individual with a single thyroid, particularly a cold, nodule to have it excised surgically, and in the case of the very young or the very old or in a male patient at the earliest possible date because the risk of malignancy is higher in these groups of patients (Taylor and Psarras, 1967; Koutras and others, 1968; Smith, 1969; Taylor, 1969).

It could be argued that since over 85 per cent of the thyroid nodules which are removed surgically are finally classified as benign these patients could have avoided an unnecessary operation. On the other hand, thyroid cancer is a slowly progressing diesase (Astwood and others, 1960). However, our policy seems justified in view of the extremely low morbidity with which this operation is accompanied. There have been no serious complications and no patient has died as a result of the operation. When the lesion appeared to be solitary, a complete lobectomy on the affected side was carried out together with the removal of the isthmus and a small slice of tissue from the apparently normal lobe of the opposite side (Crile, 1967; Taylor, 1968, 1969). In this way subsequent enlargement of the gland is made less noticeable. When the lesion proved to be malignant at operation, total thyroidectomy with preservation of at least two parathyroid glands and both recurrent nerves was carried out.

In all the patients in whom a partial or total thyroidectomy was performed replacement therapy was recommended in the form of thyroxine orally not only to provide the patient with an adequate level of thyroid hormone and thus a sense of well-being, but also to suppress the secretion of thyroid-stimulating hormone by the pituitary and thus prevent further growth of the thyroid gland or of any remaining nodular tissue.

THE RELATIONSHIP BETWEEN BLOOD-FLOW AND FAILURE OF FEMOROPOPLITEAL RECONSTRUCTIVE ARTERIAL SURGERY

By H. J. TERRY, J. S. ALLAN, and G. W. TAYLOR

SURGICAL PROFESSORIAL UNIT AND DEPARTMENT OF MEDICAL ELECTRONICS, ST. BARTHOLOMEW'S HOSPITAL, LONDON

SUMMARY

Blood-flow measured at operation in 80 limbs was found to be significantly related to the patency of the reconstruction 12 months later. The incidence of failure was 14 per cent when the flow exceeded 100 ml. per minute and was 54 per cent when the flow was less than this figure.

Although blood-flow was significantly lower in patients with obstructed distal arteries, there were wide variations in flow between limbs with similar degrees of obstruction. There was, however, a significant increase in the failure rate with increasing arterial obstruction, and where two or all three of the tibial arteries were obstructed the long-term failure rate was 48 per cent.

MOST early failures of reconstructive arterial operations occur at once, or within 24 hours of surgery, and it would seem likely that a high blood-flow through the reconstructed artery at the end of the operation would be associated with a low failure rate during the first year. Little has been published on this subject, and the conclusion of Mundth, Darling, Morow, Buckley, Linton, and Austen (1969) that there was no relationship between flow and failure rate conflicts with that of Cappelen and Hall (1967), who found that 4 out of 8 cases failed when the flow was less than 100 ml. per minute, but only 3 out of 33 failed at higher flow rates. This study was therefore undertaken to see whether the patency of the femoropopliteal segment 1 year after surgery was related to the arterial blood-flow on completion of the reconstruction and also whether these two factors were related to the degree of distal arterial disease indicated by arteriography.

Table I.—ANALYSIS OF 80 OPERATIONS (76 PATIENTS) ACCORDING TO TYPE OF OPERATION AND LENGTH OF SUBSEQUENT FOLLOW-UP

DURATION OF FOLLOW-UP	TYPE OF OPERATION			
	Femoral Rebore	Femoro-popliteal Vein-graft	Vein-graft for Popliteal Aneurysm	Femorotibial Vein-graft
12 months	14	43	4	7
Less than 12 months	1	7	0	4
Total	15	50*	4	11*

* One patient died before discharge from hospital.

PATIENTS STUDIED

Eighty limbs from 76 patients were studied. The type of operation is shown in *Table I.*

All patients suffered from atherosclerosis, and in 13 patients there was associated diabetes mellitus. The average age was 59 years. Two-thirds of the patients had ischaemic ulceration or impending gangrene of the extremity concerned. Femoral disobliterations were performed for short occlusions above the adductor hiatus with a minimally diseased popliteal artery, or in more severe disease when no suitable vein was available for a by-pass. In 50 out of the 80 limbs long autogenous vein-grafts were used because of the extensive degenerative arterial disease. Five of the femorotibial and 7 of the femoropopliteal by-pass vein-grafts were of the in situ type with the valves destroyed by retrograde passage of a Foley catheter introducer. In 3 patients the cephalic or basilic vein was used instead of, or in addition to, part of the long saphenous vein. Seventy-two of the limbs studied were sympathectomized. If this had not been done previously, ipsilateral sympathetic ablation was performed at the time of arterial surgery (Terry, Allan, and Taylor, 1970).

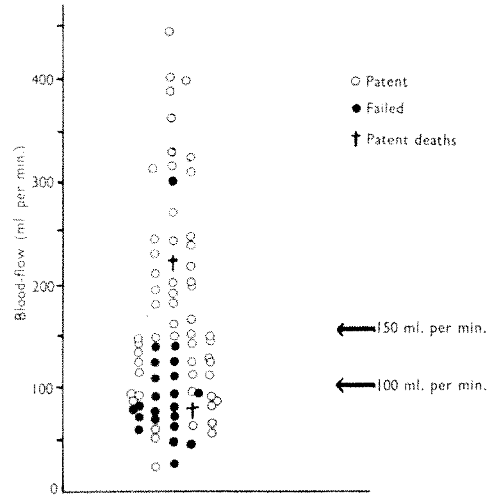

FIG. 1.—Blood-flow through the reconstructed artery (superficial femoral or popliteal artery or vein-graft) measured at operation in 80 patients.

METHODS

Blood-flow was measured at operation after the reconstructed segment was opened and a steady flow was obtained. With vein-grafts the probe was applied to the graft itself and with rebores it was placed below the distal arteriotomy whenever possible. A square-wave electromagnetic flowmeter* was used with cuff probes of type PM. Measurements were continued until the probe was removed just before skin closure.

Arteriographic Appearance.—Most systems for grading the distal arteries according to the degree of obstruction use only three categories. In this study

---

* Type 372, Nycotron, Oslo, Norway.

40 per cent of the limbs would have been placed in the third group—having only one patent tibial vessel or diffuse blocks of all three vessels. In order to evaluate more precisely the relationship of blood-flow to the severity of distal arterial obstruction each limb was placed in one of eight groups, which are listed in *Table II*. Groups 4–8 would all be described as having a poor run-off.

Follow-up.—Two patients with patent grafts died postoperatively. Sixty-six of the limbs have been followed for 12 months, and the remaining 12 for 5–11 months. The average follow-up for all surviving cases was 11·7 months. When there was clinical doubt about patency, ankle and calf pressures were measured using the Parks 801 Doppler flow-detector, as previously described (Allan and Terry, 1969).

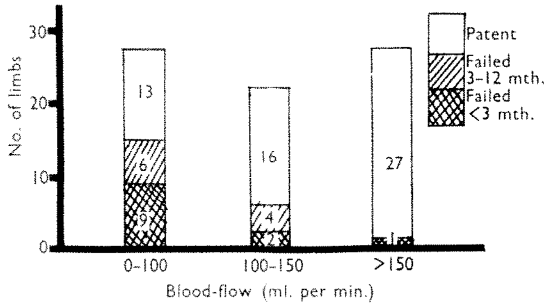

FIG. 2.—The 78 limbs are grouped according to the post-reconstruction blood-flow to show the incidence of failure within 3 and 12 months.

Percentage patency	92·6	72·7	77·7	66·6	60·0	50·0	25·0	50·0

RESULTS

1. Blood-flow and Failure.—*Fig.* 1 shows the blood-flow measured in the superficial femoral or popliteal artery or in the vein-graft of 80 limbs. There were 22 failures within the follow-up period and 2 patients with patent grafts died within 3 months of surgery. Twelve of the failures occurred within 3 months; in 9 of these cases the flow at operation was 100 ml. per minute or less. In *Fig.* 2 the limbs have been divided into three groups according to the flow, and it can be seen that the incidence of failure within 3 months was 3 out of 50 (6 per cent) if the flow exceeded 100 ml. per minute, and 9 out of 28 (32 per cent) if it was less than 100 ml. per minute ($\chi^2 = 6·3$, $0·02 > P > 0·01$).

There were 10 failures between 3 and 12 months after surgery, and the incidence of failure within 12 months was 7 out of 50 (14 per cent) when the flow exceeded 100 ml. per minute and 15 out of 28 (54 per cent) at lower flows ($\chi^2 = 8·6$, $0·01 > P > 0·001$). If one excludes 12 limbs which were followed for less than 12 months (10 patent and 2 failed) the incidence of failure at high flows was 14 per cent and at low flows 58 per cent ($\chi^2 = 8·3$, $0·01 > P > 0·001$).

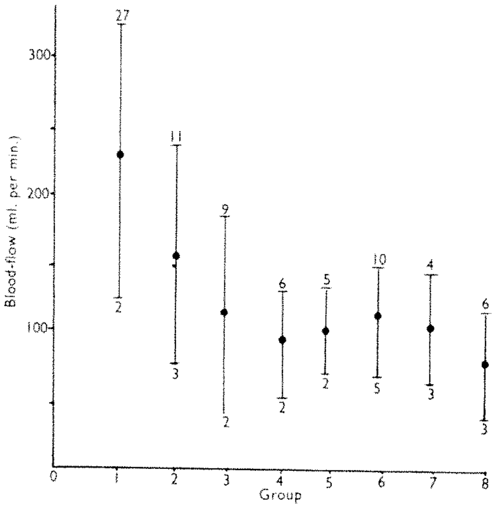

FIG. 3.—Mean blood-flow and standard deviation (S.D.) for the limbs in each group of run-off. For each group the upper figure is the number of limbs in that group and the lower figure is the number of failures within the follow-up period.

2. Arteriographic Appearance and Failure.—After allocating each limb to one of eight groups according to the state of the distal arterial tree the mean flow in each group and the standard deviation (S.D.) were calculated. The results are shown in *Table II* and *Fig.* 3. The fall in mean flow with increasing arterial obstruction is apparent in *Fig.* 3 and is found to be significant (Spearman's rank correlation coefficient, $r = 0·87$, $0·01 > P > 0·001$). In groups 1–3, which had anatomically good run-offs, flow exceeded 150 ml. per minute in 75 per cent of the limbs and 200 ml. per minute in 55 per cent. There was little difference in flow in groups 4–8.

The increasing rate of failure within 12 months as the run-off became worse (*Table II*) is also significant ($r = 0·92$, $P < 0·001$). In groups 1–3 85 per cent of the vessels remained patent, whereas only 52 per cent remained patent in groups 4–8.

DISCUSSION

Cappelen and Hall (1967) claimed that failure within 1 month after in situ femoropopliteal grafts was greater with blood-flows less than 100 ml. per minute. The flows they measured appear to have a similar distribution to those in the present report, although the majority of their cases had excellent or good run-offs. Sako (1967) felt that early failure was more common with flows in the region of 30 ml. per minute, and Mannick, Jackson, Coffman, and Hume (1967), in a study of 14 limb-salvage cases, reported that a critical level for failure could not be given as 1 case with a flow of 15 ml. per minute had remained patent. Little, Sheil, Loewenthal, and Goodman (1968) found in 40 vein-grafts that 80 per cent of those with a flow less than 60 ml. per minute thrombosed within 3 months. However, Mundth and others (1969) found no relationship between flow and failure, peripheral resistance, and the arteriographic run-off in 19 grafts. Some of their cases were followed for less than 3 months and in only 3 limbs did flow exceed 100 ml. per minute.

Table III.—CONTRIBUTING FACTORS IN THE FAILURE OF ARTERIAL RECONSTRUCTIVE SURGERY

Cause of Failure	*No. of Limbs*	*Time of Failure*
3-mm. vein-grafts	2	1 early, 1 late
Vein necrosis at upper anastomosis (3-mm. vein)	1	Early
Patent cusp, in situ vein	1	Primary failure
Vein-graft fistula, in situ vein	1	Late
Intimal dissection	1	Primary failure
Residual shelf after rebore	2	1 primary failure, 1 late
Cardiac failure	1	Primary failure

Selection of cases and operative techniques differ from centre to centre, and it is therefore difficult, in terms of blood-flow, to compare one series with another. Many factors influence the flow during an operation, in particular anaesthetic agents, systemic blood-pressure, the degree of hypo- or hypercapnia, circulating vasopressor agents, and regional or general hypothermia. It is our policy to reduce the physiological component of the peripheral resistance by generous fluid replacement, keeping the limb and body warm with a heated water-filled mattress and, usually, by lumbar sympathectomy. Where this is not done one would expect the immediate post-reconstruction flow to be influenced significantly by the degree of vasoconstriction obtaining in the distal vascular bed.

While the chances of failure with flows less than 100 ml. per minute are undoubtedly high, we would agree with Mannick and others (1967) that one critical value below which a reconstruction must fail cannot be given, as one of our reconstructions with a flow of 20 ml. per minute was patent 2 years after surgery. Some of these grafts will undoubtedly remain patent owing to the head of pressure opening up the distal arterial tree or new collaterals. On serial arteriograms taken at intervals in the postoperative follow-up period progessive dilatation of the tibial vessels may be seen, and in the early postoperative period the systolic ankle pressure may show gradual improvement over 48 hours.

Darling, Linton, and Razzuk (1967), in a study of 295 vein-grafts, felt that the commonest cause of failure related to technical problems at the time of operation, namely a vein-graft less than 4 mm. in diameter, a kinked graft, a difficult distal anastomosis due to a sclerotic popliteal artery, or a poor take-off from the common femoral artery. Baddeley, Ashton, Slaney, and Barnes (1970) were unable to support this view, the commonest cause of failure in their series being progression of atherosclerosis distally. The present study confirms the finding that failure rates are much higher in the presence of advanced atherosclerosis of the distal arterial tree, but other factors are also involved. These are set out in *Table III.* In only 1 of these cases did the flow exceed 100 ml. per minute.

It remains to be explained why primary failure, that is, failure of the reconstruction within the hospital admission period, may still occur when flows in excess of 100 ml. per minute have been recorded. In 1 of 3 such cases in the present series the cause was a technical fault, but in 2 cases no obvious reason was apparent. In our more recent experience primary failure has occurred in 2 vein-grafts where initially a flow in excess of 150 ml. per minute was measured. Both grafts were less than 4 mm. in diameter at the upper anastomosis. One failed as a result of a period of postoperative hypotension and was salvaged by thrombectomy. In the other the graft was inserted at too great a tension and became occluded when the limb was straightened.

After 12 months progression of atherosclerosis may play a part in failure caused by either inflow- or outflow-tract obstruction. However, many grafts will remain patent in the presence of a completely occluded main vessel outflow, and it would appear that a graft becomes more resistant to thrombosis once re-endothelialization of the intima and anastomotic suture lines has occurred. Restenosis of a rebored segment may occur within 12 months, and strictures of vein-grafts at the site of valve remnants have also been recorded; in these situations it is unlikely that peroperative flow measurements bear any relationship to later failure.

THE EFFECTS OF POSTURE, EXERCISE, AND BANDAGE PRESSURE ON THE CLEARANCE OF ^{24}Na FROM THE SUBCUTANEOUS TISSUES OF THE FOOT*

By A. D. B. CHANT†

VEIN CLINIC, CARDIFF ROYAL INFIRMARY

SUMMARY

The effects of posture, exercise, and bandage compression on the clearance of ^{24}Na from the subcutaneous tissues of the foot in 12 control subjects and in 32 patients with venous abnormalities have been investigated. Lowering the foot slowed clearance in the control subjects and in the patients with varicose veins, but no slowing occurred in patients with chronic deep venous thrombosis (D.V.T.). Exercise increased the clearance in the controls but this increase was less in the varicose vein and D.V.T. groups and absent in the group with venous ulcers. Treatment of the patients with varicose veins by sclerotherapy returned their exercise increment in clearance of ^{24}Na to control levels. Bandage compression increased clearance until a maximum was reached at approximately the intravascular hydrostatic pressure. Thereafter it declined. A significantly higher bandage compression was required to produce maximum clearance of ^{24}Na in patients with D.V.T. In two further experiments when bandage compression was maintained at intravascular hydrostatic pressure the effect of posture on clearance was abolished.

These observations indicate that ^{24}Na clearance may be of value in the investigation of patients with venous abnormalities.

THE original study by Kety (1949) on the relationship between the clearance of ^{24}Na and blood-flow led to the use of ^{24}Na clearance in the assessment of peripheral arterial disease. Little has been written concerning the possible use of this technique to assess patients with venous disease. Cooper, Elkin, Shea, and Dennis (1949) and McInally (1952) suggested that a relationship existed between ^{24}Na clearance and the venous system. Their findings were supported subsequently by the studies of Chant (1968).

This paper extends these original observations by studying the influence of posture, exercise, and bandage compression on the clearance of ^{24}Na from the subcutaneous tissues of the foot. The subjects investigated comprised the following groups: (1) Patients with varicose veins, (2) Patients with treated varicose veins, (3) Patients with deep venous thrombosis, (4) Patients with venous ulcers, and (5) Control subjects.

MATERIALS AND METHODS

The mean age and sex ratio of the subjects were similar in all the groups apart from a slight male predominance in the control group. The diagnostic criteria for deep venous thrombosis (D.V.T.) are set out in *Table I*. No D.V.T. was acute. No patient had clinical evidence of arterial disease. The patients in the varicose-vein group had no evidence to suggest deep venous disease but all had incompetent communicating perforating veins.

Table I.—THE DIAGNOSTIC CRITERIA IN THE PATIENTS WITH DEEP VENOUS THROMBOSIS

Experiment No.	*Age* (years)	*Criteria for Venous Obstruction*
13	34	Clinical
14	38	Radiological
15	56	Clinical
34	65	Operative and histological
35	50	Clinical
37	54	Clinical
46	41	Radiological
52	60	Radiological and operative
63	26	Radiological
66	68	Radiological
80	40	Radiological
92	36	Radiological

Investigations were performed in a temperature-controlled room ($27 \pm \frac{1}{2}°$ C.). The patient lay on a tilt table at the bottom end of which was a treadle ergometer. Following a period of acclimatization a subcutaneous injection of 0·1 ml. normal saline containing 3–5 μc. of ^{24}Na was given in the dorsal aspect of the first metatarsal space. Clearance was measured in a horizontal position (k_1) and in a sitting position with the legs supported by the treadle ergometer but sloping downwards at 45° (k_2). Exercise was also performed in this latter position, the patient moving the ergometer for 10 minutes at a work rate of 40 ft. per lb. per minute (k_e). Radioactivity was measured by a scintillation counter (Isotope Development Ltd., Type 7070) and the count rate was recorded on a chart (Elliott Automation Emrec Mk. II). The clearance of the isotope was measured for approximately 10–15 minutes in each position.

The methods of extraction of the clearance constant (k) and interpretation of the exercise are described below.

In 6 subjects (3 in the control group and 3 in the D.V.T. group) after injection of the isotope a sphygmomanometer cuff was used to simulate bandage compression. It was applied to the foot, centred over the site of the injection in order to maintain an even cuff pressure. The cuff was connected to a mercury manometer and inflated stepwise while measurements of radioactivity were taken with the subjects first in position 1 and then in position 2.

---

* Based on a paper read to the Surgical Research Society at Leeds in July, 1968.

† Present address: Lecturer in Surgery, Southampton University.

In 2 further subjects the sphygmomanometer cuff was connected to a saline reservoir with the meniscus kept at heart level whatever the subject's posture. The patient's position was then varied from horizontal to vertical in stages whilst the clearance estimations were made.

Extraction of the Clearance Constant (k) **from the Radioactivity Record.**—Count rates per minute, C (expressed as a percentage of an arbitrary chosen maximal rate), were taken from the radioactivity record at 1-minute intervals. A computer was used to calculate the regression of $\log_e C$ upon times for all experimental periods and subjects. This was done to see whether the disappearance of radioactivity from the site of injection followed an exponential course. The correlation coefficients for these regression lines did not differ significantly from 1. It was concluded that the decline of radioactivity was mono-exponential and that the slope of the regression line represented the clearance constant (k) as defined by Kety (1949).

An interpolation method was used for the measurement of radioactivity during the exercise period. The curve showing the decline of radioactivity during the post-exercise period was extrapolated backwards to the time of termination of the exercise. It was assumed that the decline in local radioactivity from the level at the start to the level at the end of the exercise period had likewise followed a mono-exponential course, and the slope of the semi-logarithmic plot of C against time interpolated as the (k) value for the exercise period. For simplification in the presentation of these results two definitions are made. The term 'postural decrement' is defined as the decrease of ^{24}Na clearance found when the limb is lowered from the horizontal to the vertical position ($k_1 - k_2$), and 'exercise increment' is defined as the increase in ^{24}Na clearance caused by exercise ($k_e - k_2$).

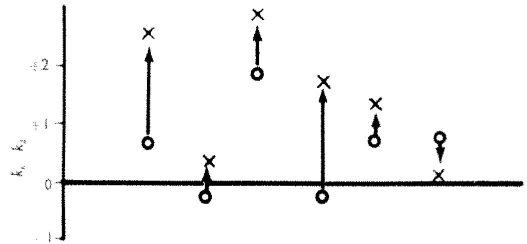

FIG. 1.—Treatment of varicose veins has improved the ability of 5 out of 6 patients to increase clearance on exercise. In the sixth, treatment produced a D.V.T. and no improvement was therefore noted. ○, Pre-treatment. ×, Post-treatment.

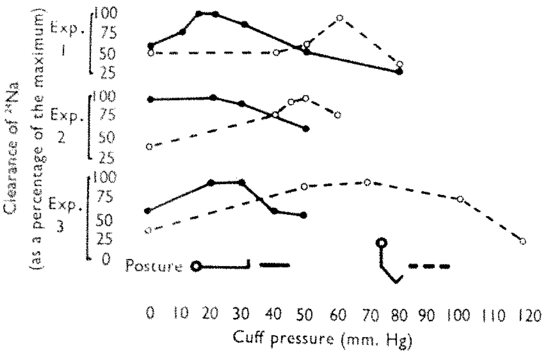

FIG. 2.—Showing the increase in clearance with increased cuff pressure until when cuff pressure exceeds intravascular pressure clearance decreases.

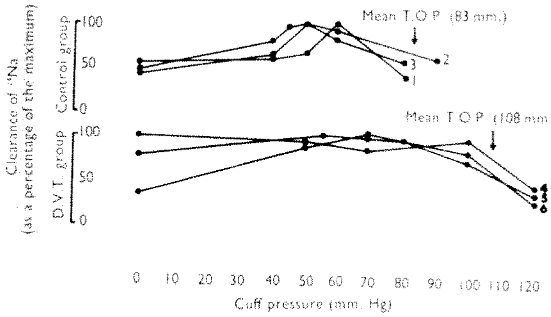

FIG. 3.—Clearance/cuff pressure curve in the vertical position. Note the significantly higher tail-off point (T.O.P.) in patients with diseased veins.

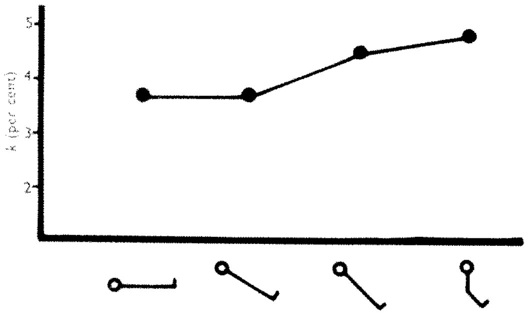

FIG. 4.—The effect on clearance of keeping the cuff pressure equal to the intravascular hydrostatic pressure by means of a saline reservoir. The usual slowing in clearance in the vertical position no longer occurs.

RESULTS

1. Influence of Posture on the Rate of Clearance of ^{24}Na.—The slowing of clearance ($k_1 - k_2$) with dependent posture is shown in *Table II*. In the control subjects there was a marked decrease in ^{24}Na clearance when the leg was lowered. In patients with varicose veins the decrease was similar, and statistically there was no difference between the groups. There is, however, a very marked difference both in the variance ($P < 0.05$) and the mean ($P < 0.001$) when these groups are compared with the D.V.T. group. In the patients with D.V.T. lowering the limb had little effect on the clearance rate. The ulcer patients included cases of D.V.T. and varicose veins. The postural decrement in their case fell midway between these groups.

2. Influence of Exercise on the Clearance of ^{24}Na.—Exercise increased clearance in both the control and the varicose vein groups (*Table II*). In the D.V.T. group, however, this effect was less and in the ulcer group it was absent altogether. The means of the control and the ulcer groups differed significantly ($P < 0.01$).

A trend is apparent from the controls with good veins to the ulcer patients whose exercise increment did not differ significantly from zero. Six patients were investigated before and after treatment of their varicose veins which were mostly confined to the calf. Treatment consisted of injection sclerotherapy to the incompetent perforating veins. Five of the 6 patients showed an increase in exercise increment (*Fig.* 1); the sixth developed a D.V.T. and his exercise increment was reduced.

Table II.—CLEARANCE CONSTANTS IN POSITIONS 1 AND 2 AND ON EXERCISE

GROUP	NO. OF PATIENTS	k_1	k_2	k_e	$k_1 - k_2 \pm$ S.D.	$k_e - k_2 \pm$ S.D.
Control	12	4·1	2·0	3·1	2·0 ± 1·0	1·1 ± 0·4
Varicose veins	12	3·8	1·6	2·3	2·2 ± 1·3	0·8 ± 1·2
D.V.T.	12	2·1	1·7	1·8	0·3 ± 0·5	0·1 ± 0·7
Ulcers	8	3·8	2·2	2·2	1·7 ± 1·7	0·0 ± 0·7

3. Influence of External Cuff Pressure on Clearance of ^{24}Na.—The result of increasing the cuff pressure was to increase clearance up to the point when the cuff pressure approximately equalled the intravascular hydrostatic pressure, when the rate of clearance fell (*Fig.* 2). The cuff pressure at which definite evidence of a fall in clearance (20 per cent maximum) had been obtained was called the 'tail-off point'. It can be seen from *Fig.* 3 that the average tail-off point for the disease group in the vertical (2) position occurred at a significantly higher value ($P < 0\cdot05$) than in the controls. In the final group of experiments the cuff pressure was maintained at the hydrostatic pressure within the vessels by means of a saline reservoir. The effect of this was to abolish the usual slowing in clearance found in dependent postures. If anything a slight increase occurred (*Fig.* 4).

DISCUSSION

The association of peripheral oedema with venous disease is well recognized. Indeed the various treatments of venous disease, for example, injection of incompetent perforating veins and bandaging, are often directed towards relieving oedema. It would seem likely therefore that if the movement of oedema or tissue fluid could be traced this measurement might form a rational basis for an objective assessment of venous disease and its treatment. It would appear from the present studies that this is now possible. Thus, in the posture experiments clearance slows when the limb is lowered; this corresponds to the pooling noted both clinically in the form of oedema and by previous plethysmographic studies (Mellander, Oberg, and Odelram, 1964). During exercise the clearance rate of ^{24}Na increases in the same way that oedema decreases.

This analogy is supported further by the results demonstrated between clearance and bandage pressure. Although similar experiments have been performed using Xe (Campion, Hoffman, and Jepson, 1968) the initial increase in clearance with pressure has not been demonstrated previously. This increase in clearance coincides with an increase in femoral vein blood-flow (Spiro, Roberts, and Richards, 1970). Doubt was cast on the interpretation of these experiments (Chant, 1970). It is interesting to note that subsequent experiments (Sabri, Roberts, and Cotton, 1971) showed this increase in flow to be time-dependent and probably due in part to the emptying of the veins on compression and partly to the removal of tissue fluid by pressure. Provided, therefore, that bandage pressure never exceeds intravascular hydrostatic pressure, then bandaging limits the formation of oedema but does not increase the vascular resistance to the detriment of blood-flow. It also appears from the sphygmomanometer cuff experiments that in patients with D.V.T., higher bandaging pressures are necessary than in control subjects. Accurate bandaging, however, presents problems. Intracapillary pressure varies with posture and exercise; it is also graded from the toe to the right atrium. A conventional bandage, therefore, to produce maximal clearance should be applied with 'tight turns at the bottom, loose turns at the top'. This type of bandage works loose and in any case is relevant only to the posture in which it is applied. The theoretically perfect hydrostatic stocking described by Wood (1968) would seem to provide an answer from the tissue perfusion viewpoint, and this is substantiated by the present experiments (*Fig.* 4).

So far the results are compatible with the concept that changes in ^{24}Na clearance parallel the movement of tissue fluid. However, the difference found in the postural response to the lowering of the limb between the control and the D.V.T. groups would on preliminary examination appear to be against this interpretation. If, as was previously supposed, the clearance of an isotope reflects blood-flow, then the decrease in clearance demonstrated in the control subjects is due to a vascular postural reflex such as the one postulated by Gaskell and Burton (1953). If this is correct then in the D.V.T. group one must assume that the disease process has in some way interfered with the reflex. There is, however, an alternative explanation which once more fits in with the concept of tissue-fluid pooling. It is likely that in cases of D.V.T. the consequent venous hypertension has led to the formation of oedema. It is probable that the oedema forms a sheath around the veins and acts in a manner similar to the hydrostatic stocking demonstrated in *Fig.* 4, thus limiting changes in clearance.

The relationship between the clearance of ^{24}Na, posture, and exercise has been shown to differ in health and disease. To assess the possible clinical application of this finding in diagnosing chronic deep venous obstruction a prospective study involving larger numbers of patients is indicated; the significant difference in the postural decrement between healthy subjects and patients with obstructed veins suggests that this is practicable, and this is supported by the findings in 1 patient in whom a diminished postural decrement predicted previously unsuspected deep-vein disease (*Table I*, experiment 52). Similarly, the exercise increment also seems to relate to the patient's venous state. The patients with the lowest exercise increment values were those with venous ulcers, while those with the highest were the control subjects. It seems likely therefore that this relationship provides the basis for the objective evaluation of treatment in venous disease. The assessment of varicose veins before and after treatment (*Fig.* 1) illustrates the potential use of the method; here the incompetent perforating veins which contribute to the inefficiency of the calf pump in such cases have been sealed by sclerosant and the exercise increment in clearance improved.

Acknowledgements.—I am grateful to Mr. H. O. Jones, Consultant Surgeon, Cardiff, for help in embarking on this research; the Ministry of Health for financial support; Dr. E. A. Ullman, St. Bartholomew's Hospital, London, and Mr. R. A. D. Booth, University of Southampton, for helpful criticisms; the Photographic Departments at Southampton University and Cardiff United Hospital, and also Miss S. Knight for the illustrations; and Mrs. J. A. Daniels for secretarial assistance.

The radiation dosage and the plan of the experiments were approved by the Medical Research Council.

PERSISTENT AND RECURRENT HYPERPARATHYROIDISM

BY ORLO CLARK* AND SELWYN TAYLOR

ROYAL POSTGRADUATE MEDICAL SCHOOL AND HAMMERSMITH HOSPITAL, LONDON

SUMMARY

During the past 11 years at Hammersmith Hospital 11 patients have had parathyroid operations following a previous neck exploration. Six had persistent hyperparathyroidism and 5 had recurrent hyperparathyroidism with a 'lucid interval' of biochemical normality of from 5 months to 11 years. Successful results were obtained in 9 of the 11 patients after a total of 29 operations, 4 of which were combined with sternotomy. The reasons for failure at operation and the medical and surgical management of these patients are reviewed.

EVER since Mandl (1926), a Viennese, performed the first successful parathyroidectomy on 30 June, 1925, surgery has been the accepted mode of therapy for hyperparathyroidism, with excellent results. Indeed, Black and Ackerman (1950) claimed that the surgical treatment of this condition was more certain and satisfactory than that of any other surgical endocrinopathy, including disease of the thyroid. Despite this assertion, there are still unsuccessful parathyroid operations even in expert hands. Probably the most famous of these was Charles Martel, a sea-captain, whose history was so graphically told by Fuller Albright in his Presidential address to the American Endocrine Society in 1948. Captain Martel had 7 operations over a period of 6 years, with the removal of two normal parathyroids and a total thyroidectomy before the offending parathyroid adenoma was removed from the anterior mediastinum by Edward D. Churchill.

The incidence of unsuccessful or 'failed' first operations for hyperparathyroidism varies. Unsuccessful or 'failed' in this context means that the condition is not permanently cured following operation. Failure may occur despite the removal of one or more tumours if there is primary chief-cell hyperplasia or there are multiple parathyroid adenomas. In contrast, 'some cures' occur when no parathyroid tissue has been removed.

Hellstrom and Ivemark (1962) reported 25 failures in 138 patients, Chamberlin, Nicholas, and Hanka (1963) 11 in 48, and we have had 6 in 99 patients. Cope, Barnes, Castleman, Mueller, and Roth (1961) reported 51 failures in 299 patients, but many of their operations were performed for diagnostic reasons.

During the past 11 years at Hammersmith Hospital 11 patients have required parathyroid operations following previously unsuccessful exploration. Five of these patients had recurrent hyperparathyroidism after a definite lucid interval and 6 had persistent hyperparathyroidism. Nine of the 11 patients were referred after unsuccessful operations elsewhere. The problems which these 11 patients presented and their management are discussed here.

The patients presented here compare in age and sex distribution with those of most other reported series. There were 7 women and 4 men with a mean age of 40 years. Two patients had a family history of endocrine disease. *Table I* lists the primary clinical manifestations which brought the patients to seek advice. In contrast to most reviews and our own total series of 99 patients with hyperparathyroidism, where the majority of symptoms related to renal involvement, 4 of the 11 patients presented with bony lesions of the jaw. Three patients complained of renal colic, 1 had painless haematuria, and 1 was found to have nephrocalcinosis. Two patients presented with dyspepsia; 1 had a duodenal ulcer and Zollinger-Ellison syndrome, while the other had developed an anastomotic ulcer 2 years following a partial gastrectomy for duodenal ulcer. Depression, accompanied by anorexia, nausea, and vomiting, was the diagnostic lead in another patient.

---

* Present address: Department of Surgery, University of California, San Francisco.

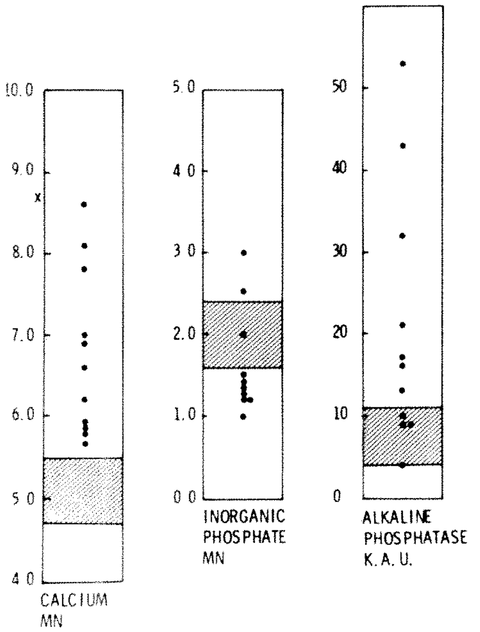

FIG. 1.—The results of the biochemical tests carried out in 11 patients.

Table I.—THE MAIN PRESENTING COMPLAINTS IN 11 PATIENTS

Clinical Complaint	*No. of Patients*	
Skeletal	4	
Jaw lesions		4
Renal	4	
Colic		3
Haematuria		1
Peptic ulcer	2	
Duodenal ulcer		1
Anastomotic ulcer		1
Mental	1	
Depression		1

Many of the patients had associated conditions which are listed in *Table II*. Hypertension, with a mean diastolic blood-pressure greater than 90 mm. Hg, was present in 6 patients and tended to be labile. Its onset was usually within 1 year of the diagnosis of hyperparathyroidism. Two were treated with antihypertensive drugs prior to parathyroidectomy. Following successful operation the blood-pressure returned to normal in 2 patients, but remained elevated in the others. Following unsuccessful parathyroid operations there was no permanent change in blood-pressure although in 1 patient it decreased for several days. During this time her serum calcium was also normal.

Radiological evidence of hyperparathyroidism was present in 8 patients when they were admitted for persistent or recurrent hyperparathyroidism. Four of these 8 patients had cystic lesions without evidence of subperiosteal resorption in their phalanges. The skeletal changes of osteitis fibrosa cystica recurred in 6 patients and in all of them the jaw was affected, being the only bone affected in 2 cases. Two patients had associated pathological jaw fractures, two of the lesions were excised radically and irradiated, and 1 of these patients also received chemotherapeutic drugs. It is of note that of the 4 patients with cystic bone changes but no subperiosteal resorption 3 had normal alkaline phosphatase and the fourth, in whom the alkaline phosphatase was elevated, had associated Paget's disease. Two of the patients with normal alkaline phosphatase, previously had typical subperiosteal resorption which disappeared following the first parathyroid exploration. The patient with Paget's disease and hyperparathyroidism had an invasive tumour which threatened breakdown of the overlying skin, necessitating surgical intervention. It seems that the combination of hyperparathyroidism and Paget's disease may present a more aggressive situation, and Jaffe (1958) reported that osteoclastoma unassociated with hyperparathyroidism is rare in the jaw except in Paget's disease. An interesting finding was profound muscular weakness in 3 patients; it involved all the muscle groups without any associated atrophy or tenderness but improved following successful parathyroidectomy.

Table II.—THE PHYSICAL SIGNS AND ASSOCIATED CONDITIONS IN 11 PATIENTS

Signs and Conditions	*No. of Patients*	
Hypertension	6	
Osteitis fibrosa cystica	6	
General		4
Local		2
Corneal calcification	5	
Renal involvement	6	
Nephrocalcinosis		2
Nephrocalcinosis + calculi		1
Nephrocalcinosis + renal tubular acidosis		1
Renal calculi		2
Muscular weakness	3	
Peptic ulcer	3	
Pluriglandular syndrome	1	
Paget's disease	1	
Carcinoma of the breast (resected)	1	
Abnormal sella turcica	1	

DIAGNOSTIC TECHNIQUES

The results of the biochemical tests are shown in *Fig.* 1. All the patients had hypercalcaemia, 8 had a low serum phosphate, and 7 had an elevated alkaline phosphatase.

It was particularly important to confirm the diagnosis of hyperparathyroidism and the tests which were most valuable in this respect included the phosphate excretion index, which was increased in all 8 patients in whom it was performed, and the cortisone-suppression test, which showed no suppression in the 5 patients in whom it was done. The cortisone-suppression test was useful in eliminating sarcoidosis and vitamin-D intoxication (Dent, 1956). Other tests included calcium-turnover studies (^{45}Ca/^{47}Ca), parathyroid-hormone immuno-assay, urinary calcium and hydroxyproline levels, and the histoloy of bone biopsy.

* Operation at Hammersmith Hospital.

Localizing procedures are useful in patients who have had previous parathyroid explorations, not only because extensive adhesions are encountered, but also because of the greater possibility that the parathyroid tumour is in an unusual position. Procedures used to localize the parathyroid tumours at Hammersmith Hospital were barium swallow, thyroid scanning, thermography, selenomethionine-75 scanning, arteriography, blue dye, and selective venous catheterization with parathyroid hormone immuno-assay. Barium swallow was of value in 2 patients and in 10 of the 99 of the entire series. It is probably the most useful of the non-specific tests. It was misleading in 6 patients, usually because of coexisting thyroid nodules. Thyroid scanning was of value in 1 patient in whom the normal outline of the thyroid was distorted. Thermography has only been used recently and has so far been disappointing. 'Hot spots' have frequently been seen on the thermogram preoperatively, but have not corresponded with the position of the tumour at operation. Of interest, however, is that the 'hot spot' has disappeared when tests have been repeated after parathyroidectomy. Selective arteriography has been performed in 4 patients and was successful in suggesting the position of the tumour in 2 but was misleading in 1. Three of the studies were percutaneous retrograde catheterizations and 1 patient had an unsuccessful operative left inferior thyroid arteriogram. In 1 of the 2 successful arteriograms there was vessel deviation and in the other there was a suggestion of a tumour blush. Although more specific than either barium swallow or thyroid scanning, arteriography has a definite morbidity and is time consuming. Ortho-toluidine blue has been used on four occasions, but was not helpful.

Selective venous catheterization and parathyroid hormone immuno-assay was performed in 3 patients and was successful in 1. The procedure has the advantage of being specific and of localizing even small hyperfunctioning tumours. In 2 patients it was not helpful because there was very little difference in the concentration of parathyroid hormone at the various assay sites. Certainly patients with multiple hyperplastic glands and those who have had previous neck operations present difficult problems in the interpretation of this procedure. Barium swallow has been used in almost all of the 99 patients in the series, whereas the other tests have been employed selectively and especially in those who have had previous neck surgery.

RESULTS OF SURGERY

The 11 patients have had 29 neck explorations, 4 of which were combined with sternotomy. Fifteen operations were performed prior to transfer to Hammersmith Hospital and 14 were carried out at this hospital. Successful results were ultimately obtained in 9 of the 11 patients. Successful initial secondary operations occurred in 7 patients but 2 patients required two procedures and 1 patient needed three explorations. The term 'successful' is used if the serum calcium returns to normal. In 1 patient the serum calcium returned to normal despite the failure to demonstrate any parathyroid glands during the operation. Two other patients had an unsuccessful operation and their hyperparathyroidism continues.* Both patients are asymptomatic and are being treated with effervescent phosphate and a low-calcium diet.

The main reasons for an unsuccessful exploration include multiple tumours (adenomas or hyperplasia), ectopic position of the tumour, small size of the tumour, inadequate exposure, lack of meticulous dissection in a dry field, confusion with thyroid adenoma, contused tumour, and tumour spillage. Multiple parathyroid tumours were found in 10 patients, of whom 6 had multiple adenomas and 4 had primary hyperplasia of all four glands. Three of the patients with multiple adenomas had recurrent hyperparathyroidism after lucid intervals of 14 months, 23 months, and 11 years respectively. As stated by Kleinfeld (1959), it is impossible to know whether their recurrent hyperparathyroidism was due to a recurrent or a missed adenoma. Two other patients, 1 with primary nodular hyperplasia and another who had three normal glands removed, had recurrent hyperparathyroidism.

Although all the tumours in these 11 patients were greater than 1·1 cm., smaller ones are not uncommon and 6 patients in the entire series of 99 patients with hyperparathyroidism had tumours weighing less than 100 mg. and measuring 1 cm. in diameter. Inadequate exposure and lack of meticulous dissection in a dry field are important and were responsible for failure in at least 1 patient. Differentiation from thyroid adenomas is at times difficult and frozen sections are then essential. When parathyroids are manipulated they frequently change colour like a chameleon and may then resemble the thyroid. Therefore a careful look at the surface of the thyroid gland should always be carried out before any manipulation. The importance of resecting the parathyroid tumour without spillage was referred to by Black and Ackerman (1950). They report 1 case of their own and 1 other (de Wesselow and de Wardener, 1949) in whom recurrent hyperparathyroidism was due to the presence of multiple recurrent pieces of parathyroid tissue. One of the cases reported here may have a similar aetiology as eight pieces of parathyroid were removed before the serum calcium returned to normal. Gentle but complete removal of all parathyroid tumours is thus essential.

The histology of the parathyroid tumours as well as the dates of resection, size, weight, and position are listed in *Table III*. There were no deaths from the secondary operations but 4 complications occurred, the most significant being recurrent laryngeal nerve injury. In the primary operations there was 1 death in a 62-year-old man who was admitted in a comatose dehydrated state with azotaemia, pancreatitis, and ilio-femoral and renal vein thrombosis. He died of cardiac arrest 24 hours after successful removal of a parathyroid tumour.

There were 2 recurrent laryngeal nerve injuries in 88 patients having their first parathyroid operation. One was of a transient nature and first became noticeable 4 days following operation, and the other was due to a recurrent laryngeal nerve which traversed the capsule of a 28-g. parathyroid tumour. In the patients undergoing secondary operations there were 2 recurrent laryngeal nerve injuries. One followed total thyroidectomy and the other occurred after a combined neck and mediastinal exploration. One was bilateral and required tracheostomy for 4 years, and the other resulted in a right vocal cord paralysis which eventually resolved spontaneously.

As seen from this review, patients requiring secondary operations for hyperparathyroidism present formidable problems and an increased risk of surgical morbidity, but the overall results are very acceptable. Localizing procedures are helpful and worth while prior to secondary operations. The difficulties encountered in these secondary operations emphasize the importance of a thorough exploration at the first operation. The surgeon must be patient and prepared to give time to what may be a long and tedious dissection to find a very small adenoma which is occasionally not much larger than a normal parathyroid gland. Even following identification of an obvious tumour and three other normal parathyroids the problem may not be resolved and life-long follow-up is recommended.

Acknowledgements.—We are greatly indebted to our colleagues in endocrinology, radiology, and pathology and in particular Professor Russell Fraser and Professor Iain MacIntyre and Dr. Joplin, Dr. Doyle, and Dr. Woodhouse. Dr. O'Riordan of the Middlesex Hospital performed the parathyroid immuno-assays and Professor Steiner carried out the venous catheterization.

THE EFFECT OF REMNANT SIZE ON THE OUTCOME OF SUBTOTAL THYROIDECTOMY FOR THYROTOXICOSIS

By A. J. HEDLEY,* W. MICHIE, T. DUNCAN,† G. HEMS, and J. CROOKS*

DEPARTMENTS OF THERAPEUTICS AND PHARMACOLOGY AND SOCIAL MEDICINE, UNIVERSITY OF ABERDEEN AND ABERDEEN ROYAL INFIRMARY

SUBTOTAL thyroidectomy is widely employed as a method of destructive therapy for thyrotoxicosis, especially in young patients in whom treatment with radio-iodine is usually avoided in this country. A review in 1967 (Leading article, *Lancet*, 1967) stated: 'subtotal thyroidectomy . . . offers the surest and most permanent relief . . . with a relapse rate of 8 per cent and an incidence of hypothyroidism around 5 per cent'. The writer did indicate, however, that our knowledge of the long-term results of surgical treatment is still incomplete. This view is confirmed by examining the reported morbidity figures from different centres for the past 10 years. The incidence of hypothyroidism varies from 3 to 28 per cent, recurrent hyperthyroidism from 1·2 to 22 per cent, and total morbidity from 4·8 per cent (Reeve, 1964) to over 30 per cent (Wilson, 1967). The great variation in these figures is difficult to explain and may reflect differences in the methods of assessing postoperative thyroid status as much as the type of surgery which has been performed.

The results of treatment of thyrotoxicosis with radio-iodine are more predictable in that there is only one major factor which determines the outcome. The effect of ionizing radiation on the replicative mechanism of thyroid follicular cells leads to hypothyroidism in a significant number of patients within their lifetime (Greig, 1965; Philp, 1966), and is probably not influenced in the long term by factors such as the presence of thyroiditis (Irvine, 1967) or modifications of dosage régimes (Philp, Harrison, Ridley, and Crooks, 1968). In contrast, there appear to be several factors which may markedly influence the response to surgical treatment, and their relative importance has still not been clearly defined. One of these is likely to be the size of the thyroid remnant, and this paper examines the relationship between this factor and the eventual thyroid status of patients treated by subtotal thyroidectomy.

PATIENTS AND METHODS

Retrospective Studies.—

a. In a retrospective study of 146 unselected patients who had been treated for thyrotoxicosis by subtotal thyroidectomy between 2 and 21 years (mean 9·4 years) previously in the same surgical unit postoperative thyroid status has been related to the remnant weight which was estimated at operation. In these patients the operative procedure was designed to leave a remnant of approximately 3–6 g. The methods used to define the thyroid status of the patients have already been reported (Hedley, Flemming, Chesters, Michie, and Crooks, 1970).

b. In a separate study the surgeon's estimate of remnant weight has been correlated with the incidence of hypothyroidism in 200 female and 38 male patients treated for thyrotoxicosis by subtotal thyroidectomy between 1965 and 1969 inclusive.

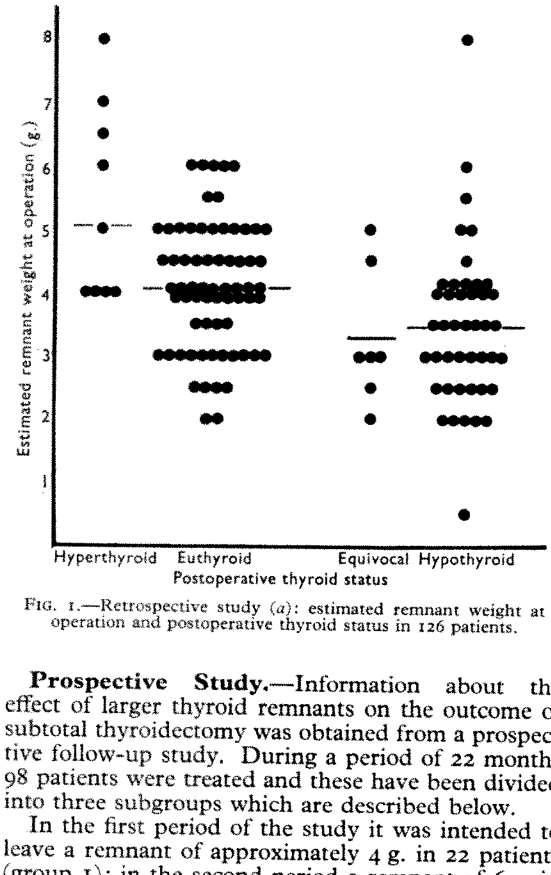

FIG. 1.—Retrospective study (*a*): estimated remnant weight at operation and postoperative thyroid status in 126 patients.

Prospective Study.—Information about the effect of larger thyroid remnants on the outcome of subtotal thyroidectomy was obtained from a prospective follow-up study. During a period of 22 months 98 patients were treated and these have been divided into three subgroups which are described below.

In the first period of the study it was intended to leave a remnant of approximately 4 g. in 22 patients (group 1); in the second period a remnant of 6 g. in 46 patients (group 2); and in the third period a remnant of 8 g. in 30 patients (group 3).

Cadaver Study.—The accuracy of subjective estimation of remnant weight by individual surgeons was assessed by experiments in cadavers. Two surgeons experienced in thyroid surgery (W. M. and T. D.) carried out subtotal thyroidectomy procedures in 19 cadavers. Estimates were made of the weight of each remnant in situ and also of the two portions of resected tissue. The remnants were then removed totally and the estimated weights of both parts of the gland were compared with the actual values obtained by weighing.

RESULTS

Retrospective Studies.—

a. This retrospective study revealed that in the 146 patients successfully followed up 36 per cent were hypothyroid at the time of the review, and in a further 5 per cent (graded as 'equivocal') some evidence of thyroid insufficiency was revealed by a therapeutic trial with thyroxine but they were not classed as hypothyroid by the criteria that we employed. A total of 6 per cent had developed recurrent hyperthyroidism at some time since operation. The estimate of remnant weight made at operation was available for 126 of these patients (*Fig.* 1). The mean estimated remnant weight of the euthyroid patients was significantly greater than in those with hypothyroidism ($P < 0{\cdot}005$) and smaller than in those with recurrent hyperthyroidism ($P < 0{\cdot}05$). However, the differences between the means of these three groups were small, being less than 1 g. in either direction, and there was extensive overlap in the estimated remnant weight for all three thyroid status categories (*Table I*). Six patients had a second operation for recurrent hyperthyroidism and in each case the estimated size of the second remnant was comparable to the first but 5 of the 6 patients had a further recurrence of hyperthyroidism.

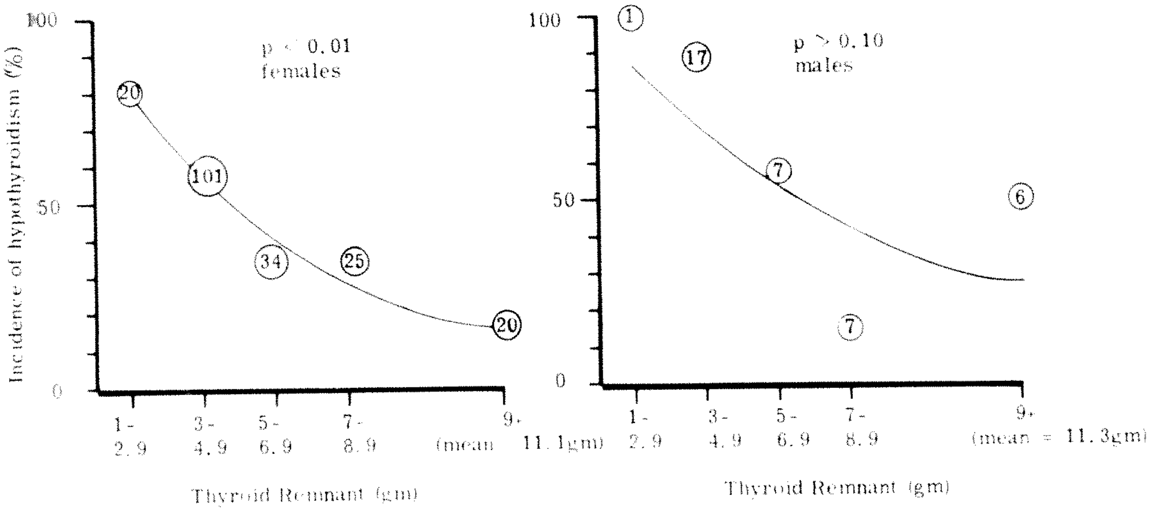

FIG. 2.—Retrospective study (*b*): relationship between the estimated remnant weight and postoperative hypothyroidism.

b. Estimated remnant weights for the 200 female and 38 male patients were divided into four categories covering the range from 1 to 9 g. or over. The proportion of patients with hypothyroidism in each remnant weight category is shown in *Fig.* 2. In the females the decrease in the incidence of hypothyroidism with increasing remnant size is highly significant ($P < 0{\cdot}01$), and a similar but less consistent trend was found in the small group of males ($P > 0{\cdot}1$). The data suggested a curvilinear relationship between the incidence of hypothyroidism and remnant weight, and the curves in *Fig.* 2 were fitted assuming a semilogarithmic relationship. Thus, as the remnant size increased the accompanying decrease in the incidence of hypothyroidism would become progressively smaller, suggesting that, in some patients, factors other than remnant size are more important causes of hypothyroidism.

Prospective Study.—The decision to leave a larger thyroid remnant at operation was followed, as would be expected, by an increase in the mean estimated remnant weight (*Table II*). The mean weight (4·19 g.) for group 1 was significantly ($P < 0{\cdot}001$) smaller than the means for group 2 (6·52 g.) and group 3 (7·33 g.). Mean remnant weights for groups 2 and 3 did not differ significantly. When, however, the thyroid status of each patient was defined at

Table I.—RETROSPECTIVE STUDY: NUMBER OF PATIENTS AND POSTOPERATIVE THYROID STATUS COMPARED WITH THE MEAN AND RANGE OF ESTIMATED REMNANT WEIGHTS AT OPERATION

THYROID STATUS	NO. OF PATIENTS	ESTIMATED REMNANT WEIGHTS (g.)	
		Mean ± S.E.M.	Range
Euthyroid	67	4·2 ± 0·14	2–6
Equivocal	7	3·3 ± 0·41	2–5
Hypothyroid	43	3·5 ± 0·18	0·5–8
Recurrence	9	5·1 ± 0·43	4–8
Total	126		

Table II.—PROSPECTIVE STUDY: NUMBER OF PATIENTS WITH THE MEAN AND RANGE OF ESTIMATED REMNANT WEIGHTS AT OPERATION

TREATMENT GROUP	NO. OF PATIENTS	ESTIMATED REMNANT WEIGHTS (g.)		DIFFERENCE BETWEEN GROUPS
		Mean ± S.E.M.	Range	
1	22	4·19 ± 0·299	2·0–7·0	1 and 2, $P < 0{\cdot}001$
2	46	6·52 ± 0·35	3·0–14·0	1 and 3, $P < 0{\cdot}001$
3	30	7·33 ± 0·34	3·5–12·0	2 and 3, $0{\cdot}1 > P > 0{\cdot}05$

12 months after operation it was found that the change in policy at operation had been accompanied by only a small and not significant ($\chi^2 = 0{\cdot}441$, d.f. $= 2$) decrease in the percentage of hypothyroid patients (*Table III*). The explanation is likely to be that although a new surgical policy was adopted there must necessarily be considerable variation in effective size of the remnant fashioned in individual patients because of such factors as initial size, consistency, vascularity, and the degree of thyroiditis in the gland.

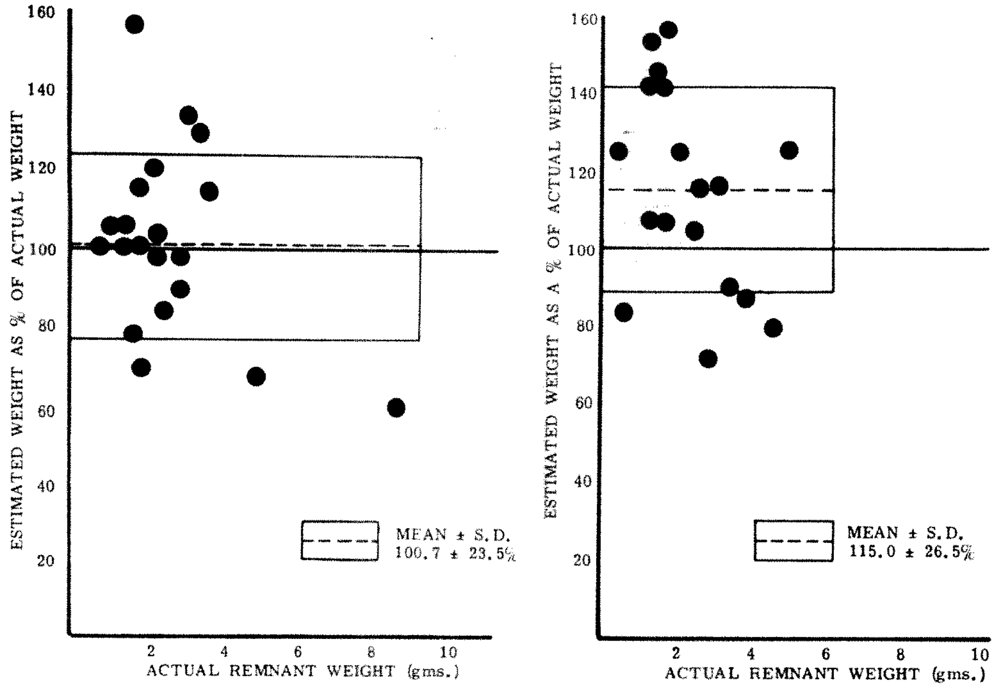

FIG. 3.—Cadaver study: distribution of the estimated remnant weights plotted against the actual weight with the mean value and standard deviation (S.D.) indicated for two surgeons.

Table III.—PROSPECTIVE STUDY: NUMBER OF PATIENTS AND POSTOPERATIVE THYROID STATUS AT 1 YEAR AFTER SUBTOTAL THYROIDECTOMY

TREATMENT GROUP	EUTHYROID	HYPOTHYROID		TOTAL
		No.	Per cent	
1	11	10	47·5	21
2	28	19	40·4	47
3	16	14	46·6	30
Total	55	43	43·8	98

$\chi^2 = 0{\cdot}441$; d.f. $= 2$

In group 1 there was no difference in the mean estimated remnant weight of the euthyroid and hypothyroid patients, while in group 2 the remnant of hypothyroid patients was in fact larger ($P < 0{\cdot}05$). In group 3 the remnant of the euthyroid patients was larger ($P < 0{\cdot}05$) and 1 of these patients developed recurrent hyperthyroidism 18 months after operation.

Cadaver Study.—This investigation was carried out to assess the extent to which variation in the surgeon's subjective assessment of remnant weight may influence the outcome of operation.

A total of 20 estimations by one surgeon and 18 by another was made on the weight of resected tissue and of the remnant in situ. Estimated weights were expressed as a percentage of the actual weights. Mean estimated remnant weights were 100·7 per cent by one surgeon and 103·3 per cent by the other (*Fig.* 3). Mean estimates of resected tissue were 123·8 and 115 per cent respectively. The standard deviations of the estimated remnant weights were 23·5 and 26·7 per cent, and using a rounded average of 25 per cent the distribution of estimated remnant weights would be as shown in *Table IV*. For instance, for 75 per cent of all the patients the estimated remnant weight would be within 63–127 per cent of the actual weight. Of the remaining 25 per cent of the patients, 20 per cent would have estimated remnants which fell within the ranges 54–63 per cent and 127–146 per cent of the actual weight and the remaining 5 per cent would differ by more extreme amounts

Table IV.—CADAVER STUDY: DISTRIBUTION OF ESTIMATED REMNANT WEIGHTS EXPRESSED AS A PERCENTAGE OF ACTUAL REMNANT WEIGHT

Percentage of All Patients	*Estimated Weight as a Percentage of Actual Weight* (g.)

from the actual remnant size (Yule and Kendall, 1958).

DISCUSSION

Several questions were raised by the first retrospective study (*a*) reported here. It shows that differences in estimated remnant weight between the groups with a different postoperative thyroid status were extremely small and almost the whole range of values for each group overlapped. These findings could be interpreted as an indication that in some patients small differences in remnant size are important, or, conversely, that remnant size has little influence on the outcome of operation. If small differences in remnant size were significant then it would be important to determine the accuracy with which remnant size can be controlled under the usual conditions of clinical surgery. The high incidence of hypothyroidism found in this part of the study could be ascribed to the radical type of resection with the implication that an improvement in the results of operation could be produced simply by increasing remnant size.

Table V.—ESTIMATED REMNANT SIZE AT OPERATION AND REPORTED MORBIDITY AFTER SUBTOTAL THYROIDECTOMY

AUTHORS	REMNANT SIZE	PERCENTAGE HYPOTHYROID	PERCENTAGE HYPERTHYROID	TOTAL MORBIDITY
Pemberton (1930)	4·5–10·5 g.	—	2·9	—
Thompson, Morris, and Thompson (1930)	2·0– 8·0 g.	—	19·5	—

Murley and Rigg (1968)	8·0 c.c.	7·5	0	7·5

* Deduced from authors' data.

A review of sixty-six reports published between 1925 and 1968 revealed only thirteen in which an attempt had been made to quantitate the remnant size (*Table V*). Estimates of remnant size varied between 0·4 and 30·5 g. but the values in ten reports lay between 2 and 10·5 g. This 'therapeutic range' has presumably been chosen on the assumption that it leads to a remission of the symptoms, and prevents recurrent hyperthyroidism, in the majority of patients. There is nevertheless great variation in the reported incidence of postoperative complications (Hedley and others, 1970). The present study, in which thyroid status has been carefully defined, suggests that postoperative morbidity may be much greater than previously supposed.

Some authors have expressed the view that there is an optimum remnant size which, in their centres, is associated with a low incidence of hypothyroidism and recurrent hyperthyroidism (Szilagyi, Barrett, and Preuss, 1955; Taylor and Painter, 1962; Murley and Rigg, 1968). The concept of a thyroid remnant of optimum size which would be associated with a low postoperative incidence of both recurrent hyperthyroidism and hypothyroidism was originally disputed by Bartlett (1951), and later studies have confirmed that régimes aiming to produce low levels of both these complications are mutually exclusive (Crile and McCullagh, 1951; Wilson, 1967).

In the second retrospective study (*b*) correlation of estimated remnant size with postoperative hypothyroidism indicated that, within the so-called therapeutic range, relatively small changes in remnant size have an important effect on the outcome of operation in some patients. The practical value of this finding is diminished because it is taken out of context and does not reflect the difficulties encountered in clinical practice when attempts are made to leave a 'standard' remnant. A group of patients treated by subtotal thyroidectomy will inevitably be heterogeneous with respect to remnant size. This is clearly shown by the prospective study in which increases in mean estimated remnant size between 4 and 8 g. did not diminish the overall incidence of apparently irreversible hypothyroidism in the group at 12 months after operation. This project was, however, associated with 1 early recurrence of hyperthyroidism and it seems inevitable that the incidence of this complication will be much higher in those patients with larger remnants. It is likely that, in comparison with the retrospective study, some reduction in the incidence of hypothyroidism was obscured because in this study thyroid status was defined at 12 months after operation using methods and criteria which detect even relatively minor abnormalities. In contrast, thyroid status was not defined in the retrospective studies until at least 2 years had elapsed after operation. Transient hypothyroidism is common after subtotal thyroidectomy and it is possible that more patients in the prospective study might have become euthyroid if thyroxine had been withheld. However, it is doubtful whether delaying treatment for an indeterminate period can be justified.

The studies on cadavers showed that the subjective assessment of remnant weight is open to considerable error. Although the overall performance is remarkably consistent, it appears that individual estimates of remnant size in 75 per cent of patients may vary by ± 27 per cent of the actual weight; for the remaining 25 per cent the variation will be much greater. In absolute terms this means that the actual weight of a remnant intended to be 8 g. might in fact lie between 4 and 12 g. Discrepancies of this order would explain the poor overall correlation of estimated remnant size and postoperative thyroid status in this and in other clinical surveys.

The information from the retrospective and prospective studies confirmed that remnant size is one of the important factors which determines thyroid status after thyroidectomy, but there is equally good evidence that the mass of the remnant as determined at operation is not always related to its functional capacity. In these patients other factors such as autoimmune thyroiditis are clearly important and hypothyroidism will not be prevented by conservative surgery.

One recent finding in our studies of thyroid remnant function is of fundamental importance when considering the influence of remnant size on the results of subtotal thyroidectomy. It is accepted that failure of the thyroid uptake of radio-iodine to suppress with the administration of exogenous triiodothyronine (T3 suppression test) is characteristic of the basic disease process in Graves' disease (Werner, 1956; Kendall-Taylor, 1972). Suppression of the uptake is evidence of a normal pituitary-thyroid axis. Recent studies (Hedley, Ross, Beck, Donald, Recht, Michie, and Crooks, 1971) using this technique in the early postoperative period have shown that a remission of Graves' disease occurs within 12 months of operation in 70–80 per cent of surgically treated patients irrespective of remnant size. Follow-up studies have shown that whereas this remission is permanent the basic disease process may persist in the remaining 20 per cent of patients for more than 20 years and it is in this group that recurrent hyperthyroidism may occur. It is likely, therefore, that modifications of the outcome of subtotal thyroidectomy will only be possible if those patients who will not enter a remission can be identified *before* operation. If they could be detected it is interesting to speculate that, while surgery remains one of the principal forms of treatment for thyrotoxicosis, morbidity might be reduced by leaving large remnants in those patients who will not remit and employing a radical resection or other forms of treatment in the group in whom the disease will persist and who might therefore develop a recurrence.

CONCLUSIONS

This study suggests that efforts to find an optimum remnant size are unlikely to be rewarding. In unselected patients with thyrotoxicosis the complications of hypothyroidism and recurrent hyperthyroidism will be inversely related and manipulation of remnant size will not be effective in reducing the total morbidity. At the present time the object of treatment should be to prevent persistent or recurrent hyperthyroidism; an appreciable incidence of hypothyroidism should be accepted as inevitable and treated promptly with replacement therapy.

THE EFFECT OF EXPERIMENTAL BILE-DUCT OBSTRUCTION ON CRITICAL BIOSYNTHETIC FUNCTIONS OF THE LIVER

BY EMANOEL LEE, B. D. ROSS, AND J. R. HAINES
NUFFIELD DEPARTMENT OF SURGERY, RADCLIFFE INFIRMARY, OXFORD

SUMMARY

Using biosynthetic activities which have a maximum energy requirement, the effect of obstruction of the bile-duct has been studied in isolated perfused rat livers, and compared with controls undergoing 'sham' ligation and with normal animals. The maximum rate of gluconeogenesis from lactate was inhibited by 67 per cent after bile-duct ligation when compared with the normal value. The maximum rate of urea synthesis which occurred in the presence of ornithine was the same in the jaundiced and in the normal animals. 'Sham' operation, without ligation of the bile-duct, inhibited gluconeogenesis by less than 20 per cent but doubled the maximum rate of urea synthesis.

It is concluded that complete biliary obstruction seriously impairs gluconeogenesis and prevents the normal increase of urea synthesis which occurs in response to trauma and that these changes develop earlier than might be expected after the onset of obstruction.

Some possible mechanisms of these effects are discussed. If similar abnormalities of hepatocyte function are demonstrated in man it is suggested that surgical relief of obstructive jaundice is indicated at an early stage.

THE chemical changes observed in the blood of a patient or animal after the bile-duct becomes obstructed are due to retention of bile rather than to a direct effect of the obstruction on the cells of the liver. Abnormalities of clinical liver-function tests are not marked unless the obstructive jaundice has been present for some time, and it is usually considered that hepatocyte function remains normal during the first few weeks after obstruction has taken place. However, most biochemical activities of the liver take place at such a rate that the standard clinical tests of function, which are relatively insensitive, remain normal until gross hepatic damage has occurred.

Recently, perfusion techniques have been developed which allow a direct study of the biosynthetic reactions of the liver. The maximum rates of energy-requiring cellular activities are more sensitive tests of liver function than are the investigations usually employed. The synthesis of glucose from lactate (Meyerhof, 1930; Hems, Ross, Berry, and Krebs, 1966), of urea from ammonia (Cohen and Sallach, 1961), and possibly of protein, are the principal reactions which consume large quantities of ATP, and require the integrated action of both mitochondrial and cytoplasmic enzymes.

In the experiments recorded in this paper ligation of the bile-duct has been used to produce jaundice, and the maximum rates of gluconeogenesis and urea synthesis in the perfused livers of jaundiced animals were compared with those in both normal and control animals. A preliminary account of part of this work has been presented previously (Lee, Ross, and Haines, 1971).

MATERIALS AND METHODS

Male albino Wistar rats weighing between 150 and 200 g. were obtained from Messrs. Scientific Products Farm, Ash, Kent, and were fed on a standard 41B diet.

Bile-duct Ligation.—Three groups of rats were prepared for liver perfusion. Group 1 consisted of those animals which had had their bile-ducts ligated and divided using an ether anaesthetic administered by the 'open' method. A control group of animals (group 2) underwent a sham operation, using an exactly similar anaesthetic. Care was taken to anaesthetize the animals in both groups for the same length of time (12 minutes). The abdomen was opened through a midline supra-umbilical incision. The duodenal loop was located and delivered through the wound under sterile conditions. The bile-duct was dissected from the surrounding structures, avoiding damage to the peritoneum over the portal vein and thus preventing inflammation and adhesions which make subsequent cannulation of the portal vein difficult. Two silk ligatures were passed behind the common duct just distal to the junction of the hepatic ducts, care being taken not to damage the pancreas. In group 1 the ligatures were tied and then the duct was cut between them. In group 2 the ligatures were removed without being tied. The animals in group 3 underwent no surgery before perfusion.

Perfusion Experiments.—Subsequently the rats were anaesthetized with intraperitoneal pentabarbitone and their livers were perfused using the technique described by Hems and others (1966) and Ross (1972) (*Figs.* 1, 2). In order to reduce the liver glycogen content and to induce maximal rates of glucose and urea synthesis all the animals were starved for 48 hours before perfusion. The animals in groups 1 and 2 therefore received only water after operation. Substrates were added to the medium after 40 minutes of perfusion and samples of the medium were taken for analysis at 15-minute intervals over the period 40–130 minutes of perfusion. Time courses of glucose synthesis and lactate removal or of urea synthesis and ammonia removal were constructed from these data.

Expression of Results.—The results are expressed as μmol per minute per g. wet weight of liver, since the ratio of wet weight : dry weight and the total weight of the liver were not significantly different in the three groups of animals 2 days after bile-duct ligation. Figures are the mean ± standard error of the mean (S.E.M.) (*see* Results).

Chemical Analyses.—

Serum proteins were determined by the micro-Kjeldahl method.

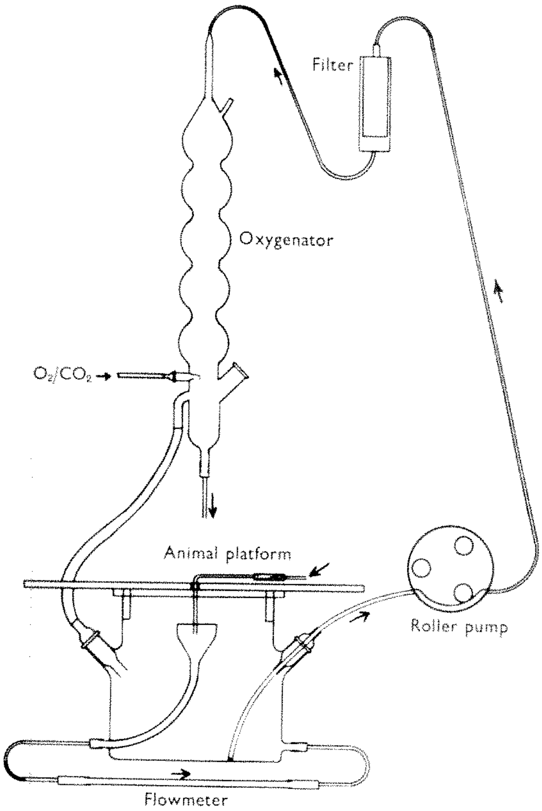

FIG. 1.—Diagram of the liver perfusion apparatus, showing the direction of circulation of the medium. The medium in the collecting vessel is lifted by the roller pump through the nylon-mesh filter to the top of the oxygenator. From there the medium passes to the reservoir whence it enters the liver via the portal vein. Excess medium leaves the reservoir by an overflow to the collecting vessel. Note the arrangement of the funnel to collect the venous outflow from the liver and to return it to the collecting vessel via a flowmeter. For clarity the animal is not shown.

Bilirubin was determined by the sulphanilic acid method in Biochemica test combination (Catalogue No. 15944 TBAA).

Lactate was determined with the Boehringer Biochemica test (ultra-violet method TC/B Catalogue No. 15972, TLAA) using a Boehringer Tecometer Photometer at 340 nm., and *glucose* was determined using the Boehringer Biochemica test combination (Catalogue No. 15754 TBAN).

Urea and *ammonia* were determined with Nessler reagent before and after treatment of the samples with urease.

Oxygen was determined in the inflowing and outflowing medium with the Scholander-Roughton apparatus. Oxygen consumption was calculated from this 'a – v' difference and the flow rates of medium through the liver determined with a siphon-flow meter.

RESULTS

Effects of Bile-duct Ligation.—

Serum Bilirubin.—The serum bilirubin of all the animals in group 1 rose significantly within 2 days of bile-duct ligation, reaching a value of 5·8 ± 1·8 mg. per cent (11 animals), compared with 0·45 ± 0·27 mg. per cent (9 animals) in the sham-operated control group and 0·72 ± 0·50 mg. per cent (10 animals) in the normal animals.

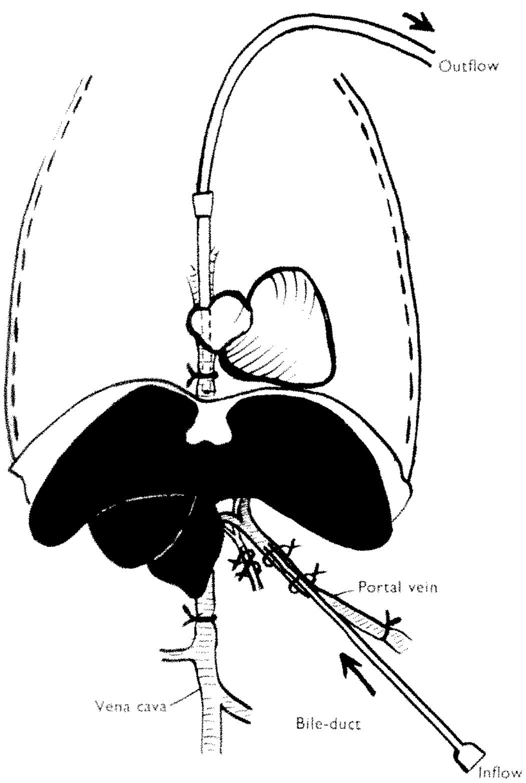

FIG. 2.—Diagram of the operative procedure for the in situ perfusion of the liver. The bile-duct and portal vein are cannulated; note that the portal vein is also tied distally. The inferior vena cava cannula is inserted through the wall of the right atrium and tied, as shown, in the vena cava above the diaphragm. Finally, the inferior cava is tied, as shown, below the liver, and the animal is connected to the perfusion apparatus via the portal cannula.

Weight Increase.—The livers of jaundiced rats were noted to enlarge about 1 week after obstructing the bile-duct. Histological examination showed that the enlargement resulted from the retention of bile in the dilated biliary tracts as well as from an increase in the number of cells in the liver, particularly in the ducts and periductal spaces. Similar changes have been reported in other animals and in man (Lieber and Stewart, 1934; Sherlock, 1963). The cellular proliferation is associated with an increase in the dry weight of the liver. No significant difference was found between the wet or dry liver weights of the 2-day jaundiced animals and the controls, the 2-day jaundiced animals and the normal animals, and the normal and control groups. However, the increase in both the wet and dry weights of the livers of jaundiced rats became significant 7 days after the ducts had been ligated (*Table I*). The wet weight increased by 34·6 per cent and the dry weight by 16·6 per cent of the control values, an alteration which correlates with the histological changes in the liver.

Serum Albumin.—The effect of ligation of the bile-duct was studied in a separate experiment in which animals were killed at 2 days and at weekly intervals up to 7 weeks after ligation of the bile-duct. No significant fall in serum albumin was observed (*Table II*) until the sixth week.

Table I.—EFFECT OF BILE-DUCT OBSTRUCTION ON THE WET AND DRY WEIGHTS OF THE LIVER

ANIMAL	NO. OF ANIMALS	WET WEIGHT (g. ± S.E.M.)	DRY WEIGHT (g. ± S.E.M.)	WET WEIGHT / DRY WEIGHT
Normal	3	6·59 ± 0·61	1·89 ± 0·17	3·48
Sham-operated (2 days)	2	6·29 ± 0·32	1·78 ± 0·01	3·51
Jaundiced (2 days)	3	6·87 ± 0·75	1·90 ± 0·13	3·61
Jaundiced (7 days)	3	8·89 ± 0·52	2·21 ± 0·16	4·20

Table II.—EFFECT OF BILE-DUCT OBSTRUCTION ON THE SERUM ALBUMIN OF RATS

Duration of Bile-duct Ligation (weeks)	*No. of Animals*	*Serum Albumin* (g. per 100 ml. of serum ± S.E.M.)
0	6	2·50 ± 0·18
1	4	2·38 ± 0·20
2	4	2·65 ± 0·30
3	4	2·40 ± 0·15
4	4	2·17 ± 0·45
5	4	2·47 ± 0·25
6	5	2·02 ± 0·18
7	4	2·05 ± 0·17

Perfusion Studies.—Perfusion of the liver by the in situ technique of Hems and others (1966) was not unduly affected soon after the operation of duct ligation, provided precautions were taken to avoid the formation of adhesions around the porta hepatis and portal vein. Two days after duct ligation perfusion proceeded normally. After a longer period, e.g., 7 days, there was an increasing incidence of complications, particularly of exudation from the surface of the liver, which made the technique of in situ perfusion less reliable. It is suggested, therefore, that the isolated perfusion technique of Schimassek (1963) may be more suitable for such delayed studies.

Flow Rate and Perfusion Pressure.—At 2 days after bile-duct ligation no increase in perfusion pressure was required. Flow-rates of 4·2 ± 1·1 ml. per minute per g. of liver in the duct-tied animals (11 animals), 3·8 ± 0·8 ml. per minute per g. in the sham-operated (3 animals), and 5·1 ± 1·1 ml. per minute per g. in the normal controls (4 animals) were observed. These flow rates adequately provided the expected oxygen requirement of the liver, and anoxia cannot therefore be suggested as an explanation for the abnormalities of the liver-function tests described below.

Glucose Synthesis from Lactate. — Addition of 1500 μmol Na-L-lactate (10 mM) to the perfusion medium results in a significant formation of glucose, which appears in the perfusion medium at a linear rate. In the present experiments the rate of glucose synthesis in the normal animals was the same as that observed by other workers (Strück, Ashmore, and Wieland, 1965; Hems and others, 1966; Exton and Park, 1967). The rate was suppressed by 67 per cent in the duct-tied animals and by 28 per cent in the sham-operated controls (*Table III*). Duct ligation therefore exerted a significant depressant effect upon the synthesis of glucose by the liver. Lactate was removed from the medium in parallel with the formation of glucose in all three groups. The ratio of lactate removed : glucose formed, which is expected to be 2, was 2·15 in the sham-operated controls, but it increased to 2·60 in the duct-ligated animals. An additional significant effect of duct ligation may therefore be the diversion of lactate to paths other than that of glucose synthesis, e.g., oxidation. Oxidation of lactate is minimal in the control animals which have been starved for 48 hours (Strück and others, 1965; Hems and others, 1966), and no increase in liver glycogen was found under these conditions of perfusion.

Table III.—THE EFFECT OF BILE-DUCT OBSTRUCTION ON THE SYNTHESIS OF GLUCOSE FROM LACTATE

ANIMAL	NO. OF ANIMALS	GLUCOSE FORMED	LACTATE USED	LACTATE USED / GLUCOSE FORMED
		(μmol per min. per g. wet weight of liver ± S.E.M.)		
Normal	7	0·97 ± 0·13	1·70 ± 0·33	1·75
Sham-operated (2 days)	7	0·70 ± 0·21	1·51 ± 0·25	2·15
Jaundiced (2 days)	5	0·32 ± 0·09	0·84 ± 0·30	2·60
Jaundiced (7 days)	3	0·36 ± 0·22	0·63 ± 0·38	1·75

Seven days after duct ligation the rate of glucose synthesis was still only 37 per cent of that in the controls (*Table III*), indicating that the animals had not adapted to the biliary obstruction within that time.

Urea Synthesis.—In the normal rat liver urea is synthesized at a high rate when ammonium salts are added to the perfusion medium (Trowell, 1942; Hems and others, 1966). The rate may be increased by up to three times by the addition of the catalyst ornithine (Krebs and Henseleit, 1932), and this yields the highest rates of urea synthesis yet observed *in vitro* (Hems and others, 1966). In the present experiments the rate of urea synthesis (expressed as μmol of ammonia removed) was lower than that observed by Hems and others (1966), possibly owing to differences in the strain of rat used. In the presence of 10 mM NH_4Cl, ammonia was removed at a rate of 1·25 ± 0·18 μmol per minute per g. (3 animals). With the addition of 400 μmol of ornithine (2·66 mM) to the medium the rate of ammonia removal was 1·68 ± 0·10 μmol per minute per g. (3 animals). The maximum rate of urea synthesis was compared for the three groups of animals. In each group the rate of urea formation was linear with time and accounted for 80–90 per cent of the ammonia removed. Duct ligation did not apparently alter the rate of urea synthesis when compared with the normal animals. However, when compared with the sham-operated controls an inhibition of 41 per cent was observed (*Table IV*). The sham operation itself resulted in a doubling of the rate of urea synthesis, and this increase was almost entirely prevented by duct ligation.

Oxygen Consumption.—Oxygen consumption by the liver has been determined in animals prepared as in Materials and Methods. The oxygen consumption of livers perfused under basal conditions without added substrate was not apparently affected by ligation of the bile-duct or by the sham operation (*Table V*). The figure of 2·11 ± 0·08 μmol O_2 per minute per g. (6 animals) for the liver perfused without substrate does not differ from that found by other workers (Schimassek, 1963; Forsander, Räihä, Salaspuro, and Maënpää, 1965; Hems and others, 1966).

Table IV.—Synthesis of Urea in the Perfused Liver of Rats with an Obstructed Bile-duct

Animal	No. of Animals	Ammonia removed	Urea formed
		(μmol per min. per g. wet weight of liver ± S.E.M.)	
Normal	3	1·68 ± 0·10	0·70 ± 0·21
Sham-operated (2 days)	4	2·83 ± 0·40	1·45 ± 0·20
Jaundiced (2 days)	4	1·87 ± 0·025	0·85 ± 0·15

Addition of 10 mM NH_4Cl and 2·66 mM ornithine to the medium resulted in a considerable increase of oxygen consumption in all three groups of animals. Assuming that $\frac{2}{3}$ mol of O_2 are required per mol of urea synthesized (Cohen and Sallach, 1961), in the normal control the extra oxygen consumption exceeded that expected (expected = 1·07 μmol per minute per g.; observed = 1·93 μmol per minute per g.), a finding which confirms that of Hems and others (1966). This difference between the expected and the observed oxygen consumption disappeared in the sham-operated animals (expected = 1·64 μmol per minute per g.; observed = 1·75 μmol per minute per g.).

The observed extra oxygen consumption in the duct-ligated animals was actually lower than that expected (observed 0·79 μmol per minute per g.; expected 1·17 μmol per minute per g.), but these figures do not represent a significant difference.

DISCUSSION

Control of Gluconeogenesis.—Inhibition of gluconeogenesis in the rat liver with an obstructed bile-duct must reflect some metabolic defect induced by the retention of a constituent of the bile or consequent upon the increased intraduct pressure. The factors which control the rate of glucose synthesis from lactate are the supply of the substrate, the transport of the substrate into the cell and between intracellular compartments, the availability of ATP, and the activity of specific rate-limiting enzymes, notably pyruvate carboxylase, phospho-enolpyruvate carboxykinase, and fructose diphosphatase (Krebs, 1964). In the present experiments there was no restriction of substrate supply nor is this likely to be a factor *in vivo*. In obstructive jaundice plasma levels of glucogenic amino-acids and of lactate and glycerol, the principal substrates of gluconeogenesis, are normal or raised (Record, Alberti, and Williamson, 1971; Record, 1972). Preliminary observations suggest that the ATP content of the liver is not abnormal during perfusion of the jaundiced rat liver (Lee and others, 1971). Furthermore the oxygen consumption of the liver with a ligated bile-duct remained normal and increased in response to the addition of substrates.

Table V.—Effect of Obstructive Jaundice on Urea Synthesis and Oxygen Consumption in the Perfused Rat Liver

Animal	No. of Animals	Time (min.)	Urea Synthesis*	Oxygen Uptake
			(μmol per min. per g. fresh weight of liver ± S.E.M.)	
Normal	1	30	—	2·0
		85	1·60	3·93
Sham-operated (2 days)	2	30	—	2·02 ± 0·05
		85	2·47 ± 0·35	3·77 ± 0·06
Jaundiced (2 days)	3	30	—	2·24 ± 0·13
		85	1·75 ± 0·17	3·03 ± 0·34

* Expressed as amount of ammonia removed.

The activity of the rate-limiting enzymes remains to be determined, but it is of some significance that the concentration of acetyl coenzyme A, the intracellular effector of pyruvate carboxylase, is decreased in the livers of rats 9 days after obstruction of the bile-duct (Record and others, 1971). Although there is no complete agreement (Krebs, Speake, and Hems, 1965; Menahan, Ross, and Wieland, 1968; Willms and Söling, 1968) concerning the physiological role of acetyl coenzyme A in controlling the rate of gluconeogenesis, a reduction in the activity of pyruvate carboxylase such as might result from lowered cellular acetyl coenzyme A levels is a likely explanation for the present results.

Control of Urea Synthesis.—The maximum rate of urea synthesis is controlled by the supply of substrate and catalyst (Krebs and Henseleit, 1932), by the activity of the rate-limiting enzymes (Schimke, 1963; McLean and Novello, 1965) and by the availability of ATP (Cohen and Sallach, 1961). In the present studies substrate and catalyst were provided in excess and there is evidence both from oxygen consumption and from direct measurement (Lee and others, 1971) that ATP was available. However, the extra oxygen consumption which accompanied the ammonium salts to the liver was less in the jaundiced liver than in the normal liver. It has been suggested that the excess oxygen consumption may be required for protein synthesis (Hems and others, 1966), and this apparent defect in the jaundiced rat liver may be a forerunner of the subsequent failure of albumin synthesis in protracted bile-duct obstruction.

Effect of Surgery on Liver Metabolism.—Gluconeogenesis and urea synthesis are considered to be increased in response to surgery; *in vivo* this may be a reflection of the extra substrate made available from tissue breakdown (Kinney, Long, and Duke, 1970). However, the present findings suggest that 2 days postoperatively the maximum rate of gluconeogenesis is not increased and may actually fall. On the other hand, the maximum rate of urea synthesis is increased by nearly 100 per cent. Under the conditions of the present experiment this observation is consistent with an increase in the activity of the enzymes of the urea cycle, since substrate and catalyst were present in excess. It may be that bile-duct obstruction inhibits urea synthesis by preventing the 'activation' or induction of the enzymes of the urea cycle which is the normal response to trauma.

CONCLUSION

Standard clinical tests of liver function are usually normal in patients (and animals) with early obstructive jaundice. The present study confirms what has been widely suspected: that the clinical tests may remain normal in the face of considerable disturbance of liver-cell metabolism. This has been revealed by the use of tests of maximal biosynthetic capacity in the isolated perfused liver, and it remains to be seen if such tests can be applied in the whole animal or in clinical practice. The results obtained support a case for the early surgical relief of obstructive jaundice.

PERIPHERAL TUBERCULOUS LYMPHADENITIS IN THE ELDERLY

By A. L. G. PEEL*

THE BOLINGBROKE HOSPITAL, LONDON

Summary

1. Retrospective and current studies of peripheral tuberculous lymphadenitis in the elderly (over the age of 60 years) are described.

2. The efficacy and side-effects of standard antituberculous chemotherapy in this group of patients are analysed.

3. Simple excisional surgery with the local instillation of streptomycin is suggested as a rational and effective method of treatment of localized tuberculous lymphadenitis in the elderly.

THE PATIENTS

1. The Retrospective Study.—Sixty-two patients presented with peripheral tuberculous lymphadenitis at St. Thomas's Hospital, London, during the period from 1958 to 1967, and 8 (12 per cent) were over the age of 60. These 8 patients were all English and had lived the greater part of their life in South London. The diagnosis was confirmed by bacteriological culture in all cases. All the patients started a course of antituberculous chemotherapy, which, if completed, comprised parenteral streptomycin for 6 months and oral para-aminosalicylic acid and isoniazid for 18 months. Surgical treatment comprised either excision of the gland group or incision and drainage. Two patients had undergone surgery for involvement of the same gland group 10 or more years previously.

Three patients failed to take the oral drugs. Two patients developed irreversible auditory nerve damage as a result of taking streptomycin. Tuberculous lymphadenitis recurred in 4 patients during follow-up.

2. The Current Study.—Six elderly patients with tuberculous lymphadenitis were seen during a 10-month period at the Bolingbroke Hospital, London. All the patients were English and lived in South London. There was no evidence of tuberculosis elsewhere in any patient. Measurement of the sedimentation rate, a chest radiograph, and culture of the urine and sputum (if any) were performed in each case. Diagnosis was confirmed by culture and histological examination of the excised tissue. Three patients had had previous surgery for tuberculous lymphadenitis. Treatment comprised excision of the affected gland group, with instillation of 1 g. streptomycin powder into the wound. One declined surgery, and her collar-stud abscess was successfully treated by aspiration and instillation of 1 g. streptomycin at weekly intervals for 1 month.

---

* Present address: The Surgical Unit, The London Hospital, London.

All the patients had primary healing of their wounds, and there was no evidence of recurrence or further tuberculous lymphadenitis during the follow-up period. No patient suffered any iatrogenic complications.

The methods and results of treatment in the retrospective and current series are summarized in *Tables I* and *II* respectively.

Table I.—THE RETROSPECTIVE STUDY OF PERIPHERAL TUBERCULOUS LYMPHADENITIS IN THE ELDERLY (1958–67)

AGE AND SEX	TREATMENT	LENGTH OF FOLLOW-UP	SIDE-EFFECTS OF CHEMOTHERAPY*	RESULTS
83 F.	Incision	18 months	Failed to take drugs	Healed
73 F.	Incision	4 years	Streptomycin deafness	Recurrent abscess at 3 years
76 F.	Excision	3 years	Never took drugs	Multiple recurrences at 6 months
60 M.	Excision	5 years	—	Persistent sinus for 18 months
77 F.	Excision	4 years	—	Healed
67 F.	Excision	5 years	Streptomycin deafness	Multiple recurrences within 1 year
63 F.	Incision	2 years	—	Healed
63 F.	Excision	9 months	Refused drugs after 4 months	Healed

* All patients started a course of anti-tuberculous chemotherapy.

Table II.—THE CURRENT SERIES OF PERIPHERAL TUBERCULOUS LYMPHADENITIS IN THE ELDERLY (1969)

AGE AND SEX	TREATMENT*	LENGTH OF FOLLOW-UP	SIDE-EFFECTS	RESULTS
81 F.	Excision of collar-stud abscess	10 months	None	Healed
64 M.	Wide excision	18 months	None	Healed
64 F.	Local excision	15 months	None	Healed
83 F.	Aspiration	16 months	None	Healed
85 F.	Excision	16 months	None	Healed
77 F.	Excision	12 months	None	Healed

* Streptomycin powder (1 g.) was instilled locally at the time of surgery.

DISCUSSION

Peripheral tuberculous lymphadenitis is becoming less common when all age-groups are considered, but an increasing percentage of elderly patients is found. Fraser (1965) found that 9 out of 18 women reviewed at the Southampton Chest Hospital with peripheral tuberculous lymphadenitis were over the age of 60.

Site.—Cervical lymph-glands are most commonly involved and although 2 cases of axillary lymph-gland involvement are recorded in the retrospective series the incidence of the latter ranges from 3 to 10 per cent, according to the series (Fraser, 1965; Kent, 1967).

A Localized or a Generalized Manifestation of Tuberculosis?—In neither the retrospective nor the current study was there any evidence of active tuberculosis elsewhere at the time of treatment or during the period of follow-up. In contrast, Fraser (1965) states that 15 of his 30 cases had active tuberculosis elsewhere at the time of presentation, or during the preceding 10 years, but he does not comment on the age of these patients. Miller and Cashman (1955) consider tuberculous lymphadenitis to be a localized disease in children.

Treatment.—Chemotherapy has not superseded surgery in the treatment of tuberculous lymphadenitis nor has it eliminated relapses (Fraser, 1965). In the retrospective study 3 patients (37 per cent) failed to take the drugs and 2 suffered permanent side-effects (deafness). Excision and local instillation of streptomycin have avoided these problems without impairment in the quality of the results.

Relapses.—Kilpatrick and Douglas (1957) state that 46 per cent of their cases, received from two Edinburgh hospitals, had previous lymphadenitis, and that 15 per cent of their personal cases relapsed despite full anti-tuberculous drug therapy. Gillam and Knowles (1963) found that there was a relapse rate of 25 per cent in patients studied from University College Hospital, but found complete excision under chemotherapeutic cover to be successful for disease localized to the upper cervical region. Cover was maintained until the skin had healed. The relapse rate in the present retrospective study was 4 cases (50 per cent), with 3 occurring in the first year. It seems that although the majority of relapses occur early the rate is, to a certain degree, proportional to the length of follow-up, but lack of relapse in the small current series is encouraging, and it is particularly satisfactory that this has been achieved with none of the side-effects seen in elderly patients on anti-tuberculous drugs.

Acknowledgements.—I am grateful to Mr. R. S. Lawrie and Mr. J. M. Pullan for permission to study the patients under their care, and to Mr. M. R. Williams for his helpful criticism of this paper.

SHORT NOTES OF RARE OR OBSCURE CASES

TUMORAL CALCINOSIS

By DEREK BERG
ANGAU MEMORIAL HOSPITAL, LAE, NEW GUINEA

SUMMARY

An extreme case of tumoral calcinosis is presented. This condition is common in the highland natives of New Guinea and is commonly referred to as 'hip stones'. The pathogenesis, clinical findings, and treatment are discussed and the relevant literature is reviewed.

TUMORAL calcinosis, which is locally referred to as 'hip stone', is not uncommon in the Eastern and Central Highlands regions of New Guinea. Found also in other areas of New Guinea as well as in South, Central, and East Africa, the condition has received little publicity in medical journals. It is, however, of clinical interest and presents a diagnostic problem to the uninitiated.

CASE REPORT

A female, aged 43 years, from the Chimbu district of the Central Highlands, was admitted to the Goroka Base Hospital complaining of hard and painful lumps over both greater trochanters, the lateral humeral condyles, and the left lateral ankle malleolus. There was an offensive, thick, whitish discharge from both trochanteric lumps, and old surgical scars were apparent over both hips and elbows. The patient was apyrexic, ambulatory, and in reasonable health. She complained of pain within both hip lumps and of the general inconvenience of all her lumps.

Owing both to language difficulties and to a general lack of appreciation of time and dates an accurate history was difficult to obtain from the patient. It would appear that the lumps had first appeared in the region of the elbows some 7 years previously and over both hip-joints 5 years previously. She had sought surgical relief 3 years previously and an attempt had been made at that time to remove the lumps. Recurrences had developed within a few months of surgical removal.

Radiographs of the hip, elbow, and ankle-joints revealed extensive but patchy calcification within the soft tissue near but not connected to these joints (*Figs.* 1, 2). Repeated serum calcium estimations were within normal limits and we were unable to culture organisms from the discharging sinuses. Radiographs of the chest and long bones failed to reveal any abnormality.

The patient requested surgical removal of her lumps, and this was carried out at two separate operations on 23 Feb. and 4 March, 1971. Very large, poorly circumscribed calcified masses were removed from both trochanteric regions, the elbows, and the left ankle. The specimens were sent to Dr. Wilkey, Pathologist at Port Moresby, who reported that the microscopic picture was typical of tumoral calcinosis and commented that he had not previously heard of a case with so many lesions.

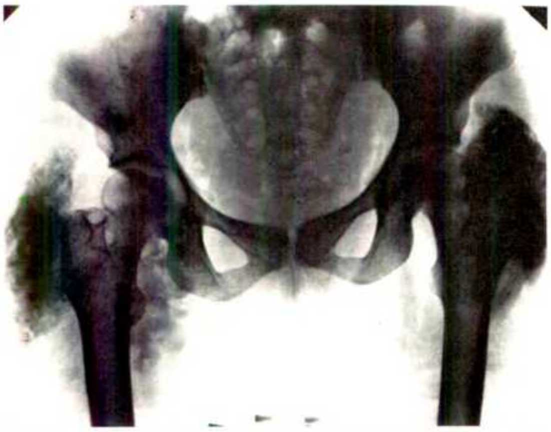

FIG. 1.—Radiograph showing calcified lumps over both greater trochanters.

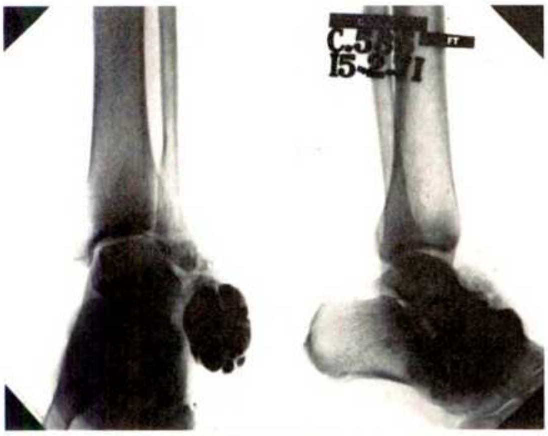

FIG. 2.—Radiograph showing calcified lumps over both ankle-joints.

The patient made an uneventful recovery and was subsequently discharged from hospital. Unfortunately follow-up studies will probably be impossible as these people for various reasons will not attend regularly at out-patients' clinics.

AETIOLOGY AND PATHOGENESIS

In the New Guinea Highlands, as no doubt in various other lands, the indigenous people frequently sleep on the bare ground or boards. This in many cases leads to prolonged intermittent ischaemia involving the subcutaneous tissue surrounding the pressure areas. Fat necrosis results with subsequent calcification. Once established, the area of necrosis and calcification seems to increase in size, frequently with a breakdown of the overlying skin and the discharge of a white chalky fluid through the resulting sinus. In some cases a secondary chronic infection develops.

Macroscopically the mass may be subcutaneous or intramuscular. It lies within a collection of thick fibrous tissue with which it blends and ramifies and from which it cannot be shelled out. This fibrous tissue does not easily separate out from the surrounding normal tissue and it may ramify deeply and extensively, as in the case presented here. The tumour is partially calcified and may be extremely hard and it frequently contains cystic areas with whitish chalky material. In the region of the greater trochanter the trochanteric bursa lies deep to the tumour and has to be removed with the tumour. The tumour does not appear to arise from or within the bursa although this has been suggested by Koten (1969). A secondary bursa may, however, be formed in association with the tumour.

CLINICAL FINDINGS

The clinical findings have been well described by McClatchie and Bremner (1969).

The condition occurs in adults of both sexes. There is usually a solitary, hard, and slow-growing tumour in the vicinity of a joint. Occasionally the lesions may be multiple. Some tumours contain softer cystic areas with a chronically discharging and sometimes secondarily infected sinus. Episodes of pain and tenderness punctuate the course of the condition, and are caused by the aseptic inflammatory reaction which accompanies episodes of necrosis within the mass (Smith, 1968). Secondary infection may cause further pain and discharge.

Once seen and recognized the condition is rarely misdiagnosed thereafter. The radiographic appearances are typical (*Figs.* 1, 2). These reveal radio-opaque areas of calcification throughout the mass which vary in density but do not involve the joint.

TREATMENT

It is generally agreed that only wide excision will cure the condition. This is achieved in most cases by simply removing a large block of tissue including the tumour. In the case of the true hip stone, excision will include removal of the trochanteric bursa. Primary closure and drainage are usually adequate and where secondary infection is present an antibiotic cover is a wise precaution.

Where the tumour is recurrent and has ramified widely, as in the case presented here, total surgical excision is a formidable procedure. There are no planes of demarcation between the tumour and normal tissue, and the anatomy in the vicinity is distorted; blood-loss may be considerable and the surgeon should be prepared for a major operation.

DISCUSSION

Tumoral calcinosis has been reported from Zambia, Rhodesia, Uganda, Kenya, and South Africa (McClatchie and Bremner, 1969; Sonnenfeld, 1970) as well as from numerous areas on the island of New Guinea.

The condition masquerades under many pseudonyms in different districts, being variously referred to as 'hip stone', 'ankle stone', 'calcified bursa', 'calcification of a lipoma', 'Kikuyu bursa', etc.

The size and multiplicity of the leasions make the case presented here a little unusual, but there is every reason to believe that it is nothing more than an extreme example of multiple tumoral calcinosis.

Pathological calcification is commonly classified as 'dystrophic calcification', 'metastatic calcification', and 'calcinosis'. Dystrophic calcification is the deposition of calcium in degenerative tissue, and it is not dependent upon an increase in the calcium content of the blood but appears to be influenced by a local relative alkalinity of the damaged tissue (Anderson, 1964). This is the most frequent type of pathological calcification and occurs in areas of tuberculous necrosis and in degenerative tumours, and gives rise to tumoral calcinosis in areas of subcutaneous fat necrosis as described in this paper.

Metastatic calcification is a precipitation of calcium salts owing to a disturbance of the calcium and phosphorus metabolism and is often associated with an excess of calcium in the circulating blood. This may be a sequela of hyperparathyroidism, hypervitaminosis D, and destructive bone tumours.

The ischaemic necrosis that results in tumour calcinosis is caused by intermittent pressure over a period of years, and it occurs in reasonably healthy adults. The skin is not initially involved. In all these respects this condition differs from the ischaemic necrosis commonly found in the bedridden, elderly, sick, or paraplegic patient.

It is interesting to speculate why in some cases of tumoral calcinosis the lesion grows rapidly even after the removal of the precipitating cause and why recurrence is apt to occur after incomplete removal. In these respects tumoral calcinosis behaves like a locally invasive neoplasm.

A detailed follow-up study of a series of these cases would be a difficult task but is long overdue and may well throw some light on this interesting condition.

RUPTURED MYCOTIC ANEURYSM OF THE SPLEEN

By HEATHER M. DUKES* and JOHN M. MYNORS
HARARI HOSPITAL, UNIVERSITY OF RHODESIA, SALISBURY

SUMMARY

The fourth recorded survivor of a ruptured splenic aneurysm is presented. He is also remarkable for his multiple pathology including bacterial endocarditis, aortic incompetence with multiple peripheral embolism, and neurofibromatosis.

It is emphasized that mycotic aneurysms of the spleen are an unusual complication of bacterial endocarditis, and a high index of suspicion is essential for their diagnosis. Treatment must be prompt and effective.

SINCE 1770 when Beaussier described the first case of splenic aneurysm there have been over 300 reported cases, but few cases survive rupture and fewer still are diagnosed prior to surgery or death. The incidence of splenic aneurysms in the general population is 0·05 per cent (Lindboe, 1932). Most authors agree that atherosclerosis is the most important aetiological factor, being responsible for 66–77 per cent of cases, but there is controversy as to whether congenital defects or mycotic emboli occupy second place (Cosgrove, Watts, and Kaump, 1947; Bergner and Bentivegna, 1967; Baron, Weinshelbaum, and Block, 1968).

The incidence of rupture of all splenic aneurysms is reported to be 34–46 per cent, but this may be an over-estimate because many patients have been treated conservatively with success for up to 18 years (Jones and Finney, 1968).

The case of ruptured splenic aneurysm reported by Baron and others in 1968 was the second to have been diagnosed preoperatively and only the third to survive. We now present the fourth survivor whose condition was also diagnosed correctly preoperatively.

CASE REPORT

A 23-year-old African man was admitted on 29 Jan., 1969, having awakened 4 hours earlier with mid-abdominal pain and dizziness followed by vomiting. In November, 1968, he had had an episode of pain in the right arm just above the elbow, of sudden onset, which had been succeeded by swelling. Both the pain and the swelling had persisted unaltered for 2 weeks and had then gradually subsided. Early in January, 1969, the patient had begun to have attacks of abdominal pain; initially the pain had been supra-umbilical but later it had become generalized. Two weeks before admission he had developed pain of sudden onset successively in his left ankle, 2–3 days later in the medial side of the left thigh just above the knee, and 3–4 days after that in the left groin which had soon been followed by a swelling. On admission he still had pain in all three positions in the left leg, but neither pain nor swelling was present in the arm.

The patient was grossly anaemic with slight ankle oedema, a collapsing pulse accompanied by a diastolic murmur of aortic incompetence, a blood-pressure of 200/90 (in the left arm), and a weak right radial and left posterior tibial pulse. In the upper part of the left thigh there was a mass with a thrill, a murmur, and expansile pulsation over its lower and medial part. The abdomen was tender and the spleen was palpable, but there were no splinter haemorrhages nor petechiae and the skin was disfigured by neurofibromata and café-au-lait patches. Diagnoses of aortic incompetence with subacute bacterial endocarditis and of multiple peripheral embolism with neurofibromatosis were made. At this stage the abdominal signs were considered to be due to mesenteric vascular occlusion but at no time was blood passed per rectum.

The patient's haemoglobin was 34 per cent with 12 per cent reticulocytes; packed cell volume, 16; mean corpuscular haemoglobin concentration, 31; white cell count, 7100; platelets, 125,000; erythrocyte-sedimentation rate, 35 mm. per hour. Electrolytes were normal and the urine showed no abnormality. The liver-function tests were normal, but the Venereal Diseases Research Laboratories' test was strongly positive. The blood cultures were always sterile.

During the next few days the patient improved after treatment with blood transfusion, digoxin, and frusemide, but on 9 Feb. he had an exacerbation of abdominal pain, collapsed, and became very anaemic. There was generalized abdominal tenderness, which was maximal in the left hypochondrium, with shifting dullness. Blood was obtained on abdominal paracentesis. A tentative diagnosis of a ruptured splenic artery aneurysm was made.

At laparotomy the peritoneal cavity contained dark blood with clots in the splenic region and pelvis and a ruptured spleen showing evidence of a recent infarction centrally and an old subcapsular haemorrhage. There was a small splenic artery aneurysm situated approximately 5 cm. from the splenic hilum but it was intact. The spleen was removed and the splenic artery was ligated proximal to the aneurysm.

The patient's postoperative progress was interrupted by sudden collapse and pyrexia 9 days after operation followed 4 days later by a severe herpetic eruption around the mouth and face. His collapse was attributed to septicaemia, but no organisms grew on blood culture. After a further 4 days the aneurysmal haematoma in the left thigh became painful and began to expand and pyrexia returned. It became clear that the aneurysm was now infected, and it was excised on 28 March, the haematoma being evacuated at the same time and the first perforating branch of the profunda femoris (the artery of origin) ligated. Sections of a portion of the resected artery showed some replacement of the smooth muscle of the media by collagen together with disruption of the internal elastic lamina, but there were no signs of inflammation.

The infected haematoma yielded a profuse growth of *Klebsiella* sp. which was sensitive to ampicillin, chloramphenicol, colistin, framycetin, garamycin, and tetracycline.

The patient has remained well since, and when last seen (on 21 Jan., 1970) the blood-pressure differed in the two brachial arteries, being 130/40 on the left and 130/60 on the right, but there were no other changes in his state.

DISCUSSION

Cosgrove and others (1947) reported 12 cases of mycotic aneurysms out of 60 splenic aneurysms

---

* Present address: Department of Surgery, Queen Elizabeth Hospital, Birmingham 15.

(20 per cent). Their average age was 24 years and there was an equal distribution between the sexes. The aneurysms were 2–3 cm. in size and occurred on the finer branches of the splenic artery. In 7 of the 12 patients there were also multiple splenic infarcts. Microscopy showed intimal thickening with hyaline degeneration of the media and fibrosis.

Stengel and Wolferth (1923) discovered 15 mycotic aneurysms in 264 cases of splenic artery disease (6 per cent). They considered that the septic emboli were most frequently arrested at the primary bifurcation of the splenic artery and it was here that the aneurysms were mainly found.

Pregnancy seems to precipitate rupture of splenic aneurysms. Owens and Coffey (1953) found that 23 per cent of the cases in their series were pregnant while in the series of Cosgrove and others (1947) 25 per cent of the cases were pregnant, only 1 of whom survived.

The mortality-rate after rupture approaches 100 per cent, probably owing mainly to failure to recognize the condition even at laparotomy (Heggtveit, 1963). Rupture appears to occur in two stages in many patients, the first stage being rupture either slowly or quickly into the retroperitoneal tissues or the lesser sac. This stage is followed at a varying interval of time (up to 48 hours—Machemer and Fuge, 1939) by rupture into the general peritoneal cavity or into a viscus, often the stomach. The differential diagnosis is that of an acute abdomen with signs of sudden and profuse haemorrhage into the peritoneum or as a haematemesis and/or melaena.

Treatment of a ruptured aneurysm must be surgical with excision of the involved artery with or without splenectomy and partial gastrectomy if the stomach is involved.

CONCLUSION

The case reported here is remarkable for surviving a ruptured mycotic splenic aneurysm and for his multiple pathology. The diagnosis was suggested preoperatively by association of the facts that the patient was under treatment for bacterial endocarditis and had a history suggestive of multiple mycotic aneurysms and that there were overt signs of an aneurysm in the profunda femoris artery. The splenic artery is the second commonest intra-abdominal artery to form aneurysms, the aorta being the first (Bottiglieri, Palmer, and Litalo, 1964). Although nothing was grown from the blood and the histology of the aneurysm was non-specific, the peripheral aneurysm was infected macroscopically prior to surgical intervention and yielded a profuse growth of *Klebsiella* sp. at operation. Immediate operative intervention was essential for the survival of the patient.

It is stressed that mycotic aneurysms of the splenic artery are an uncommon complication of bacterial endocarditis, but can be rapidly fatal unless clinicians are aware of the condition and treatment is prompt and effective.

A CASE OF GALL-STONE ILEUS IN THE ABSENCE OF A BILIARY-ENTERIC FISTULA

By J. H. Newman*

Bristol Royal Infirmary

Summary

A case of gall-stone ileus is reported in which at operation no fistula between the biliary tree and the gut was found. The obstruction was removed and cholecystectomy and exploration of the common bile-duct were performed with a successful outcome. The pathogenesis of intestinal obstruction due to gall-stones in the absence of a fistula is briefly discussed.

Gall-stone ileus is now well recognized and some series describe preoperative diagnostic rates of 80 per cent or more (Figiel, Figiel, Wietersen, and Dranginis, 1955; Haffner, Semb, and Askhus, 1969), but it is rare for intestinal obstruction to be caused by a stone which has entered the bowel through the ampulla of Vater and not via a fistula. Andersson and Zederfelt (1969) have recently stated: 'Since stones which pass the ampulla of Vater are small they do not cause obstruction unless anatomical strictures from cancer or inflammatory disease are present.' Not all share this view, but all agree that such occurrences are rare indeed.

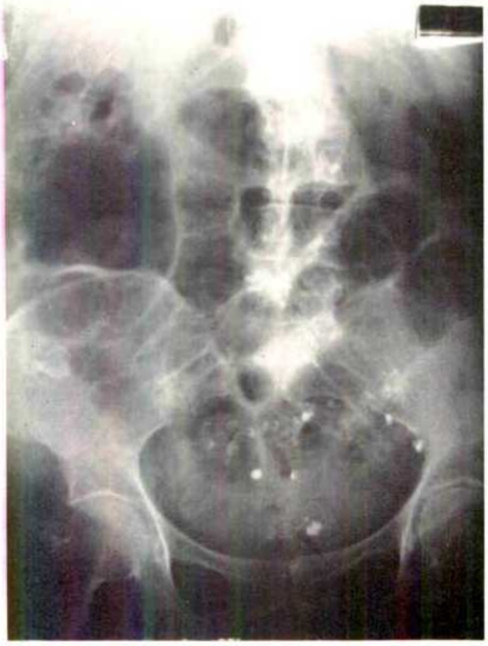

FIG. 1.—Supine radiograph of the abdomen, showing dilated loops of small bowel and an aberrantly located gall-stone in the right iliac fossa.

The purpose of this paper is to present a case of gall-stone ileus in which the causative enterolith undoubtedly entered the bowel from the common bile-duct via the ampulla of Vater.

CASE REPORT

Mrs. C. P., an 81-year-old woman, was admitted on 4 Dec., 1970, complaining of a constant ache in the right iliac fossa which had been present for 6 days. During this time she had been vomiting copiously, but this had not relieved her pain. There had been no alteration in bowel habit and she had passed faeces 24 hours before admission.

Previous history included an episode of rectal bleeding in 1970 which had required hospital admission and which had been diagnosed after barium-enema examination as being due to diverticular disease. There was no past history of jaundice or indigestion.

Examination revealed a well-orientated but dehydrated old lady who was neither anaemic nor jaundiced. Her temperature was 36·2° C., pulse-rate was 80, and blood-pressure was 150/90 mm. Hg. The abdomen was not distended but exhibited generalized tenderness which was most marked in the right iliac fossa. Bowel-sounds were normal, no masses were palpable, and rectal examination was normal.

The following investigations were performed: haemoglobin, 18·7 g. per 100 ml.; packed-cell volume 56 per cent; white blood-count, 18,000 per mm.^{3}; blood-urea, 140 mg. per 100 ml.; serum potassium, 3·2 mEq./l.; midstream urine, sterile. An abdominal radiograph showed a dilated loop of colon in the region of the hepatic flexure; there were no signs of obstruction.

A provisional diagnosis of diverticulitis was made and the patient was treated with intravenous fluids and antibiotics. Her condition remained satisfactory and her bowels were opened three times in the next 5 days. However, on 12 Dec. she developed abdominal pain and started to vomit again and increasing abdominal distension was noted. An abdominal radiograph (*Fig.* 1) confirmed intestinal obstruction and surgery was advised.

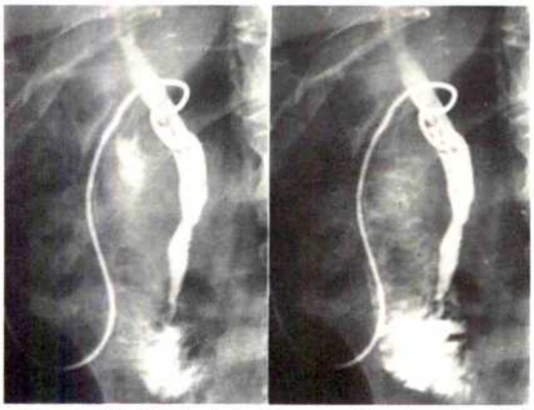

FIG. 2.—The T-tube cholangiogram performed on the eighth postoperative day, showing no remaining stones and no fistula between the common bile-duct and the gut. The lower end of the common bile-duct tapers normally.

At operation there was gross diverticular disease of the sigmoid colon and marked distension of the small bowel owing to an obstruction 60 cm. from the ileocaecal valve. The small bowel appeared otherwise normal. Gall-stones were palpable in the gall-bladder and common bile-duct. There were no adhesions between the gall-bladder and the bowel. The obstruction was found to be due to an impacted stone which broke on manipulation. An enterotomy was made and pieces of an obvious gall-stone were removed. Cholecystectomy and choledocholithotomy were performed, five stones being removed from the common bile-duct. Operative cholangiography was undertaken and showed that the common bile-duct was free of stones and no fistulous connexion with the bowel was shown, though both the cystic duct and the common bile-duct were noted to be dilated.

Postoperative progress was uneventful. A T-tube cholangiogram (*Fig.* 2) on the eighth postoperative day showed neither stones nor fistula.

The stones from the ileum, the common bile-duct, and the gall-bladder (*Fig.* 3) were analysed chemically and found to be identical, all containing cholesterol and bile-salts. The gall-bladder showed the histological changes of chronic cholecystitis.

DISCUSSION

In 1900 Courvoisier performed autopsies on 36 cases of gall-stone ileus, and in 7 he was unable to demonstrate a fistula. A similar finding was reported by Collins and Claxton (1966), who were unable to demonstrate a fistula at an autopsy performed 2 months after an operation for the relief of intestinal obstruction due to a gall-stone. However, it is known that fistulae can close spontaneously (Raiford,

1962) and it is impossible to be certain that this had not occurred in these cases. Three cases of gall-stone ileus in the absence of a fistula at operation have been reported; in 2 of these (Mulder and Flynn, 1958; Warner and Swann, 1951) the patient had previously undergone a gastrectomy of the Polya type, and the stones were thought to have enlarged whilst stationary in the afferent loop. In the third case (Dulin and Petersen, 1939) the stone had probably enlarged in a duodenal diverticulum. No such blind pockets were found at laparotomy in the present case.

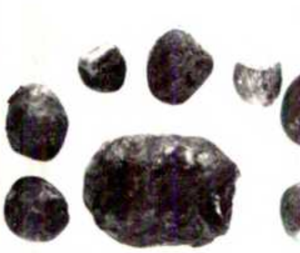

FIG. 3.—The gall-stones removed from the ileum, gall-bladder, and common bile-duct.

The various forms of enterolith have been reviewed by Singleton (1970), who classifies gall-stones as secondary true enteroliths because they are formed outside the intestine. Primary bile-acid enteroliths are much less common, but can enlarge in diverticula to a sufficient size to cause intestinal obstruction. It has been suggested that since these enteroliths resemble gall-stones they may be responsible for several cases of obstruction apparently due to a gall-stone (Armitage, Fowweather, and Johnstone, 1950). However, in the present case laboratory analysis of the stones from the ileum, the common bile-duct, and the gall-bladder showed them to be identical and there can be little doubt that the obstruction was caused by a stone or possibly an aggregation of small stones which had formed in the biliary tree.

Wakeley and Willway (1935) have discussed the ways by which stones enter the bowel and illustrate a case where a stone was about to ulcerate through the lower end of the common bile-duct into the duodenum. That such a fistula can form seems plausible, but none was present in the case presented here as two cholangiograms showed a relatively normal lower end to the common duct (*Fig.* 2). Choledochoduodenal fistulae are said not to heal spontaneously (Maingot, 1968) and would be unlikely to do so while several stones remain in the common bile-duct. The obstruction in this case must therefore have been formed by a stone or stones which had entered the bowel from the biliary tree. No fistula could be demonstrated either at laparotomy or by two cholangiograms and it would seem highly likely that the stone had passed through a dilated ampulla of Vater.

Acknowledgement.—I would like to thank Mr. H. J. Espiner for his permission to publish this case and for his help in preparing this report.

HAEMOPERITONEUM COMPLICATING SECONDARY CARCINOMA IN THE LIVER

By ALI AHMED and C. METCALFE-GIBSON
UNIVERSITY OF MANCHESTER AND MANCHESTER ROYAL INFIRMARY

SUMMARY

Haemoperitoneum complicating primary hepatic carcinoma is well documented but secondary hepatic carcinoma rarely causes intra-abdominal haemorrhage. A case of haemoperitoneum from secondary pancreatic carcinoma of the liver is reported.

A CASE of haemoperitoneum due to haemorrhage from a secondary hepatic carcinoma of pancreatic origin is described. This is the first report of such a case due to pancreatic carcinoma.

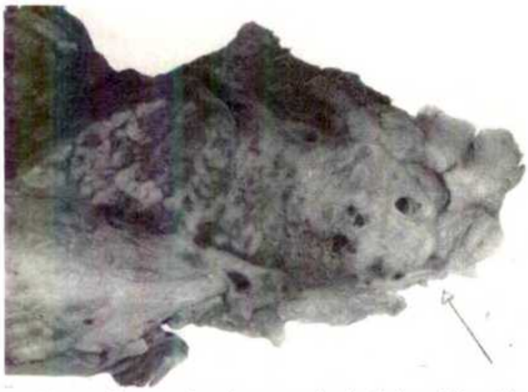

FIG. 1.—Pancreas showing tumour in the body and the tail.

CASE REPORT

W. H., a previously healthy 72-year-old man, was admitted to another hospital with a 3-week history of decreasing appetite, lethargy, and shortness of breath on exertion. On the day of admission he had felt unwell and had had a fainting episode.

On admission the patient was shocked, and he had a blood-pressure of 90/50 and was grossly anaemic (Hb, 55 per cent). The abdomen was distended and a vague epigastric swelling was palpable. Despite resuscitation the patient's condition deteriorated and the following day a peritoneal tap revealed fresh blood. A tentative diagnosis of a slowly leaking abdominal aortic aneurysm was made and the patient was transferred to the Manchester Royal Infirmary.

At laparotomy 2 litres of fresh blood were drained from the peritoneal cavity. The aorta and major vessels were intact. The pancreas felt hard and irregular and the upper para-aortic and coeliac lymph-nodes were enlarged and firm. The liver was enlarged and showed diffuse nodularity. The source of haemorrhage was a small ulcer on the inferior aspect of the right lobe of the liver. A biopsy was taken from this site and the area was sutured. The patient's condition deteriorated and he died a few hours later.

At autopsy the abdomen was distended and contained about 1·5 litres of deeply blood-stained fluid. A large clot was present in the right subphrenic area. Several grey-white nodules measuring up to 1 cm. in diameter were seen in the pelvic peritoneum and the posterior parietal peritoneum.

The head of the pancreas appeared normal. A hard, ill-defined, grey-white mass showing areas of haemorrhage and necrosis was present in the body and the tail of the pancreas (*Fig.* 1). Histologically the tumour was a poorly differentiated adenocarcinoma (*Fig.* 2).

The liver was enlarged and the external surface showed numerous, small, raised, reddish-brown nodules. On section the general pattern of the nodules was suggestive

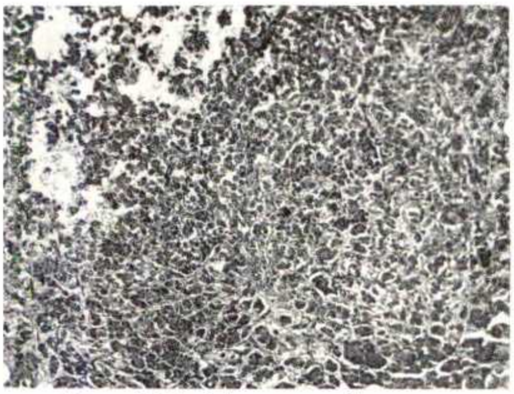

FIG. 2.—Histological appearance of the tumour.

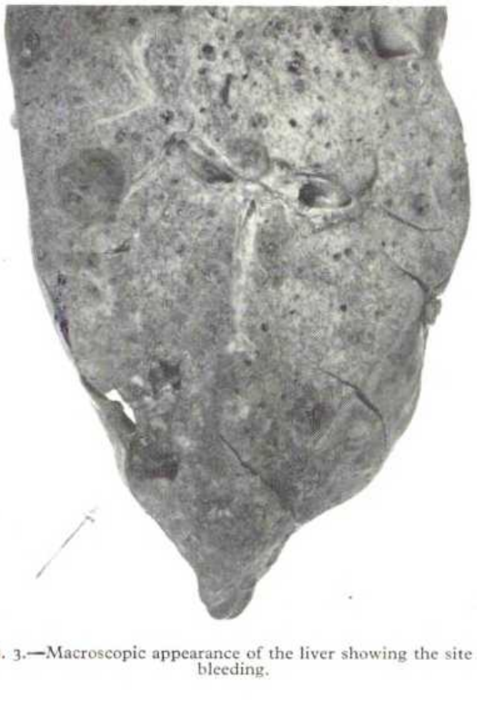

FIG. 3.—Macroscopic appearance of the liver showing the site of bleeding.

of a vascular distribution. A number of more typical grey-white secondaries measuring up to 1·5 cm. in diameter was seen. At one site in the right lobe there was a necrotic ulcerated area, 3 cm. in diameter, containing blood-clot (*Fig.* 3).

Histologically the appearance of the tumour deposits and the biopsy from the bleeding site resembled the primary lesion in the pancreas. The tumour was infiltrating the portal venous system and several deposits were seen in the hepatic parenchyma. Many of these deposits showed haemorrhage and necrosis.

The splenic vein was partially occluded by tumour but the main portal vein did not appear to be involved. The spleen (130 g.) was of normal size but the cardio-oesophageal veins were rather prominent, suggesting some degree of portal hypertension.

The lymph-nodes of the peripancreatic region and the porta hepatis were enlarged and contained tumour.

DISCUSSION

Haemorrhage from secondary hepatic carcinoma is a rare condition (Gribble and Blair, 1962). Specter and Chodoff (1950) reported a case of haemoperitoneum from a cavitated metastatic adenocarcinoma of the liver. The origin of the tumour was uncertain but histological appearances were suggestive of a primary in the kidney or the adrenal gland. Although these authors believed that their case of haemoperitoneum due to metastatic tumour of the liver was the first recorded case, Bettini (1956) was able to find 10 reported cases of haemorrhage from metastatic tumours and he added a further case of his own. None of these cases was of pancreatic origin.

Involvement of the portal vein by tumour is usually seen in pancreatic carcinomas arising in the head or the body of the pancreas, whereas invasion of the splenic vein and its possible extension into the portal vein are more apt to occur when the tumour is situated in the body or tail of the pancreas (Winston Evans, 1966).

In contrast to the rather slow, prolonged bleeding seen in the present case haemorrhage associated with primary hepatic carcinoma tends to be massive owing to the greatly increased hepatic blood-flow in the latter condition (Wartnaby, Bouchier, Pope, and Sherlock, 1963).

In the differential diagnosis of intra-abdominal haemorrhage this rather rare cause from secondary hepatic carcinoma should be borne in mind.

Acknowledgement.—We wish to express our thanks to Mr. W. McN. Orr, under whose care this patient was admitted, for his permission to publish the case and for his helpful advice and criticism.

LUMBOSACRAL AGENESIS IN A 60-YEAR-OLD MAN

W. J. NICOL

ORTHOPAEDIC SENIOR REGISTRAR, DUNDEE ROYAL INFIRMARY

SUMMARY

A case of lumbosacral agenesis below the third lumbar vertebra in a 60-year-old man is described. The patient is thought to be the oldest survivor with such an extensive defect.

CASE REPORT

C. McN., a 60-year-old man, one of a large family with both older and younger healthy brothers and sisters whose mother had died in her seventies, had first been admitted to hospital for the investigation of a urinary-tract infection and left-sided colic at the age of 59 years.

He had regarded himself as a freak of nature from an early age because he had never been able to walk. His legs had been diminutive and wasted at birth though movements at the hips and knees had been present and sensation intact. He had not gone to school because of difficulty in controlling micturition. He had taught himself to read and write and had grown to develop a healthy attitude to his deformity. He had dreaded the idea of being investigated in hospital as he felt nothing could be done for him. He found he could control micturition by regularly compressing his abdomen manually. Regular purgation kept his bowel movements under control. He had lived a wheel-chair life indoors till the age of 40 years, when he had procured an invalid car.

On examination the patient was found to have strong, well-developed upper limbs and shoulders but his trunk tapered to a small mobile pelvis and diminutive lower limbs. Movements of the hips and knees were reduced by wasting of all the muscles and gross contractures. Examination of the chest revealed a ventricular septal defect and an electrocardiograph showed a grossly abnormal record suggesting anterior myocardial infarction and left ventricular hypertrophy. Biochemical and haematological investigations revealed no gross pathology. A radiograph of the lumbar spine and pelvis (*Fig.* 1) showed the spine to terminate blindly at the third lumbar vertebra, the sacrum to be absent, the ilii joined at a synarthrosis, the pelvis and hips to be grossly distorted, and the left hip to be dislocated. Intravenous pyelography revealed no significant pathology. His urinary infection responded to a course of ampicillin and his renal colic subsided.

The patient is now at home where he dresses himself and attends to his own toilet. No further investigations are contemplated. Permission to take a photograph was not granted.

DISCUSSION

Since Hohl (1850) first reported a case of sacral agenesis increasing numbers of cases have been documented. Most describe various degrees of sacral and lumbosacral agenesis in infants and children. Freedman reviewed the literature in 1950 and classified previously recorded cases of spinal agenesis according to the level of the lowest vertebra present. *Table I* summarizes all recorded live cases of lumbosacral agenesis with their known period of survival. Those rare cases involving the lower thoracic vertebrae are included, while those with absence of the sacrum or coccyx as the only spinal defect are excluded.

* Duration of survival is estimated by the age at death or the age at the time of reporting.

The oldest case described by Banta and Nichols (1969) is a 25-year-old female with a rudimentary first lumbar vertebral body who was first seen at the age of 7 months. Freedman (1950) reported the case of a 61-year-old man with absence of the sacrum below the second sacral segment who was able to get about quite well though his legs had been wasted since infancy. His last 7 years had been spent in an institution. The case reported here is thought to be the longest survivor with the most extensive spinal defect.

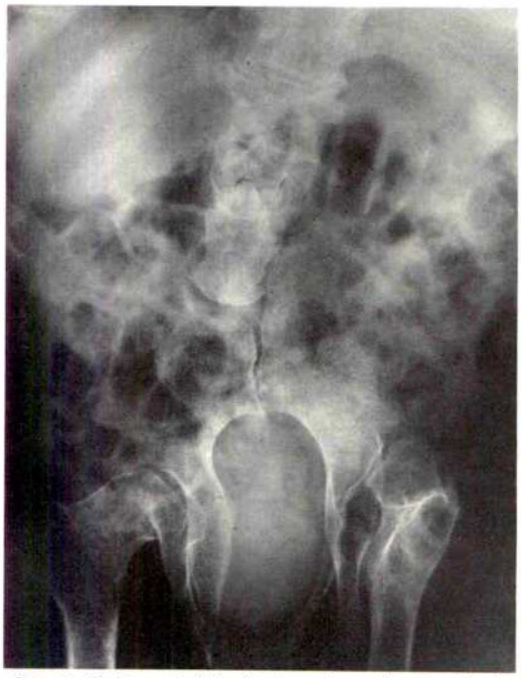

FIG. 1.—Radiograph of the lumbar spine and pelvis, showing the spine terminating blindly at the third lumbar vertebra, the sacrum absent, the ilii joined at a synarthrosis, and the pelvis and hips grossly distorted. The left hip shows dislocation which is probably neurogenic.

Acknowledgements.—I am indebted to Mr. J. P. A. Weaver, Senior Lecturer in Surgery, University of Dundee, for permission to examine his patient and for giving me access to his records; to Mr. K. L. G. Mills, Senior Lecturer in Orthopaedic Surgery, University of Dundee, for his constant encouragement; and to Mr. R. G. Donovan, Chief Photographic Technician, Department of Orthopaedic Surgery, University of Dundee, for considerably improving on a poor radiograph.

LEIOMYOMA OF THE APPENDIX

BY T. H. CULLEN AND H. J. VOSS
KETTERING GENERAL HOSPITAL

SUMMARY

A case of a very large leiomyoma of the appendix is reported. References to this condition are rare and the presentation of this case is unusual.

ALL surgeons with some experience of abdominal surgery will have met with leiomyomas of the wall of the intestine. These benign tumours are often an incidental finding on abdominal exploration in the course of treating some other condition, although they may cause symptoms of their own accord, usually presenting as gastro-intestinal haemorrhage or intestinal obstruction.

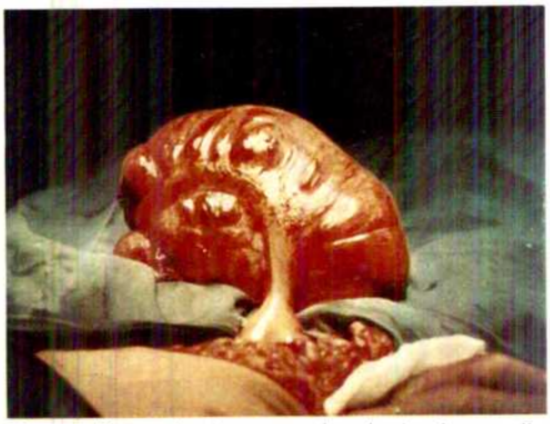

FIG. 1.—Photograph taken at operation, showing the appendix stretched out over the large leiomyoma.

Some are discovered only at routine post-mortem examination, having been symptomless during life.

The unusual features of the tumour reported here are the site of origin, the size, and the mode of presentation.

CASE REPORT

R. W., aged 50 years, was referred to the medical out-patients' clinic of Kettering General Hospital in June, 1970, for investigation of chest pain on exertion. Ten years previously this patient had had melaena from a duodenal ulcer, and in January, 1970, he had had deep-vein thrombosis in his right leg and had been treated with anticoagulants. Examination by a medical colleague revealed little of significance except for a mass in the lower abdomen which felt like an enlarged bladder. This mass did not appear to alter after the patient had passed a moderate amount of urine, but bimanually it seemed to be related to the prostate and bladder. On further questioning he complained of increased frequency and some dribbling at the end of micturition. He was then

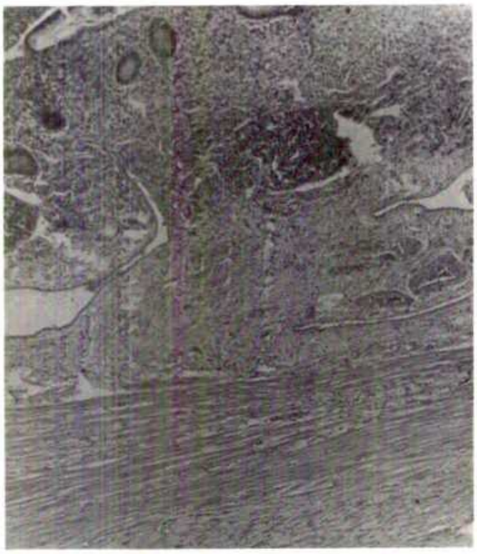

FIG. 2.—Leiomyoma arising from the outer muscular layer. H. and E. (× 42.)

seen by one of the authors (T. H. C.) and he certainly appeared to have chronic retention associated with a minimal degree of benign prostatic enlargement. His haemoglobin was 15·2 g. per cent, E.S.R. 4 mm. fall in 1 hour, blood-urea 31, and the midstream urine contained no white cells and was sterile on culture. An intravenous pyelogram revealed a soft-tissue tumour lying in the pelvis above the bladder; apart from a trace of residual urine in the bladder after micturition the urinary tract was normal. Lateral tomography did not help to elucidate the nature of the tumour and laparotomy was advised.

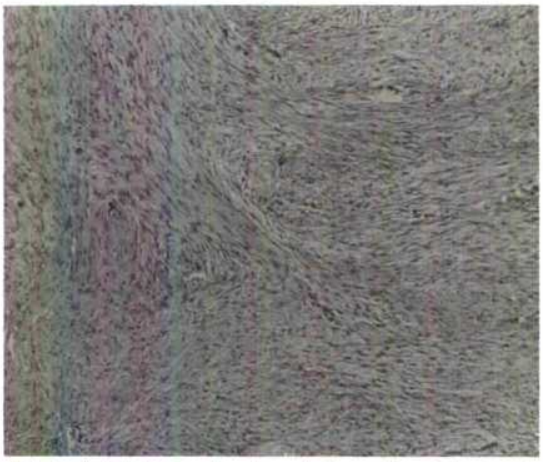

FIG. 3.—Interlacing bundles of muscle-fibres. H. and E. (× 42.)

OPERATION (T. H. C.).—On 9 Oct. the abdomen was explored through a right lower paramedian incision. A large, hard, encapsulated mass was found in the pelvis. A piece of gut was stretched over its surface and once this was identified as the appendix the mass and the appendix were easily removed (*Fig.* 1). No other abnormality was found in the abdomen.

The patient's postoperative progress was uneventful. He was discharged from hospital on the fourth day after operation.

PATHOLOGICAL REPORT (H. J. V.).—Naked-eye examination of the specimen revealed a circumscribed pale tumour with a glistening surface measuring 15 × 10 × 8 cm. Along one border the appendix (10 cm. in length) was partly embedded, one surface lying free, the other being half embedded in the tumour. On section the appendix was somewhat flattened by the tumour but not apparently inflamed. The tumour arose from or was continuous with the embedded muscular layer of the appendix. The tumour itself was pale buff coloured, firm, and of a whorled pattern—a typical appearance of a leiomyoma.

Microscopic examination showed a flattened but otherwise normal appendix. The mucosa and submucosa were surrounded by the normal longitudinal and concentric muscular layers. From the longitudinal layer there arose a leiomyoma (*Fig.* 2), consisting of interlacing bundles of smooth muscle-fibres (*Fig.* 3). Although there was some variation in the size of the cells there was little nuclear pleomorphism and no mitotic activity to suggest malignancy (*Fig.* 4). The appearance did not differ from that of a benign leiomyoma which is not infrequently found in the stomach or small intestine. In spite of its size the tumour had clearly grown outwards and had not projected into the mucosa.

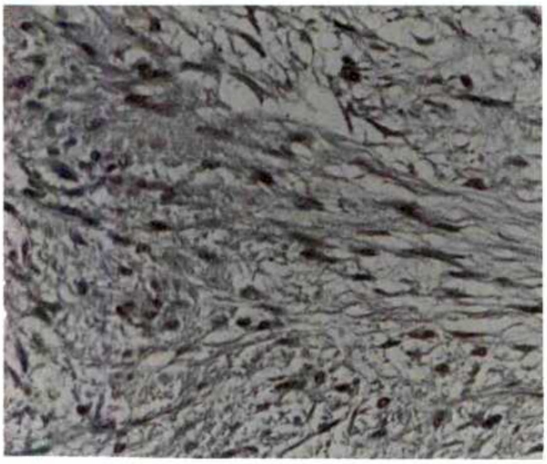

FIG. 4.—High-power view of the well-differentiated smooth muscle-fibres. H. and E. (× 86.)

DISCUSSION

We have been able to find two references to leiomyoma of the appendix in the literature.

Dobrov (1968) found one leiomyoma of the appendix in a series of 6662 appendicectomies carried out in the clinic of the Faculty of Surgery of the Medical Institute of Astrakhan; he was unable to find any reference to leiomyoma of the appendix in the literature. The leiomyoma reported in his paper was described as a thickening at the tip of the appendix the size of a hazel nut; this was discovered incidentally during a laparotomy for acute cholecystitis. Naka, Shinno, Aikawa, and Kuranishi (1969) also report a leiomyoma of the appendix, which was found in an appendix removed for acute appendicitis. It is described as a small, white, hard swelling the size of the tip of the little finger.

Doubtless other small tumours of this nature have been discovered in appendices removed at operation or found at routine post-mortem examination but have not been reported in the literature.

Acknowledgements.—We are indebted to Mr. R. R. Popham and to the technical staff of the Department of Pathology for the photographs.

REVIEWS AND NOTICES OF BOOKS

Orthopaedics for the Undergraduate. Fractures. By W. A. CRABBE, M.D., F.R.C.S., Orthopaedic Surgeon, Guy's Hospital, London. 8½ × 5½ in. Pp. 256 + vii. Illustrated. 1971. London: William Heinemann Medical Books Ltd. £3·30.

THIS is a useful book for students, for it sets out in a lucid and dogmatic way the causes, treatment, and after-treatment of fractures. Quite a feature of the book is the large number of illustrations—all line drawings and very informative.

A good knowledge of this book would get any student a pass mark in orthopaedics at a final examination.

In this age of trauma a sound knowledge of the treatment of fractures is essential to all practitioners.

Tracheostomy and Artificial Ventilation. Second edition. Edited by STANLEY A. FELDMAN, Consultant Anaesthetist, Westminster Hospital, London, and BRIAN W. CRAMLEY, Consultant Anaesthetist, Canterbury Group of Hospitals. 9 × 6 in. Pp. 151 + viii. Illustrated. 1971. London: Edward Arnold (Publishers) Ltd. £3.

THE second edition of this most useful book has been brought up to date and new chapters have been added. Today with intensive-care units in an ever-increasing number of hospitals the usefulness of this book is very apparent. The illustrations are clear, and they do enhance the text.

All hospital residents, students, and nurses will find in this book a clear, factual account of the several problems involved in the care of tracheostomy cases.

Ano-rectal Malformations in Children. By F. DOUGLAS STEPHENS, D.S.O., M.S. (Melb.), F.R.A.C.S., Melbourne, and E. DURHAM SMITH, M.D. (Melb.), F.R.A.C.S., F.A.C.S., Melbourne. 9 × 6 in. Pp. 411 + xvi. Illustrated. 1971. London: Lloyd-Luke (Medical Books) Ltd. £11·70.

ANORECTAL malformations are common in children and the majority of cases are seen in paediatric hospitals. When it is considered that there are some 37 regularly occurring types of these deformities it will be seen how important is such a book as this. The authors have made a comprehensive survey of these deformities and have added their own personal survey of their cases.

The book commences with a historical review of anorectal deformities from the year 650 B.C. to the present day.

Deformities in the male are considered at some length and are contrasted with those occurring in the female. It is interesting to read of the proposed international classification of anorectal anomalies which should be accepted by surgeons throughout the world. The various deformities are described in detail and are illustrated by line drawings and clinical photographs. The pre- and postoperative clinical photographs are particularly good.

The various operative techniques are described in detail. The results of operative treatment, the complications which may arise, and the assessment of continence make interesting reading.

There is a comprehensive list of references at the end of the book as well as three appendixes which are of real value.

This is a most useful reference volume on an important subject.

Patients, Hospitals and Operational Research. By G. M. LUCK, B.A., M.Sc., J. LUCKMAN, M.Sc., B. W. SMITH, B.Sc., M.B.C.S., and J. STRINGER, M.A., Institute for Operational Research, London. 8½ × 5½ in. Pp. 210 + xv. Illustrated. 1971. London: Tavistock Publications Ltd. £3·75.

ANY advice which will improve the working of the National Health system in this country will be welcome, for it must be said that there is room for improvement at the present time.

The Institute for Operational Research, which has fostered this book, has done a good job. It seeks to improve the process of decision-making at all levels of management. Such problems as case study, uneven workloads in special departments, planning surgery, and nursing techniques are all considered and debated. Most of the projects described in this book concern the systems relating to the care of patients, including their admission, diagnosis, treatment, and discharge. There can be no doubt that doctors, administrators, and nurses will find this book useful. Anything which improves the efficiency of our hospital system is of value at the present day.

Progress in Pediatric Surgery. Vol. 3. Edited by P. P. RICKHAM, W. CH. HECKER, and J. PRÉVOT. 9 × 5½ in. Pp. 167. Illustrated. 1971. Munich: Urban and Schwarzenberg. DM.45.

THIS is the third volume in the present series and it contains some interesting articles. Quite a feature of this series is the summary at the end of each article in English, French, and German.

This paper-back is apt to stress the rare cases in paediatric surgery but perhaps this is a good feature. An interesting article on the forms of congenital deformities of the chest reveals the fact that depression deformities of the sternum are extremely common, while protrusion deformities of the sternum are less common. The aetiology and pathogenesis of funnel chest are considered in great detail.

Subvesical urinary obstruction is an important congenital defect and various experiments on rabbits and pigs reveal some interesting results.

Such problems as the administration and design for intensive therapy in surgery of the newborn, the results of long-term positive-pressure ventilation, and the function of the cardia in childhood are discussed at length.

This is an interesting and stimulating book and it should be read by all surgeons who have infants and children under their care.

It is not often that a book is edited by an Englishman, a German, and a Frenchman, but the result is a great success. Is this a forerunner of the Common Market and its surgical literature?

Facial Prostheses. By ALAN CLIVE ROBERTS, T.D., C.G.I.A., F.R.S.H., F.B.I.S.T., A.I.S.T., A.I.Mech.E., St. Luke's Hospital, Bradford. 9½ × 7 in. Pp. 128 + x, with 138 illustrations. 1971. London: Henry Kimpton. £3·50.

THIS book contains a wealth of material dealing with facial reconstruction by means of various prostheses. The use of prostheses goes back a long way in time. Artificial eyes were used in Egyptian mummies and the ancient Chinese made use of facial prostheses from clay, wax, and wood. Two world wars and the increase in road accidents have provided a spate of cases which called for facial prostheses often after surgery had done its best.

The modern use of plastics has played a part in the making of prostheses. In dental surgery also the use of a prosthesis is frequently called for.

The author of this useful book has had an enormous experience both in this country and America of cases which required special prostheses. He discusses preconstructive planning and techniques to obtain the exact topography of the defect. He also deals with the use of synthetic materials and the effects of colour and light so that there is a minimum of contrast.

At the end of the book there are a number of clinical case histories and photographs showing the condition before and after the fitting of a prosthesis.

This book will interest a wide range of clinicians and plastic and dental surgeons as well as ophthalmic surgeons.

Handbuch der Medizinischen Radiologie; Encyclopedia of Medical Radiology. Part 3. Spezielle Strahlentherapie Maligner Tumoren. Edited by A. ZUPPINGER, Bern. 10½ × 7½ in. Pp. 642 + xv. Illustrated. 1971. Berlin: Springer Verlag. DM.296.

THIS volume which is part of the extensive encyclopaedia of medical radiology is devoted to the radiation treatment of tumours of the female genital organs, the male genitalia, and the urinary tract. All the chapters are authoritatively written by experts whose vast personal experience in their respective fields comes through very well. The chapters dealing with the female genitalia and uterus are in German, while the large section on the urinary tract is in English and the extensive contribution by Bloom and Wallace is particularly good. There are extensive references for all the chapters and, as usual, a detailed index. The illustrative radiographs are clear but unfortunately the publishers have stuck to the positive reproduction method.

This volume will be welcomed by radiotherapists and indeed by anybody treating malignant tumours and will obviously become a standard reference work. It is likely, however, that at £36 this book will be for libraries only. It is also somewhat debatable whether an authoritative volume like this should be produced in two languages, two-thirds of the book being in German and one-third in English. If the book were all in English its appeal would almost certainly be greater.

Congenital Deformities of the Testis and Epididymis. By C. GORDON SCORER, M.A., M.D., F.R.C.S., F.R.C.S. (Edin.), and GRAHAM H. FARRINGTON, M.Ch., F.R.C.S. 9½ × 5½ in. Pp. 203 + ix. Illustrated. 1971. London: The Butterworth Group. £4·20.

THIS book would have been enjoyed by John Hunter. Undescended testis affects about seven out of every thousand males born alive in this country, or about five thousand new babies every year, but its diagnosis and treatment are still uncertain and clouded with doubts about the time when operative treatment should be undertaken and what should be done. For every boy with a really undescended testis who is referred to a surgeon eight or nine boys with retractile testes are also referred by general practitioners and school medical officers who have examined their patients with cold hands or in a chilly room. There is not much doubt that the very good results of surgical treatment which have sometimes been claimed in the past depended very largely on the inclusion in the series of a very large proportion of boys with retractile rather than undescended testes.

This is an excellent book which gives a clear account of the whole subject of congenital abnormalities of the testes. It is well illustrated with good, simple diagrams and photomicrographs. There is a proper emphasis on early operative treatment to allow of what normal development may be possible after placing the testis in the scrotum. There is a reasonable discussion of the risks of malignant change in the undescended testis and of the results of treatment and the chances of fertility. This book should be read by all surgeons who have to deal with undescended testes and by all paediatricians who will find much to stimulate thought about this very difficult surgical and social problem as well as the means to modify some of the extravagant and erroneous opinions which are still too widely accepted about the results and value of even modern methods of treatment of the undescended testis.

Schweitzer. A Biography. By GEORGE MARSHALL and DAVID POLING. 9 × 6 in. Pp. 342 + xviii. Illustrated. 1971. London: Geoffrey Bles. £3·50.

THIS is by far the best book that has so far been published about that controversial figure, Albert Schweitzer. The authors of this book have carried out their task in an excellent fashion and have written a true biography of a great man. The photographs in this book are excellent and the reader is given a very good idea of the mentality and characteristics of Schweitzer.

The footnotes and chapter references are very helpful, as is the chronological biography at the end of the book.

It is given to few men to study theology, philosophy, music, and medicine and to become an expert in all. In this book we get an image of the real man, namely a respected philosopher, a renowned Biblical scholar, and a liberal rebel in a conservative European Protestant church. He was an accomplished organist and interpreter of Bach, a crusader for world peace, and a winner of the Nobel Peace Prize in November, 1953. He made his philosophy of 'reverence for life' an ethic for the world. His hospital in Lambaréné, which is still in operation, is a model of what the European might have given to the African native throughout colonial history.

Schweitzer was a prolific writer, not only on medical and social subjects, but also on musical ones.

This biography, which is praised by his only daughter, Rhena, is a wonderful book of memories of a really great man.

Physiology of the Eye. Third edition. By HUGH DAVSON, D.S.C. (Lond.), London. 9 × 6 in. Pp. 643 + vii. Illustrated. 1972. Edinburgh: Churchill Livingstone. £6.

WE welcome the new third edition of this important work because it is an excellent exposition of ophthalmic physiology in one volume.

All branches of surgery today demand a very thorough knowledge of physiology, and in ophthalmology this is even more important.

This book, which is well illustrated, is divided into five sections: the vegetative physiology and biochemistry of the eye, the mechanism of vision, the muscular mechanisms, visual perception, and visual optics.

The problem of intra-ocular pressure is discussed in detail. Visual acuity and colour vision are explained in a very practical way.

Many of the illustrations in this book are original. They are also very striking and do help to explain the written word. There are some 80 new illustrations in this edition.

This book should prove invaluable to physiologists and ophthalmologists and also for students taking the B.Sc. in physiology.

Shands' Handbook of Orthopaedic Surgery. Eighth edition. Edited by R. BEVERLY RANCY, sen., M.D., North Carolina, and H. ROBERT BRASHEAR, jun., M.D., North Carolina. 9½ × 6½ in. Pp. 543 + xiv. Illustrated. 1971. London: Henry Kimpton. £7.

THIS is the eighth edition of *Shands' Handbook of Orthopaedic Surgery* and Dr. A. R. Shands, jun., has now joined the editorial board. A book that has held its own for 35 years with eight editions over this period must be good. In the sixteen chapters which comprise this volume every facet of orthopaedic surgery is considered.

The volume is written in clear, decisive prose and the illustrations have been well chosen and are well produced.

The chapters on bone tumours and amputations are outstanding.

This new eighth edition will prove even more popular with students and practitioners than earlier ones.

The Lacrimal System. Edited by EVERETT R. VEIRS, M.D., Texas. 9½ × 6½ in. Illustrated. 1971. London: Henry Kimpton. £10·10.

THE various articles in this volume were presented at a symposium held in Mexico City in March, 1970. Every aspect of the lacrimal system has been well covered.

The book is divided into six parts. Part 1 deals with the congenital anomalies of the lacrimal system, such as absence of the gland, absence of tear secretion, and aberrant gland tissue. Part 2 is concerned with disorders of the lacrimal gland including tumour formation.

In part 3 disorders of the lacrimal canaliculi come under review. The use of silicone lacrimal tubes is advocated in some cases of injury.

Part 4 deals with disorders of the lacrimal sac, part 5 is concerned with external dacryocystorhinostomy, and part 6 is a summary of the various papers.

Mr. A. Werb, a surgeon at the Corneo-plastic Unit, Queen Victorial Hospital, East Grinstead, Sussex, contributes a very practical article on the surgical technique of dacrocystorhinostomy, and illustrates his article with some excellent pictures.

It is only by reading such a book as this that one realizes how many surgical conditions may affect the lacrimal apparatus.

This book should be in every medical library as an important book of reference.

Current Concepts of the Histology of Oral Mucosa. Edited by C. A. SQUIER, The London Hospital Medical College, and JULIA MEYER, Chicago. 10 × 7 in. Pp. 305 + xvi. Illustrated. 1971. Springfield, Ill.: Charles C. Thomas. $18.75.

THIS book contains the proceedings of a symposium held at the University of Illinois College of Dentistry in June, 1970. It is an important book because it represents the first comprehensive account of the histology of the mucous membrane of the mouth.

The numerous illustrations are excellent and are quite a feature of the book. They include some good electron micrographs.

The book should prove an excellent reference volume to dental students and pathologists. It should also interest all research workers in oral histology and dermatologists who may be interested in this special field.

Although, as one would expect, the majority of the contributors come from America there are some from Canada, England, and Scotland.

This is a useful reference volume on an important subject.

Notes on Dental Materials. By E. C. COMBE, M.Sc., Ph.D., A.R.I.C., Illinois. 9 × 5¼ in. Pp. 265 + xi. Illustrated. 1972. Edinburgh: Churchill Livingstone. £2·90.

THIS book is a *must* for all dental students, for it is the only book which gives a synopsis of the subject of dental materials. No student today can carry all these facts and figures in his head and this small book will be a valuable reference book. The book is small enough to go into the pocket and, what is more, the price is very reasonable.

The book is divided into two sections: dental materials science and applied dental materials. The whole field is covered in a very comprehensive way.

Newer dental materials are also discussed, including polycarboxylate cements, composites, spherical amalgam alloys, polyester impression materials, and epimines.

At the end of the book there are a dozen blank pages for notes—an excellent idea, for the student can make notes of the ever-appealing new materials used in dentistry.

Fundamental Skills in Surgery. Second edition. By THOMAS F. NEALON, jun., M.D., New York. 9¾ × 6½ in. Illustrated. 1971. London: W. B. Saunders Co. Ltd. £5.

THE second edition of this book for students and hospital residents has been carefully revised, and it will continue to take its place as one of the really useful books for students. The illustrations which are mostly line drawings are quite a feature of the book.

Die Fettembolie. By Dr. GYORGY SZABO, D.S.M., Budapest. 9¼ × 6½ in. Pp. 284. Illustrated. 1971. Budapest: Akadémiai Kiadó. £4·20.

THE problems of fat embolism are discussed in this book. Having studied many publications from all over the world the Hungarian author of this book, which is edited in German, gives the results of his own investigations in which he and his colleagues checked the tests made by others or invented original tests.

Some facts seem to be proved according to this book; for instance, the fat of fat emboli in the lungs originates from the bone-marrow, which seems logical as the majority of the cases occur after bone fractures.

Transport of the fat is by the venous pathways and the circulating fat obstructs the lung capillaries, but breakdown of the fatty acids may cause toxic damage to the capillary walls.

Having passed the barrier of the lung capillaries the fat enters the main circulation, often resulting in fat embolism of the brain and the kidneys.

The obstruction of the lungs may cause dilatation of the right heart, while arterial hypoxaemia is the most dangerous consequence.

Diagnosis of fat embolism must be made in the first place by clinical observation; dyspnoea, rising body temperature a few hours or days after serious fractures, unrest, impaired consciousness, some neurological symptoms, and petechiae of the skin should arouse suspicion of the presence of fat embolism.

The radiographic picture of the lungs is rather typical (snow-storm), and arterial hypoxaemia is one of the most important laboratory findings.

Attempts at systemic treatment, which means elimination of the fatty substances from the circulation, did not meet with convincing results; the hopeful publications about therapy with decholin, heparin, and humalbin that should combine and neutralize the fatty acids did not convince the author, although the author still uses humalbin.

Symptomatic treatment may be life-saving; treatment of shock helps the patient to survive the effects of fat embolism; oxygen therapy certainly is indispensable and probably the most important measure. The author does not mention the use of protease inhibitors, such as trasylol which is employed by some German authors.

The final chapter mentions the juridical implications; the problems for the pathologist are the conclusion of death by violence after having noticed a fat embolus and the question whether the fat embolism was the main cause of death.

An excellent book that should be studied with great interest.

Ileostomy Care. By MARSHALL SPARBERG, M.D., Chicago. 9 × 6 in. Pp. 161 + xi. Illustrated. 1971. Springfield, Illinois: Charles C. Thomas. $9.75.

THIS is a useful little book, for it gives a detailed account of the after-treatment of an ileostomy. It is a very practical account and the illustrations depicting the changing of the various ileostomy appliances and dressings are excellent.

The book is divided into three sections. Section 1 deals with the immediate preoperative and postoperative care, the construction of the ileostomy, and the application of the appliance. Section 2 is devoted to ileostomy complications, while Section 3 contains some useful appendixes, including a glossary of ileostomy terms.

Surgery and the Allergic Patient. Edited by CLAUDE A. FRAZIER, M.D., Ashville, North Carolina. 9¾ × 6½ in. Pp. 191 + xviii. Illustrated. 1971. Springfield, Illinois: Charles C. Thomas. $12.50.

THIS book has been written by a group of well-known American medical specialists and edited by a distinguished allergist. Every facet of this curious condition has been discussed in detail, and preoperative care in an allergic patient is set out in full.

With the extensive use of penicillin all over the world the number of penicillin-sensitive patients has increased enormously. This is particularly stressed in this book.

It often happens that a known allergy of a patient, such as asthma or urticaria, may occur before an operation.

In this book there is a very thorough coverage of the management of anaphylaxis; a special kit has been designed for immediate treatment of this condition.

This book will appeal to all surgeons and physicians who have to deal with allergic patients.

BOOK NOTICES

[The Editorial Committee acknowledge with thanks the receipt of the following volumes. A selection will be made from these for review, precedence being given to new books and to those having the greatest interest to our readers.]

The Importance of Cineangiography in the Hemodynamic Study of Aortic Valvular Disease. By HAROLD EIE. 8¾ × 6 in. Pp. 97, with 28 illustrations. 1970. Oslo: Universitetsforlaget. N.Kr. 75.

Aide-Mémoire de Détermination Bactérienne. By R. G. CAPET, Montreal. 9¾ × 7 in. Pp. 135. 1970. Paris: Vigot Frères.

Scaphoide Genou—Jambe Spastique. By R. JUDET, Paris. 9½ × 6½ in. Pp. 188. Illustrated. 1971. Paris: Masson et Cie Editeurs. 74F.

The Metabolic Basis of Surgical Care. By WILLIAM F. WALKER, Ch.M., F.R.C.S. (Edin.), F.R.C.S. (Eng.), Dundee, and IVAN D. A. JOHNSTON, M.Ch., F.R.C.S. (Eng.), Newcastle upon Tyne. 8½ × 5½ in. Pp. 251 + x. Illustrated. 1971. London: William Heinemann Medical Books Ltd. £3.

Orthopaedics in Infancy and Childhood. By G. C. LLOYD ROBERTS, M.Chir. (Cantab.), F.R.C.S., London. 8¾ × 5½ in. Pp. 337 + x. Illustrated. 1971. London: The Butterworth Group. £6·75.

Proceedings of the Symposium on Epidural Analgesia in Obstetrics. Edited by ANDREW DOUGHTY, M.B., B.S., F.F.A. R.C.S., Kingston-upon-Thames. 8¾ × 5½ in. Pp. 119. Illustrated. 1972. London: H. K. Lewis. £1·50.

Surface and Radiological Anatomy. By W. J. HAMILTON, M.D., D.S.C., F.R.C.S., F.R.C.O.G., F.R.S.E., London, G. SIMON, M.D., F.R.C.P., D.M.R.E. (Cantab.), F.F.R., London, and S. G. IAN HAMILTON, M.A., M.Chir. (Cantab.), F.R.C.S. Pp. 397 + x. 1971. Cambridge: W. Heffer and Sons Ltd. £6.

Die Inaktivitäts-Osteoporose. By J. MACH, Rostock. 8½ × 5¾ in. Pp. 207. Illustrated. 1971. Berlin: Verlag Volk und Gesundheit. 44.80 M.

Dextran: Current Concepts of Basic Actions and Clinical Applications. Compiled and edited by JOHN R. DERRICK, M.D., Texas, and M. MASON GUEST, Ph.D., Texas. 9 × 6 in. Pp. 222 + xiv. Illustrated. 1971. Springfield, Illinois: Charles C. Thomas. $14.75.

Urologische Operationslehre. Vol. 8. By G. W. MÜLLER, Magdeburg, W. WELRHEIM, Magdeburg, and G. W. HEISE, Magdeburg. 10½ × 7¼ in. Pp. 172. Illustrated. 1971. Leipzig: Georg Thieme. 53 M.

Cancer do Pulmão. By JESSE P. TEISCEIRA, Rio de Janeiro. 8½ × 6 in. Pp. 197 + xiv. Illustrated. 1971. Rio de Janeiro: Editora Guanabara Koogan S.A. No price given.

KEEPING THE STERILE FIELD STERILE

–that is the objective of patient drapes in theatre

BARRIER* Theatre Drapes — unlike absorbent cotton drapes — are treated to resist strike-through of fluids — thus reducing the risk of bacterial transfer to the open wound.

BARRIER* Theatre Drapes also provide a number of other advantages:—

✳ Drapes are folded, cuffed and marked for convenient, aseptic handling.

✳ A full range of both composite and single item drape sets are available for the majority procedures.

✳ Presented in both sterile form and for inclusion in hospital prepared packs.

✳ Complemented by an advanced and unique drape system of absorbent/repellent adhesive towels.

✳ Completely disposable, reducing the work load in service departments and eliminating associated laundry problems.

For rapid, safer post operative wound healing
Redivac closed suction apparatus
TO PREPARE RE
KEEP UPRIGHT
IMPORTANT
Zimmer

First intention wound healing after operation is prolonged by the accumulation of tissue fluids and blood at the site. This accumulation often encourages infection.

The problems associated with these traditional procedures are solved by Redivac Closed Suction Apparatus, which removes blood and tissue fluids and avoids the formation of haematoma.

The Redivac evacuator bottle supplies a negative pressure of 600 mm Hg. The drainage tube is laid in the wound and is passed through intact skin, some distance from the incision. It is then connected to the evacuator bottle and suction commenced.

The Redivac Closed Suction System is simple, inexpensive and comfortable for the patient. It is applicable in all deep surgical procedures. The Redivac Closed Suction System facilitates nursing and results in shorter hospitalisation of patients.

no fear
no infection
no pain

with a Porges golden balloon catheter

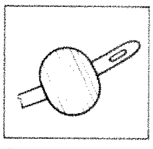
No pain : it has an impeccably smooth surface and the balloon when deflated leaves no protrusion. This allows easy insertion and withdrawal.

No fear : the patient feels completely reassured. He will be utterly relaxed during catheterization. A large surface for vesical support is obtained through even inflation of the balloon, ensured by reinforcing ribs.

No infection : the incorporation of active bacteriostatic compounds into the latex prevents any urinary tract infection.

Our research department has devoted all its efforts to the production of catheters which satisfy all clinical requirements :

The Porges balloon catheter



the golden catheter
created for the patient's safety and comfort.

FOGARTY CATHETERS FOR ACUTE VASCULAR OCCLUSION

FOR: Venous Thrombectomy

Occlusion/Emergency Tamponade

Arterial Embolectomy

Dilation/Creation of Atrial Septal Defects in Infants

Double Lumen Balloon Catheter/Creation of Atrial Septal Defects in Infants

Biliary Balloon Probe/Exploration and Removal of Debris and Stones

Irrigation

Rugged Universal Hub Fits All Luer-Lok Type Syringes

BALLOON CATHETER CONCEPT

Each catheter has a specially constructed balloon at the distal tip (except Irrigation Catheter). In thrombectomy and embolectomy, when the catheter is introduced into a vein or artery, the instrument follows the path of least resistance and the tip threads itself past the thrombus or plaque. The balloon is then inflated with sterile fluid and the catheter withdrawn, bringing the clot with it. As an emergency tamponade, for dilation, or as a biliary probe, the balloon is similarly inflated.

GENERAL DESIGN FEATURES

1. Tips on the various types are specially designed for the particular procedure; all are soft and atraumatic.
2. Controlled symmetrical balloon geometry.
3. Secure balloon attachment by epoxied suture.
4. Length marked catheter bodies.

After 3,500 years, don't catgut sutures belong in the museum?

Isn't it extraordinary that catgut sutures, which were used in Egypt in Tutankhamun's day, are still found in theatres in 1972?

Today, there is a scientific alternative. DEXON was created in the Davis and Geck laboratories specifically for use as a suture. It is absorbable, inert, strong and supple.

If you aren't using DEXON sutures in your theatre, shouldn't you find out about them? Before someone accuses you of living in the past.

Man-made, absorbable homopolymer of polyglycolic acid.
Supplied non-needled, or on DAVIS + GECK

OP-SITE BARRIER

TRADEMARK

The most effective adhesive drape

Unlike other sterile adhesive drapes, Op-site can breathe.

Which puts it at something of a premium. Because it allows a continual exchange of gases: oxygen to the skin, water vapour away from it.

There's no maceration of tissue and no perspiration build up to loosen the adhesive. Just total conformability and strict adhesion throughout.

Because of this, Op-site may be sutured through and left to protect the skin till the stitches are removed.

Post-op protection makes sense. Use Op-site.

Hospital Medicine at its best

ASSOCIATION OF SURGEONS OF GREAT BRITAIN AND IRELAND

1973 MOYNIHAN PRIZE

The Association of Surgeons of Great Britain and Ireland is offering a Moynihan Prize of £100, together with a Medal, for the best short paper (12 minutes) on new work delivered at the Annual Meeting in Aberdeen from April 4th–6th, 1973. All authors should have been qualified for less than fifteen years. In the case of multiple-author papers, the Medal will be presented to the person reading the paper, and the award may be divided between the authors.

Any Fellow or Associate Fellow wishing to submit or to sponsor a short paper for this Prize is asked to send the title, together with ten copies of an abstract, to the Honorary Secretary, Association of Surgeons of Great Britain and Ireland, at The Royal College of Surgeons, 35/43 Lincoln's Inn Fields, London, WC2A 3PN, *by* 30 *October*, 1972. He should also give the date of qualification of the author or authors.

If selected, competitors will be required to submit a manuscript suitable for publication four weeks before the Meeting. All papers which are delivered at the Meeting will be published in the *British Journal of Surgery* in the following October.

August, 1972.

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·10	£2·80	£3·20	£3·80	£4·30	£4·80	£5·90	£6·90
4	2·70	3·90	4·60	5·40	6·16	6·90	8·40	9·90
6/8	4·50	5·80	7·10	8·30	9·60	10·80	13·40	15·90

14/16	8·70	11·10	13·50	15·90	18·30	20·70	25·50	30·30
18/20	11·40	15·10	18·20	21·30	24·50	27·70	33·90	39·00
COVERS	1·50	2·10	2·70	3·30	3·90	4·50	5·70	6·90

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 57. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners Ltd., St. Martin's House, 159 Clapham High Street, London, S.W.4.*

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

no fear
no infection
no pain

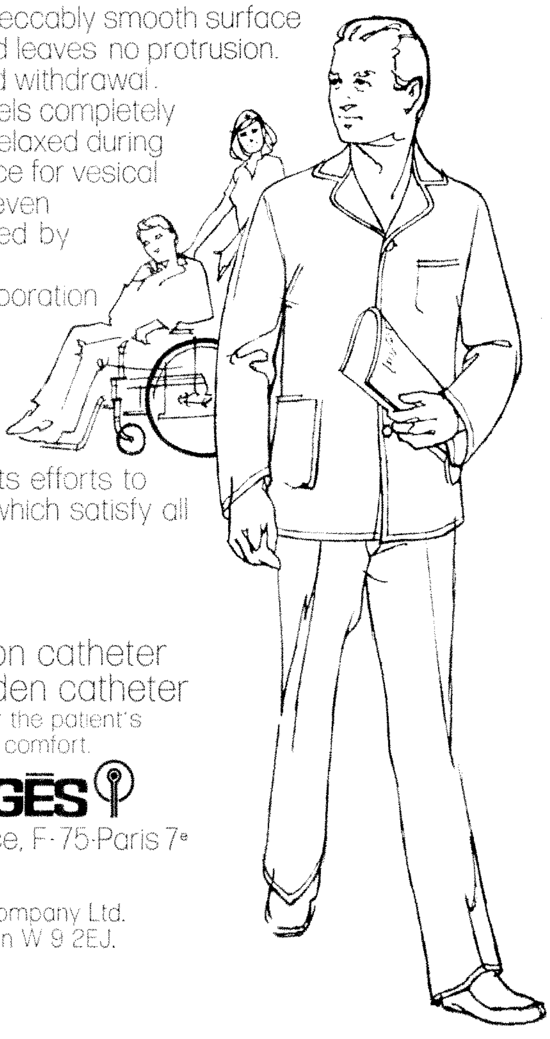
with a Porges golden balloon catheter

No pain : it has an impeccably smooth surface and the balloon when deflated leaves no protrusion. This allows easy insertion and withdrawal.

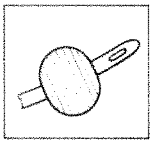
No fear : the patient feels completely reassured. He will be utterly relaxed during catheterization. A large surface for vesical support is obtained through even inflation of the balloon, ensured by reinforcing ribs.

No infection : the incorporation of active bacteriostatic compounds into the latex prevents any urinary tract infection.

Our research department has devoted all its efforts to the production of catheters which satisfy all clinical requirements :



The Porges balloon catheter



the golden catheter

created for the patient's safety and comfort.

The problem of nutritional deficiency in surgery

In surgery of the GI tract the malnourished patient is a poor surgical risk. Pre-operative parenteral nutrition ensures adequate provision of nitrogen and calories and the correction of any electrolytic imbalance. This is best achieved by the use of SERVIER intravenous nutritional solutions.

Trophysan*
A solution of amino-acids with mineral and vitamin additives for parenteral nitrogen provision.

Sorbitol (Egic) 30%
An easily-assimilated and molecularly stable solution, with a neutral pH, providing adequate carbohydrate calories.

Lipiphysan*
An isotonic fat emulsion with 5% Sorbitol (Egic) for the pre- and post-operative resuscitation of depleted patients.

When nutritional deficiency is a problem, Servier has the solution.

RADIOTOM 619

for surgical diathermy

The *RADIOTOM 619 is a universal electrosurgical apparatus designed to meet all the clinical requirements of general surgery and the special requirements of neurosurgery.

The RADIOTOM 619 can be placed on a trolley. The small dimensions and the low weight of the unit also make it possible to mount it in a ceiling column, build it into a wall or to use it on a wall bracket or a floor column.

ORIGINAL PAPERS

FRACTURES OF THE FLOOR OF THE ANTERIOR CRANIAL FOSSA

THE SELECTION OF PATIENTS FOR DURAL REPAIR

By ANTONY JEFFERSON and GERALD REILLY

DEPARTMENT OF NEUROLOGICAL SURGERY, THE ROYAL INFIRMARY, SHEFFIELD

SUMMARY

1. A series of 87 patients operated on because of subfrontal fractures is reported. In 73 of these a fistulous lesion (connecting the brain with the nose or the accessory air sinuses) was displayed and was repaired. Almost always a bifrontal exploration has been made, because the lesions were bifrontal in 43 per cent of cases. The mean follow-up period was 4 years; to date no instances of postoperative meningitis or rhinorrhoea have occurred.

2. Our experience suggests that cerebrospinal rhinorrhoea accompanying fractures of the facial bones (without fractures of the skull vault) can safely be treated conservatively.

3. Damaged brain adheres to the lips of the torn dura and *permanently* prevents natural healing, thereby creating a continuing threat to life. Consequently it is recommended that all frontal fractures lying below the hairline and all comminuted anterior temporal fractures should be referred for expert neurosurgical/neuroradiological assessment. This is because 42 per cent of the patients requiring operative repair were selected after tomographic studies of the anterior fossa; they had not presented with the classic criteria of cerebrospinal rhinorrhoea, intracranial air, or meningitis.

FRACTURES of the floor of the anterior cranial fossa which allow the intracranial contents to communicate with the nasal cavity or with the accessory air sinuses are widely recognized to be potentially dangerous. This fact is known to every general surgeon, who will most probably expect a history of meningitis, cerebrospinal rhinorrhoea, or air within the skull to substantiate the diagnosis.

In an earlier communication (Jefferson and Lewtas, 1963) an instance was cited of an 18-year-old male who died of his first attack of pneumococcal meningitis without any preceding cerebrospinal rhinorrhoea. It was this event which first focused our attention on the potential dangers of these lesions. The intervening years have been marked by no exactly similar instances, although we have seen cases from time to time which prove that pneumococcal meningitis (even when promptly treated) can still prove fatal. This subsequent period has also allowed us to accumulate more data and to crystallize our ideas. To our certain knowledge dangerous fractures exist in the absence of cerebrospinal rhinorrhoea, intracranial air, or meningitis. We believe that it is possible to identify the majority of these lesions before serious complications develop. It is our purpose in this contribution to define how this may be done, for the need to detect and to repair the fistulous fracture remains as urgent as ever.

Table I.—AGE AND SEX OF THE PATIENTS IN THE PRESENT SERIES

Age-group (years)	*Male*	*Female*
0–10	2	1
11–20	18	4

Reason for Operation	*No. of Patients*
Radiographic	35
Initial trauma (e.g., compound fracture)	13
Meningitis	11
Watery nasal discharge	19
Intracranial air	7
Exploration to confirm anticipated intact dura	2
Total	87

CASE MATERIAL

The cases considered here are an unselected series of 87 patients operated upon in the Department of Neurological Surgery, the Royal Infirmary, Sheffield, under the care of one of us (A. J.) over a 15-year period. The distribution according to age and sex is shown in *Table I*, and the reasons for operation are listed in *Table II*.

All except 8 patients underwent exploration using a bifrontal osteoplastic bone-flap (brief details of the operation are included below). The balance of the operated patients had a unilateral bone-flap or a frontal trephine. (Exploration through a frontal trephine was used in 2 of the earliest cases as a means of confirming that *no* potentially dangerous lesion was present.)

A further 32 patients were considered as possible candidates for surgical repair but were rejected after appropriate study.

It should be noted that 30 per cent of the patients needing repair were referred without the possibility that a fistulous fracture might exist having been suspected.

OPERATIVE TECHNIQUE

Because a bifrontal exploration has been proved to be necessary in 43 per cent of the patients who required a dural repair, and because we have found no absolute method of identifying preoperatively those lesions which are bilateral, we recommend that a bifrontal exploration should be used routinely.

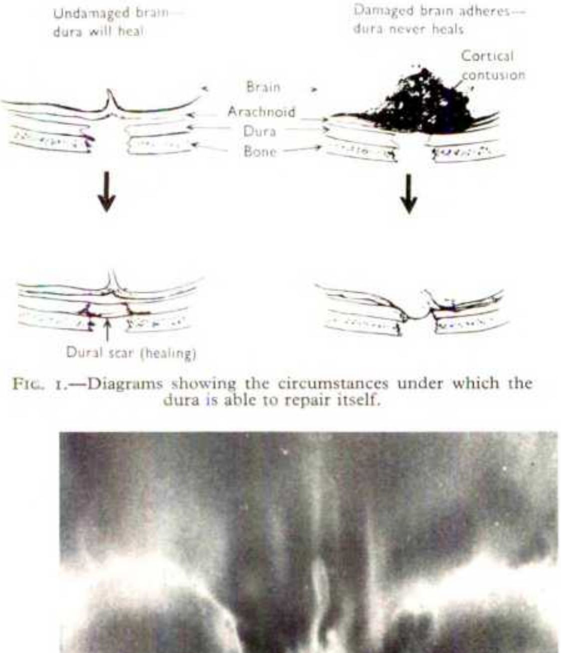

FIG. 1.—Diagrams showing the circumstances under which the dura is able to repair itself.

A coronal skin incision is made and a six-point bone-flap outlined. It is important to place the central bur holes exactly in the midline. While the bone-flap is being elevated the dura must be stripped carefully from the inside of the skull. In contrast to the views of some neurosurgeons, we have ample proof that the resultant exposure of the sagittal sinus creates no special hazards.

The dura is opened bilaterally and both subfrontal regions are thoroughly inspected from within the dura. All adhesions between pia-arachnoid and dura are systematically divided using sharp dissection. Extensive probing of the dural defects can only serve to increase them and consequently we do not recommend it. A dural graft is necessary whenever a fracture (usually a comminuted fracture) is located lying within an area of defective dura and overlying either an accessory air sinus or the roof of the nose. The injured area on the cortex is covered with gelatin foam and a tissue graft is placed on the floor of the

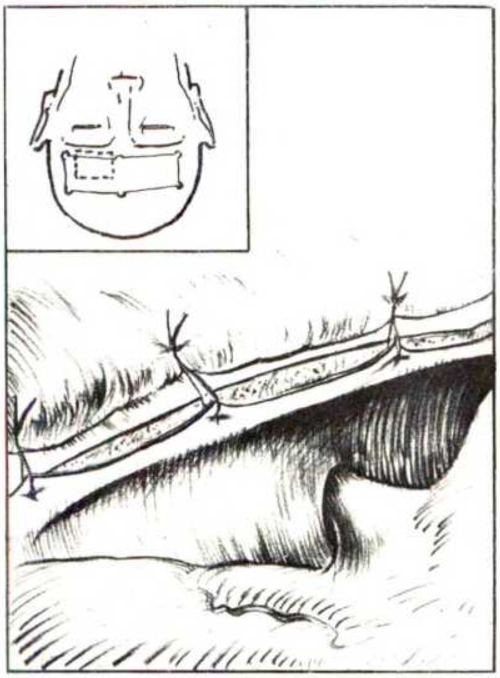

FIG. 2.—Left subfrontal region approached intradurally. The left frontal pole is held retracted. A funnel of brain is herniated into the dural defect; sharp dissection will be necessary to free this.

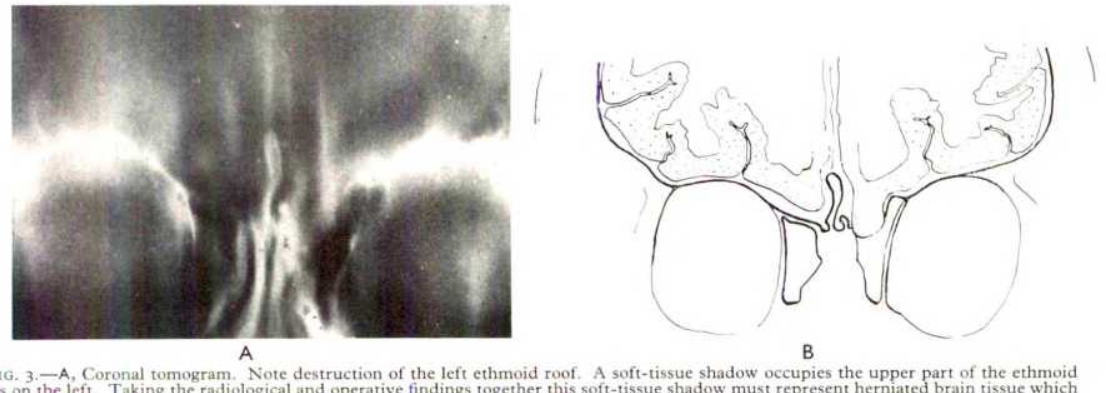

FIG. 3.—A, Coronal tomogram. Note destruction of the left ethmoid roof. A soft-tissue shadow occupies the upper part of the ethmoid sinus on the left. Taking the radiological and operative findings together this soft-tissue shadow must represent herniated brain tissue which is shown diagrammatically in B.

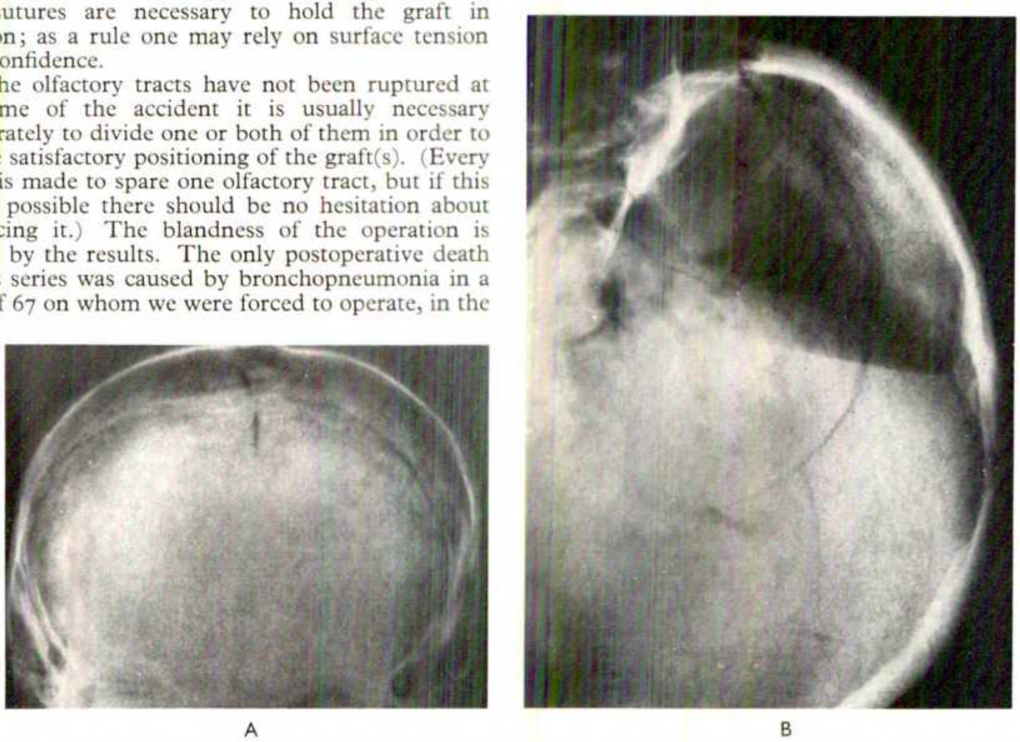
anterior fossa to cover the dural defect by a comfortably wide margin. In 85 per cent of the cases the tissue used has been pericranium stripped from the bone-flap itself. Only when the amount of pericranial tissue available is insufficient for the needs of the situation is a graft of fascia lata employed. It is in the minority of cases (approximately 15 per cent) that sutures are necessary to hold the graft in position; as a rule one may rely on surface tension with confidence.

If the olfactory tracts have not been ruptured at the time of the accident it is usually necessary deliberately to divide one or both of them in order to ensure satisfactory positioning of the graft(s). (Every effort is made to spare one olfactory tract, but if this is not possible there should be no hesitation about sacrificing it.) The blandness of the operation is shown by the results. The only postoperative death in this series was caused by bronchopneumonia in a man of 67 on whom we were forced to operate, in the face of a known chest infection, because of progressive drowsiness associated with an increasing collection of intracranial air. Moreover, there have been only 3 instances of postoperative complications (1 haematoma, 1 cerebral oedema, and 1 postoperative bone-flap infection in a case where the frontal sinus had been shattered by the accident). These complications all received appropriate treatment with a satisfactory outcome.

Apart from loss of olfactory function, there have been no instances of any neurological deficits following these operations.



A B

FIG. 4.—A, Anteroposterior radiograph of the skull. Note the small collection of air subdurally adjacent to the falx. B, Brow-up lateral radiograph of the skull. The sharp horizontal posterior outline of the main collection of air reveals this to be in the subdural plane.

PATHOLOGY

Although the dura is able to repair itself, it is not sufficiently recognized that when dura has been lacerated, and the overlying brain and arachnoid have also been injured, healing is *permanently* prevented by the damaged tissue which has adhered to the lips of the torn dura. When these circumstances accompany a fracture in the roof of an air sinus a permanent potential path between the intracranial cavity and the external world will result. This concept is shown diagrammatically in *Fig.* 1. The typical appearance of a herniated sleeve of brain and arachnoid as seen at operation is shown in *Fig.* 2.

Fig. 3 illustrates the radiological correlate of this appearance. This radiograph was obtained in a patient who had been injured 7 years previously and who was referred on account of headaches and mild diplopia. He had never suffered cerebrospinal rhinorrhoea, meningitis, or been known to have had any intracranial air. At operation a large wedge-shaped defect in the roof of the anterior part of the ethmoids was disclosed; it measured at least 0·5 cm. at its widest point and 2·5 cm. from front to back. The defect was closed using a pericranial graft.

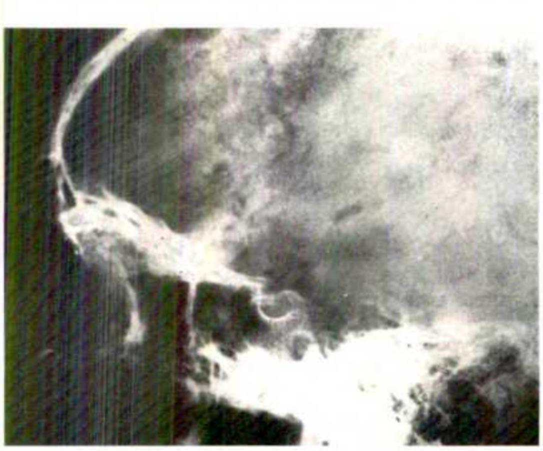


FIG. 5.—Brow-up lateral radiograph of the skull. Note that air, although diffusely scattered in the subarachnoid plane, is concentrated in the suprasellar region. This patient had a fracture involving the sphenoid sinus (*see Fig.* 11 A).

CLINICAL PRESENTATION

From the clinical point of view the fractures with which we are concerned are usually considered under the following headings:—

1. The Presence of Intracranial Air.—Apart from any sagittal projections which may seem appropriate, the radiographs which are essential in the study of post-traumatic intracranial air are those obtained using the brow-up lateral projection and a horizontal beam. Any air which is detected may be in one of four planes.

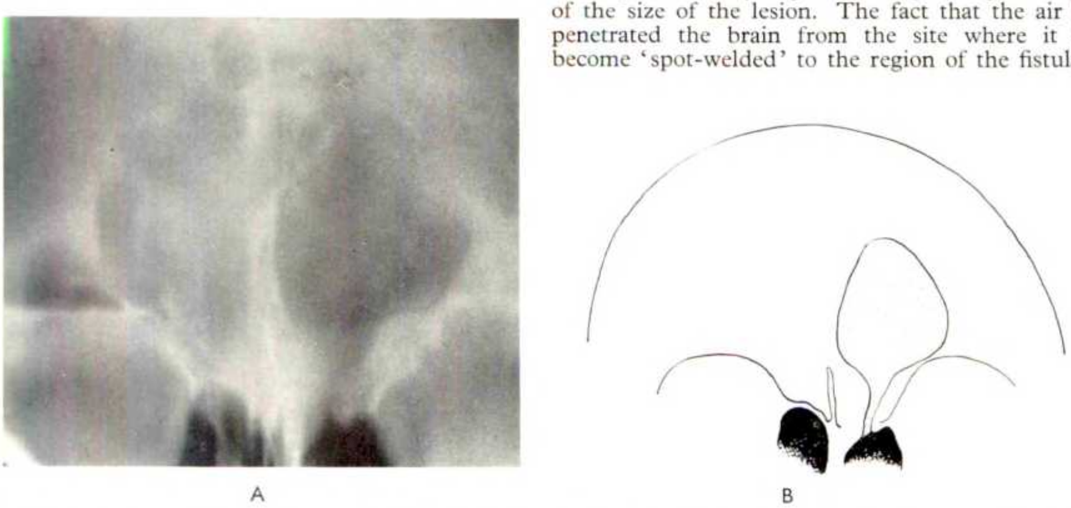

FIG. 6.—A, Tomogram of the skull with coronal cut through the ethmoid roof. Note (*a*) the disruption of the ethmoid roof on the left, and (*b*) the air-filled stalk running from the ethmoid sinus into the left frontal intracerebral aerocele. B, Explanatory line drawing traced from the original film and omitting the frontal sinus shadow.

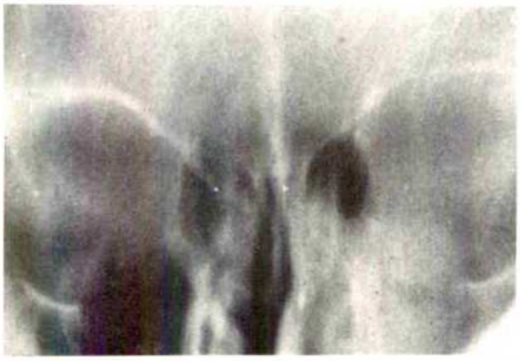

FIG. 7.—Coronal tomogram of the skull, showing an extensive defect in the right ethmoid roof.

a. Subdural.—When air from an anteriorly placed subfrontal fistula gains access to the inside of the skull it can collect in the subdural plane if the damaged arachnoid has not adhered to the margins of the fistula. The amount of air in the subdural space may be minute, as in *Fig.* 4 A, or massive, as in *Fig.* 4 B.

b. Subarachnoid.—Subarachnoid air is relatively uncommon and is most likely to be found in quantity when the fracture involved the sphenoid sinus (*Fig.* 5). This is because cerebrospinal fluid drains very freely via this particular fracture and large amounts of air reach the subarachnoid space (chiasmatic and carotid cisterns) in exchange.

c. Intracerebral.—After the brain has become adherent to the fistulous lesion a sudden increase in air pressure within the sinus or nose may result in the explosive entry of air into the substance of the frontal lobe. Such air splits the white matter, usually causing remarkably slight neurological signs in spite of the size of the lesion. The fact that the air has penetrated the brain from the site where it has become 'spot-welded' to the region of the fistula is sometimes dramatically shown by the shape of the pattern of air, i.e., a clear-cut stalk may be seen running from the floor of the skull (*Fig.* 6).

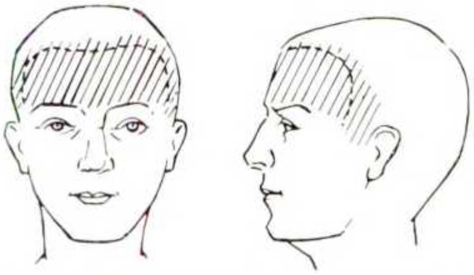

FIG. 8.—Diagram in which the shaded area outlines the region in which skull fractures may prove to be compound; such fractures may cause the intracranial cavity to communicate with the nose or an accessory nasal air sinus.

d. Intraventricular.—Early after an injury air may reach the ventricles either when there is a very large amount of subarachnoid air or when a frontal intracerebral aerocele has ruptured into the anterior horn. As a delayed or late phenomenon following an extensive frontal lobe and subfrontal injury, air can enter the frontal horn directly from the fistula via a fairly short 'corridor' which is traversing an area of softened atrophic brain.

2. Cerebrospinal Rhinorrhoea.—Among our patients there were no more than 19 (22 per cent) in whom cerebrospinal rhinorrhoea was the factor initiating a dural repair. Copious rhinorrhoea is associated with fractures which involve the sphenoid sinus, fractures which have damaged the cribriform plate (where there is no brain to plug the opening), or when post-traumatic atrophy has allowed the lateral ventricle to empty directly into the fistula (*see* Intraventricular Air above). In most other circumstances rhinorrhoea is sporadic.

It must be remembered that when there have been fractures which involve the accessory air sinuses (including the maxillary sinus) there may be a post-traumatic nasal discharge not easily distinguished from cerebrospinal fluid. Vasomotor rhinitis may cause diagnostic difficulties which can sometimes be resolved simply by the administration of antihistaminic drugs. (Indeed, there were 2 patients in this series whom we diagnosed retrospectively as suffering from rhinitis. Both of them had had frontal injuries but exploration showed no lesion and their nasal discharge persisted harmlessly at intervals for some years postoperatively.)

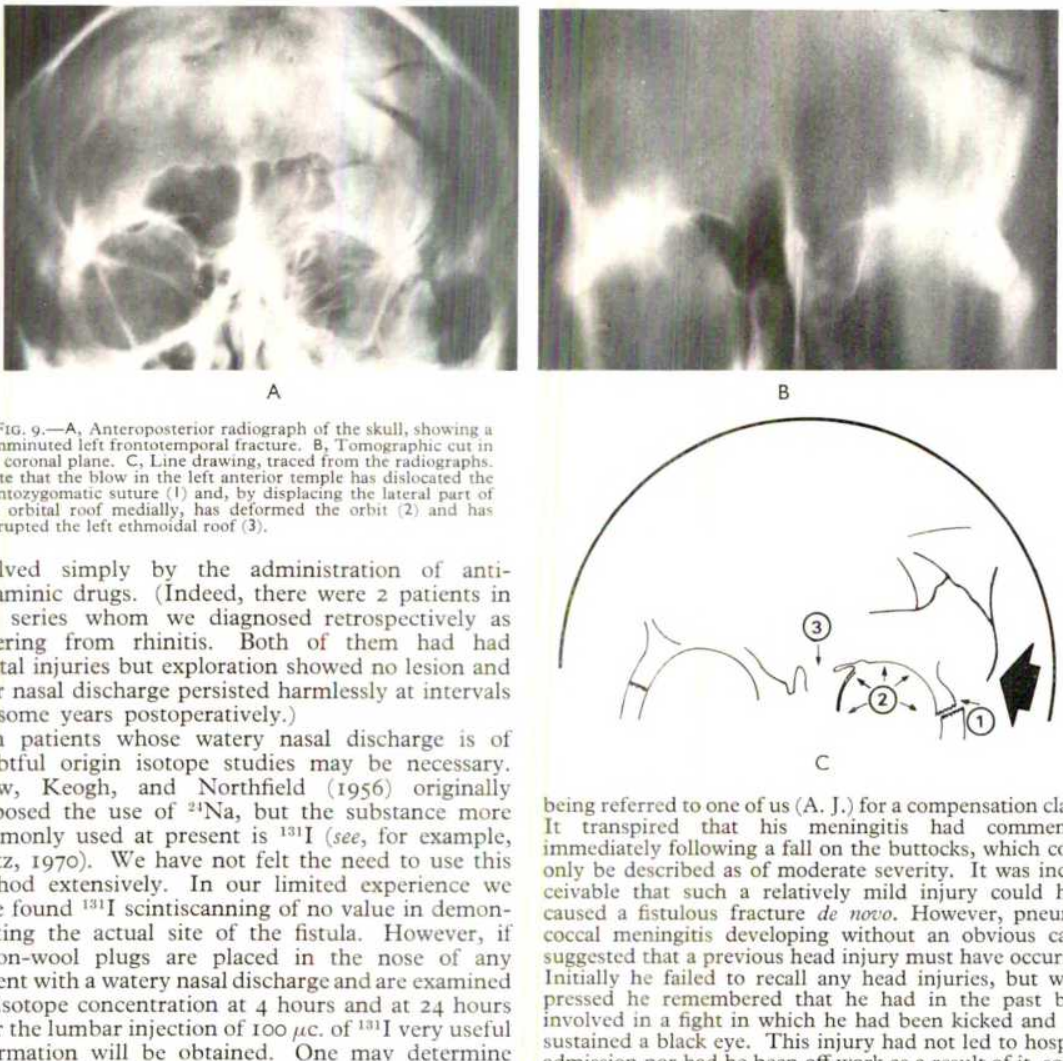

FIG. 9.—A, Anteroposterior radiograph of the skull, showing a comminuted left frontotemporal fracture. B, Tomographic cut in the coronal plane. C, Line drawing, traced from the radiographs. Note that the blow in the left anterior temple has dislocated the frontozygomatic suture (1) and, by displacing the lateral part of the orbital roof medially, has deformed the orbit (2) and has disrupted the left ethmoidal roof (3).

In patients whose watery nasal discharge is of doubtful origin isotope studies may be necessary. Crow, Keogh, and Northfield (1956) originally proposed the use of ^{24}Na, but the substance more commonly used at present is ^{131}I (*see*, for example, Dietz, 1970). We have not felt the need to use this method extensively. In our limited experience we have found ^{131}I scintiscanning of no value in demonstrating the actual site of the fistula. However, if cotton-wool plugs are placed in the nose of any patient with a watery nasal discharge and are examined for isotope concentration at 4 hours and at 24 hours after the lumbar injection of 100 μc. of ^{131}I very useful information will be obtained. One may determine thereby whether or not the fluid is indeed cerebrospinal fluid and one may gain an estimate of the rate at which it is being poured out. Some further remarks on cerebrospinal rhinorrhoea are found below in connexion with fractures of the middle third of the face.

3. Meningitis.—Eleven patients in this series underwent operation because of a preceding attack of meningitis. The responsible organism was the pneumococcus in 4 of them, while no organism could be isolated in the remainder. A dural graft was found to be necessary in every patient in whom preceding meningitis provided the reason to explore the subfrontal fracture.

One case illustrates the dangers of accepting the diagnosis of pneumococcal meningitis (in the absence of a known pneumococcal septicaemia) without inquiring very closely into the patient's past history.

Case 1.—A male, aged 30 years, had been admitted under a general physician and received effective treatment for a proved pneumococcal meningitis 11 months prior to being referred to one of us (A. J.) for a compensation claim. It transpired that his meningitis had commenced immediately following a fall on the buttocks, which could only be described as of moderate severity. It was inconceivable that such a relatively mild injury could have caused a fistulous fracture *de novo*. However, pneumococcal meningitis developing without an obvious cause suggested that a previous head injury must have occurred. Initially he failed to recall any head injuries, but when pressed he remembered that he had in the past been involved in a fight in which he had been kicked and had sustained a black eye. This injury had not led to hospital admission nor had he been off work as a result of it, so the event had not impressed itself on his memory. Armed with this past history, tomograms of his skull were obtained (*Fig.* 7) and a defect was seen in the roof of the right anterior ethmoid with clear evidence of an associated right frontal skull fracture. At operation a large defect (8 × 4 mm.) was found in the roof of the right ethmoid; it lay within an even bigger area of defective dura (4 × 3 cm.). The brain was prolapsed into the defect. The prolapsed brain was cut free and the defect was closed with a pericranial graft. He has remained well thereafter.

One must assume that the fall on to the buttocks caused a tear of the scar tissue at the fistula sufficient to allow pneumococci to penetrate from the ethmoid sinus into the subarachnoid space.

4. Radiological Studies including Tomography.—It has been our practice to regard with suspicion every patient with a fracture inferior to the hairline or with a comminuted fracture of the anterior temporal region (*Fig.* 8). This is because either group may harbour a fistulous fracture involving the floor of the anterior cranial fossa. In the case of the anterior temporal fracture the danger is associated with the medial limits of the fractured area, which may extend up to (*Fig.* 9) or even across the midline in the floor of the anterior fossa.

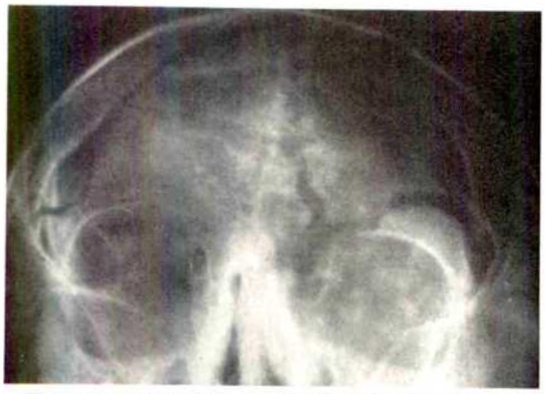

FIG. 10.—Anteroposterior radiograph of the skull of a male, aged 17 years, without previous rhinorrhoea, meningitis, or intracranial air. The severity of this fracture of itself indicates that a compound fracture must be present.

There are occasions when the extent and position of the fractures shown on the plain radiographs make it indisputably clear that the floor of the anterior cranial fossa must have been disrupted (*Fig.* 10). However, only about half of the plain radiographs have spelt out a clear danger signal. For this reason we refer all patients suspected of a fistulous fracture for tomography. It is essential that the tomograms are obtained using individual cuts at 0·5-cm. intervals. Tomographic cuts in the coronal plane (*see Figs.* 3, 6, 7, 9 B) are easier to interpret and more often useful than those in the sagittal plane, but sagittal tomograms are sometimes diagnostic (*Fig.* 11).

5. Anosmia.—Preoperative examination showed that 19 of our patients had bilateral and 12 had unilateral anosmia. Although traditional clinical medicine attaches considerable importance to the presence of anosmia in the assessment of patients with fistulous subfrontal fractures, our experience has forced us to place little or no reliance on the presence of anosmia in the selection of patients for surgery. As an example one may cite a patient in whom bifrontal exploration showed the dura to be intact on the side on which olfaction was absent, and it was necessary to divide the functioning olfactory tract in order to effect a satisfactory repair on the other side.

6. Optic Nerve Injuries.—Unilateral damage to the optic nerve was noted in 25 per cent of the patients, and in a further 2 per cent there was bilateral damage. In our series optic nerve injury has had no relevance to the selection of cases for surgical repair of the torn dura, so that although these injuries are of great interest and importance it is inappropriate to discuss them further here.

7. Frontal Lobe Syndromes.—Florid frontal lobe syndromes (e.g., apathy, personality disturbance, incontinence) occasioned by severe trauma to both frontal lobes have occurred in 16 per cent of the patients. With 1 exception such patients have required a dural graft.

FIG. 11.—Same patient as in *Fig.* 5. A, Tomographic cut in the sagittal plane clearly shows the fracture in the anterior wall of the pituitary fossa. B, Sagittal tomographic cut through the anterior fossa, following recent head injury. Arrow marks the prominent up-ended sliver of bone.

MIDDLE-THIRD FRACTURES

Copious rhinorrhoea may sometimes occur with fractures of the middle third of the face but with *no* fracture of the skull vault. (Intracranial air may also be found in such cases.) These events result from a split in the dura above the roof of the nose which differs from the other instances to which we have referred in one vital essential, which is that with every facial fracture the impact (and consequent acceleration/deceleration injury) has been partially absorbed by the crumbling of the facial skeleton. In consequence there is little likelihood of injury to the brain (cf. *Fig.* 1). In these circumstances one may confidently predict that when reduction of the facial fracture leads to prompt cessation of the rhinorrhoea (or to rapid resolution of the intracranial air), then no further surgery will be required, for the dura will heal unimpeded by the interposition of pia-arachnoid and brain.

The truth of these contentions was impressed upon us after 5 patients with rhinorrhoea following fractures of the middle third of the face had been subjected to negative exploration of the floor of the anterior fossa. Following this experience we refer such patients for tomographs of the floor of the anterior fossa when the treatment of the facial fracture has been completed and the splints have been removed. If the tomographs confirm that the floor of the anterior fossa now appears to be intact the patients are discharged from further neurosurgical supervision. Follow-up of these patients has shown that they have all remained free from further rhinorrhoea and from meningitis.

EFFICACY OF THE TREATMENT AND THE CASE SELECTION

The effectiveness of these intradural grafts is proved by the fact that so far we have not encountered any instances of postoperative meningitis or postoperative recurrence of cerebrospinal rhinorrhoea. The mean period of follow-up of the operated patients in this series is 4 years.

We have had the opportunity to study the late histological appearance of an intradural pericranial graft in a patient with spontaneous cerebrospinal rhinorrhoea which arose from the chronic raised pressure of an intracranial tumour. Macroscopically the graft was seen to have adhered where it had been placed, and *Fig.* 12 shows it to have merged with the normal dura, re-creating a complete protective barrier against infection.

Table III.—PATIENTS SUBJECTED TO NEGATIVE SURGICAL EXPLORATION IN THE PRESENT SERIES

Reasons for Operation	*No. of Patients*
Rhinorrhoea with middle-third fractures	5
Rhinitis	1
Subdural air	2
Exploration to confirm anticipated intact dura	2
Misinterpretation of the radiographs (i.e., fistulous fracture falsely identified)	4
Total	14

We have to admit that in evolving what we now regard as sound principles for the management of these patients we were initially guilty of excess enthusiasm. This caused 14 patients to be subjected to a negative surgical exploration. The reasons for these operations are shown in *Table III.*

We are naturally embarrassed to report an incidence of 16 per cent with negative findings at operation but we feel sure that the figure now would not exceed 5 per cent, for we have learned to reject the misleading middle-third fractures, and we know that small amounts of subdural air which resolve within 2 days may be ignored when the radiographs are normal. Two cases were explored 10 years ago, in the very early stages, when we wished to verify our predictions at a time when we were breaking new ground. Finally, not only have we learned to read the radiographs more precisely, but also we have learned that only really first-class films may be relied upon. In the past 5 years a total of 37 patients underwent exploration and only 2 have provided negative findings.

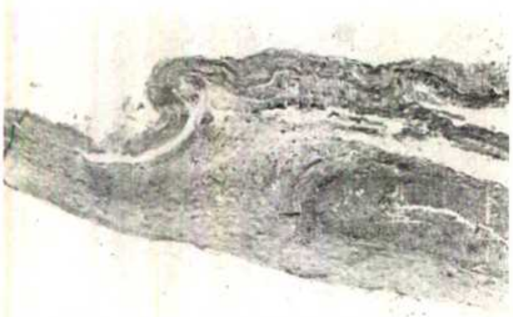

FIG. 12.—Histological appearance of an intradural pericranial graft (× 18) obtained 7 months after an operation made necessary by an intracranial tumour. Note that the grafted area has fused densely with the normal dura which is seen on the left.

With regard to the diagnostic weight which may be attached to a history of meningitis, intracranial air, or rhinorrhoea in the head-injured patient we have found as follows. Preceding meningitis is always (100 per cent) diagnostic of a fistulous fracture. Intracranial air has been misleading on 2 occasions out of the 7 in which it has been observed, whilst watery nasal discharge was misleading 6 times and diagnostic on 13 occasions (*Table III* explains how these 'false positives' arose).

The justification of our criteria of case selection may be found in the fact that among the 73 patients who needed a dural repair no less than 31 were selected entirely because of the radiographic features of the skull fracture. In other words, 42 per cent of necessary operations were *not* based on the classic criteria of preceding meningitis, intracranial air, or cerebrospinal rhinorrhoea.

DISCUSSION

The management of the particular variety of compound skull fracture which is created by fistulous fractures in the floor of the anterior fossa has been gradually evolving over the years. Before the advent of antibiotics and before improvement in anaesthetic techniques neurosurgical procedures had a potential danger that probably equalled that of the fistulous fracture. It was thus originally reasonable for didactic authorities to recommend conservative treatment; that is to say, if cerebrospinal rhinorrhoea ceased, then operation could be avoided. However, it is generally agreed that such 'healing' of these fractures can be proved histologically at autopsy to be most unsafe (Linell and Robinson, 1941). Dietz (1970) in his recent thorough review of the problem castigates such 'healing' as 'sham-healing'.

Our point of view is based firmly on that of Jefferson and Lewtas (1963), who said that one of the chief enemies of logical thought concerning fractures involving the frontal and ethmoid sinuses was that most published articles were concerned largely, if not wholly, with cases which at some time had been known to have cerebrospinal rhinorrhoea, air within the skull, intracerebral abscess, or meningitis. If they lived long enough all cases with fistulous subfrontal fractures would eventually fit into at least one of these categories. However, because the infective complications would not invariably respond to treatment they were convinced that the fistulous dural lacerations must be recognized before infection developed.

It is perhaps not generally recognized just how long the interval between injury and meningitis may be. In 1 of our own patients it was 24 years, and in a case recorded by Strenger (1958/9) it was 31 years. Thus, given a fistulous fracture the affected person simply has to go on living and sooner or later invasive bacteria (usually pneumococci) will penetrate the flimsy tissues at the border of the air sinus and the brain. Because the Department of Neurological Surgery at the Royal Infirmary, Sheffield, does not admit unselected patients with head injuries we can provide no meaningful figures concerning the number of affected patients. However, the observed frequency of cerebrospinal rhinorrhoea among large series of skull fractures is approximately 2·5 per cent (Lewin, 1954; Mincy, 1966; Raaf, 1967). Our own findings suggest that for every patient with a skull fracture and cerebrospinal rhinorrhoea there are two additional patients who harbour fistulous lesions which require repair. Utilizing the above figures one may compute that at least 7 per cent of patients with skull fractures require a dural repair. Whilst this figure may be excessive one must conclude at least that the fistulous fractures are sufficiently numerous to demand that those in charge of the head-injured patient are aware of the extent and nature of this particular problem.

If it be agreed that all these injuries should be carefully studied the means of detecting the fistulous lesions require a brief discussion. It must be made clear at the outset that the final case selection which involves specialized techniques and critical interpretation of the radiological data is a matter for the specialist. Thus, the general or accident surgeon who can refer his patients to the neurological surgeon needs only to be aware of the problem, and we advise him to be guided mainly by the simple rule illustrated in *Fig.* 8 and to remember that the trauma may seem trivial to the injured individual (*see* the present *Case* 1). Reverting to techniques of case selection, radiological methods provide the key to most of these; apart from the plain radiographs, tomographs (Dietz, 1970), or stereoscopic radiographs (Johnson and Dutt, 1947; Grote, 1966), subdural air injections have been proposed (Jefferson and Lewtas, 1963). However, we may report that over the years subdural pneumography, although still of occasional use, has been largely supplanted by ever more technically skilful tomography.

It was Eden (1942) who introduced the intradural approach which was taken up and whose merits were made so clear by Lewin (1954). We have always used the intradural approach because, in view of the anatomy of the lesions as depicted in *Fig.* 1, it is a logical necessity to do so. Our results (i.e., no recurrences to date) are not unique and they compare favourably with the 12 per cent recurrence rate (Adson and Uihlein, 1949) of the extradural approach.

Our management of this problem has been in most respects similar to that of Lewin (1966) although it is probably the nearest of all to that of Dietz (1970). Lewin (1966) appears not to have looked for these lesions quite so aggressively as Dietz (1970), who believed that *all* fistulous fractures must be picked out from among the general run of head injuries before the dangerous complications develop. It is interesting that among the dangerous complications we have encountered only 1 abscess. This was a small 'silent' lesion which was displayed during the course of a routine operation. (Its presence merely caused us to perform the operation in two stages.) Perhaps the rarity of abscesses in this series reflects one of the benefits of treating all patients at risk *before* the complications develop.

Unlike other series (cf. Dietz, 1970) we have encountered no patients with fistulous fractures associated with injuries of the intracranial portion of the internal carotid artery.

The views which we have adopted regarding rhinorrhoea or intracranial air associated with fractures of the middle third of the face without an associated fracture of the skull vault may not be universally held, but we believe that time will show them to be valid. That such fractures seldom require a dural repair was also the view of Boering and Beks (1963).

The seeking out of the potentially dangerous fracture by the neurosurgeon backed by a skilled radiological department seems, as a policy, to have justified itself. As long as antibiotics cannot be relied upon to control every attack of meningitis aggressive surgery recommends itself when the surgical risks are negligible. We may conclude by recalling that the régime propounded here has made 31 vulnerable patients (who would otherwise have remained undetected and at risk) safe from the hazards of intracranial infection.

Acknowledgements.—It is a pleasure to record our very real gratitude to Dr. N. A. Lewtas for his radiological advice and opinion. We are also indebted to Miss J. M. Osborne and Mrs. K. Byron-Thomson for their skilled radiographic technique.

VESICO-INTESTINAL FISTULAE

By NORMAN SLADE AND CHRISTOPHER GACHES
SOUTHMEAD HOSPITAL, BRISTOL

SUMMARY

Vesico-intestinal fistulae carry a serious prognosis by the nature of the underlying pathology. The inflammatory lesions offer the best hope for surgery and the necessity for early radical surgery in this group is stressed. The clinical details of 74 cases of vesico-intestinal fistulae are given together with their investigations, treatment, and results. The improved results over the past 10 years appear to bear out the necessity for early treatment.

THE first description of a vesico-intestinal fistula was probably made in A.D. 200 (Pascal, 1899), but the first full case reports were not recorded until much later by Cripps (1888). Further reports then followed of increasing numbers of cases (Sutton, 1921; Kellogg, 1938; Mayo and Blunt, 1950; Pugh, 1964).

It should be noted that a fistula between the urinary and alimentary systems can occur at any level—from the duodenum to the rectum and the renal pelvis to the urethra (Critchley, 1967)—but that the vast majority involve the terminal ileum or the sigmoid colon with the bladder or prostatic urethra.

No. of cases with no abnormality on examination	9	4	1

L.I.F./R.I.F. = Left iliac fossa/right iliac fossa.

The aetiology of vesico-intestinal fistula has varied considerably over the past century as the once common diseases, such as typhoid, tuberculosis, amoebiosis, and actinomycosis, have become rare and most cases now have either diverticulitis or malignancy as their underlying aetiological cause (Ewell, 1954, Lockhart-Mummery, 1958; Pugh, 1964). Such fistulae are complications of pre-existing disease and their prognosis is determined by the primary pathology. In general the permanent spontaneous closure rate is probably very low, being most likely in the prostato-rectal or vesico-rectal examples of traumatic origin. The average life expectancy after the development of a fistula was 3 years (Kellogg, 1938). Pugh in his 1964 series gives a gross mortality of 18 per cent. The present series of 74 cases of acquired vesico-intestinal fistulae (*Table I*) represents the experience in the Bristol Urology Department during the years 1950–70. These cases have been treated at the Southmead General Hospital or at the Bristol Royal Hospital, either by urologists or in conjunction with their general surgical colleagues. The vesico-rectal fistulae form a small group on their own and have been included for the sake of completeness. These 12 cases consist of 8 postoperative fistulae (prostatectomy and abdominoperineal excision of the rectum), 2 cases arising directly from a rectal carcinoma, and 1 involving trauma to the rectum. An additional case arose as a result of extension of a tuberculous prostatic abscess. It is interesting to recall that there have been very few post-prostatectomy fistulae and none in the last 10-year period. Both examples of this fistula type followed the attempted enucleation of a small firm prostate and not a carcinoma as might have been expected. This finding would tend to underline the importance of transurethral prostatic resection in the treatment of such cases. Those cases arising after abdominoperineal excision of the rectum may often be in advanced carcinoma where the general condition of the patient and local recurrence preclude any surgical repair. There are certainly many more terminal cases of rectal carcinoma with fistula formation that are not repaired as such, or indeed, may never been seen in hospital. The traumatic case followed an accident in which the patient, a male aged 26 years, alleged he sat down suddenly on a lavatory brush handle, the latter entering the rectum and penetrating the anterior rectal wall and the bladder just above the inter-ureteric bar. The fistula healed spontaneously after a period with an indwelling urethral catheter and defunctioning colostomy.

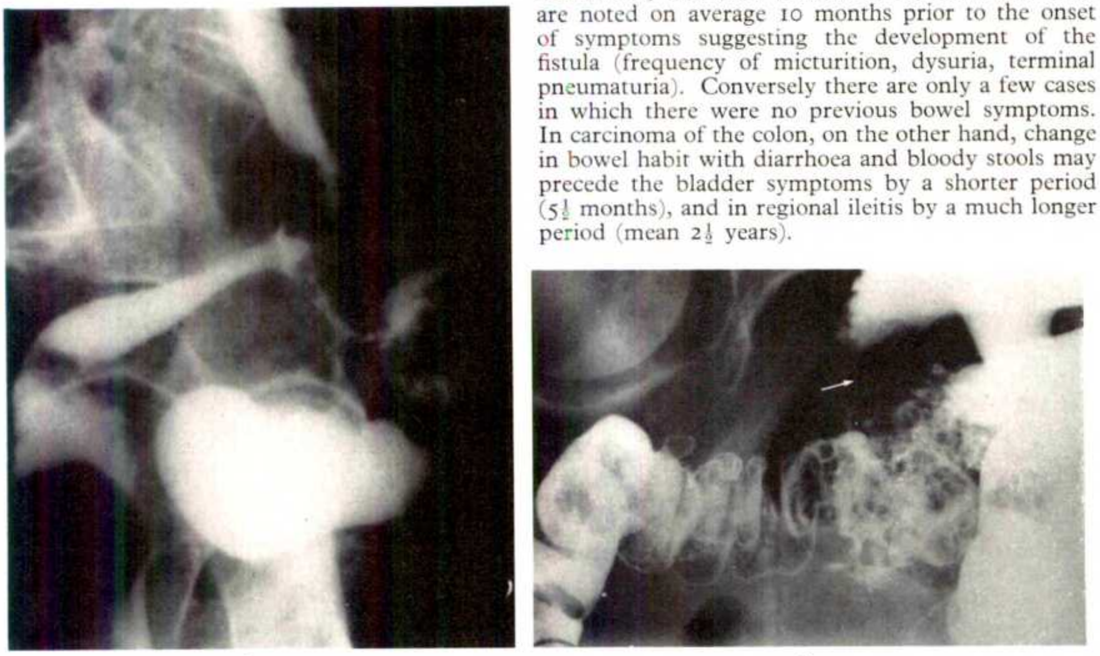

FIG. 1.—Barium-enema radiographs demonstrating fistulous tracks. A, Communications via a pericolic abscess cavity. B, Direct communication from an area of diverticular disease.

The two remaining groups of vesico-colic and vesico-ileal fistula form the great majority of the total cases, and are the most interesting from a diagnostic and therapeutic viewpoint. They are by no means rare, but are less frequently seen today owing to earlier diagnosis and treatment of the causal disease. This trend has become increasingly apparent over the past 20 years.

Whereas the number of fistulae caused by neoplasms of the bowel and bladder have remained roughly constant, those caused by chronic inflammatory disease have been reduced in number and show a marked change in sex incidence and aetiology. Robinson (1953) compared the 1921 and 1940 Mayo reports. In the 1921 series the majority of cases was in females and was caused by salpingitis, whereas in the 1940 series no case of salpingitis was quoted and the majority was in males and was the result of diverticulitis. This pattern is shown in comparison with other authors (*Table II*).

The age and sex distribution of the present series are given in *Table III*.

SYMPTOMS

Symptoms may be due either to the abnormal communication between the bowel and the bladder or to the primary pathological process (*Table III*). The latter usually precedes the former by a period of months or years depending on the nature of the disease. In diverticulitis, for example, colicky pain, tenderness, and even a mass in the left iliac fossa are noted on average 10 months prior to the onset of symptoms suggesting the development of the fistula (frequency of micturition, dysuria, terminal pneumaturia). Conversely there are only a few cases in which there were no previous bowel symptoms. In carcinoma of the colon, on the other hand, change in bowel habit with diarrhoea and bloody stools may precede the bladder symptoms by a shorter period (5½ months), and in regional ileitis by a much longer period (mean 2½ years).

It is inevitable that such a bizarre symptom as terminal pneumaturia is so often the precipitating cause for a patient seeking medical advice, and indeed this is pathognomonic of vesico-intestinal fistula if recent endoscopy and diabetes mellitus can be excluded. The passage of faecal matter in the urine and urine per rectum also suggest a fistula and call for urgent investigation. The differential diagnosis of diverticultis from carcinoma of the colon is naturally of great importance. A previous history of diverticulitis alone where this is the cause of the fistula is given in 50 per cent of cases (Lockhart-Mummery, 1958). Only in approximately 12 per cent of patients with colonic carcinoma is there a history suggesting diverticultis, with coexisting carcinoma and diverticulitis in 3 per cent of cases.

INVESTIGATIONS

A summary of those investigations concluded in this current series is given in *Table IV*. Routine excretion pyelography is unlikely to further the diagnosis but is of importance in the assessment of renal function and to exclude abnormality in the upper urinary tract. Barium-enema examination may demonstrate the presence of diverticulosis or diverticulitis or may suggest the presence of a colonic neoplasm. Demonstration of the fistula by modern techniques and screening methods is becoming increasingly common (*Fig.* 1).

From *Tables III* and *IV* it can be seen that cystoscopy and bimanual pelvic examination under anaesthesia, together with the history, make a firm diagnosis possible in the majority of cases. The importance of careful bimanual palpation under anaesthesia cannot be overestimated. The cystoscopic appearances are characteristic: the fistula, usually small, lies on the posterior bladder wall—on the left side in vesico-colic and on the right side in vesico-ileal fistula. Pus, faecal matter, or gas bubbles may sometimes be seen issuing from it, or the bladder fluid may be seen to be passing into it. The surrounding area is oedematous and dusky red, often with heaped-up polypoidal mucosa which at first sight may be mistaken for tumour. The muscle bundles are prominent with an appearance of local trabeculation and the bladder usually shows a generalized gross cystitis. Occasionally it is remarkably normal apart from the fistulous area. A bladder-wall biopsy is often useful (*Fig.* 2), but it should be noted that a negative biopsy taken in cases of suspected carcinoma by no means excludes the diagnosis.

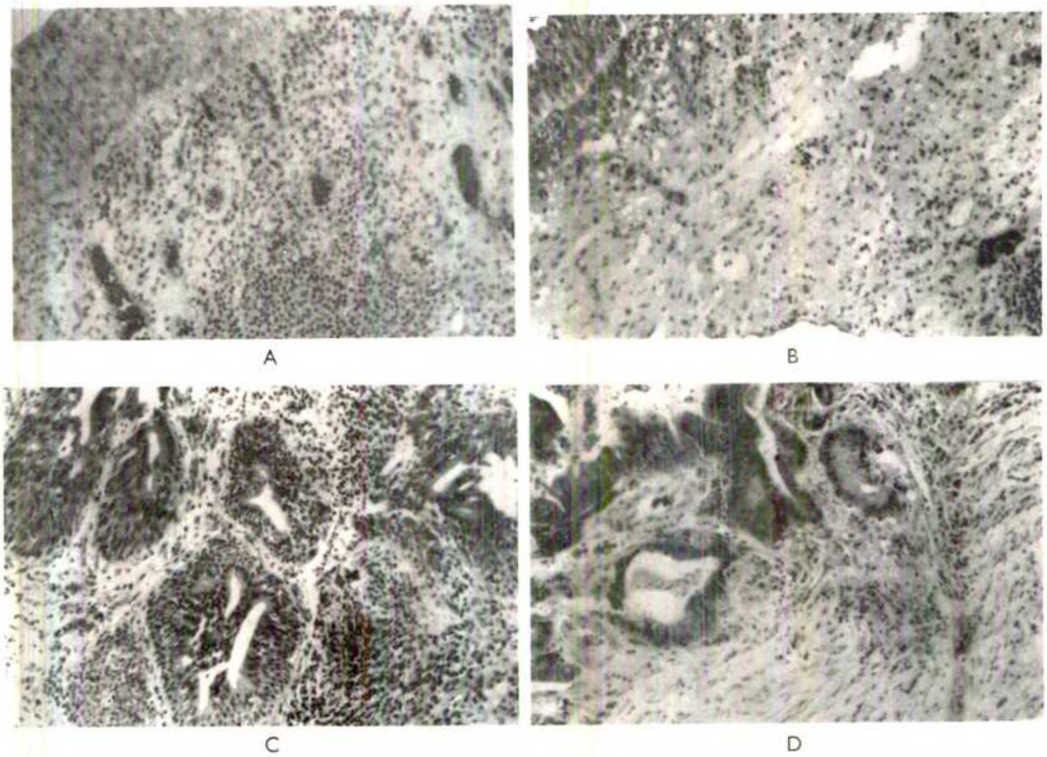

FIG. 2.—Bladder biopsies obtained by transurethral resection. H. and E. (× 150.) A, Chronic inflammatory change of diverticulitis. B, Mild inflammation but no neoplastic invasion seen (carcinoma of the colon). C, Intense round-cell infiltration suggestive of Crohn's disease. D, Identification of adenocarcinoma in addition to inflammation (carcinoma of the colon).

Table IV.—THE INVESTIGATIONS CARRIED OUT IN THE PRESENT SERIES

INVESTIGATION	DIVERTICULITIS		CARCINOMA OF COLON	
	No. of Cases (Total, 35)	Findings	No. of Cases (Total, 19)	Findings
Urography	22	21 normal; 1 irregular bladder base. No fistula seen	8	7 normal; 1 irregular bladder base. No fistula seen
Barium enema	21	21 with diverticular disease. 9 fistulae seen	6	6 showed evidence of carcinoma
Sigmoidoscopy	12	Of no value	8	6 showed tumour—no other help
Cystoscopy	34	31 with inflammation/oedema. 15 fistulae seen	16	16 with inflammation/oedema. 5 fistulae seen
Examination under anaesthetic	28	24 with a mass in the left iliac fossa or pelvis adherent to the bladder	19	19 with a mass in the left iliac fossa or pelvis adherent to the bladder
Bladder biopsy	11	11 with inflammation only	13	8 showed carcinoma. 5 with inflammation only

On bimanual examination a mass can nearly always be felt and its size, extent, and fixity to the bladder assessed. Finally, dye solution instilled into the bowel or bladder may help to demonstrate the fistula. Where colonic carcinoma is the cause of the fistula the case is usually advanced and a palpable mass is the rule, fixed to the bladder. Finally, laparotomy is indicated in all but a few cases and is another reason why further elaborate investigations can be avoided.

TREATMENT

By the very nature of the lesion causing vesico-intestinal fistula the prognosis is serious and one can assume that to cause fistula formation there must be moderate to gross extramural extension of the pathological process. There appears to be few recorded cases of spontaneous cure even in the inflammatory cases. From 1843, when Borrier de Melle suggested colostomy, until 1884 this simple method of drying up the fistula was used. From 1884 onward (Cripps, 1888) direct attack on the fistula, either transvesical or transperitoneal, was attempted with or without a preliminary colostomy.

Mayo and Miller (1940), who attributed the causes to diverticulitis in 60 per cent of cases, considered that a proximal colostomy should precede any surgical approach. This was supported by Dixon (1936), Jones (1936), and Pemberton (1945), who agree that fistulae rarely close spontaneously and colostomy alone is not a cure. In 5 of our cases a fistula developed in spite of a defunctioning colostomy.

Table V.—DETAILS OF THE TREATMENT CARRIED OUT IN THE PRESENT SERIES

TREATMENT	DIVERTICULITIS	CARCINOMA OF COLON	CROHN'S DISEASE
Total number of cases	35	19	7
No operation	4	4	0
Preliminary colostomy	11	4	0
Resection with previous colostomy	11	4	0
Resection with additional colostomy	13	9	1
Resection without colostomy	5	0	6
Closure of colostomy	10	2	1

Table VI.—THE MORTALITY IN PATIENTS WITH CARCINOMA OF THE COLON

Mortality	*No. of Cases*
Less than 1 week	6
2 months	3
3 months	3
6 months	3
8 months	1
12 months	1
18 months	1
4 years	1
Total	19

In deciding on the type of surgery indicated the extent and character of the primary lesion must be considered, together with the possible presence of sepsis and obstruction. The fistula in an otherwise uncomplicated carcinoma of the sigmoid with a direct communication into the bladder through the base of the ulcer must be quite different from that due to diverticulitis which is the result of rupture of a peri-diverticulitic abscess into the bladder—the 'foyer intermédiaire' of Chauvannez.

In this present series the stages of treatment to which the patients were subjected are indicated in *Table V*. Simple diversion of the faecal stream by colostomy is a reasonable palliative procedure in cases of advanced neoplasm with some expectation of life. In those cases of operable carcinoma the surgical procedure indicated is that for the uncomplicated carcinoma with the addition of partial cystectomy where the bladder-wall has been invaded. The very poor prognosis in those patients with carcinoma of the colon has again been borne out in this present series (*Table VI*) as in those of other authors (Mayo and Miller, 1940; Goodwin, Winter, and Turner, 1960). There were only 3 survivors over a 12-month period, the longest survival time following operation being 4 years.

It is the inflammatory cases which offer a real chance to the surgeon, and here the treatment consists of resection of the sigmoid colon with restoration and repair of the bladder with or without a preliminary colostomy. Colostomy alone is now rarely practised for cases of diverticultis as advised by Lockhart-Mummery (1929). Even if the fistula closes after an interval there is a high incidence of recurrence of the fistula or recrudescence of the diverticulitis if the colostomy is closed. Colostomy and simple repair of the fistula were practised by Grey Turner and Rutherford Morrison. This involved separation of the colon from the bladder and repair of the defects which were covered with omentum. This procedure is open to the same objection as colostomy alone, and anything short of resection frequently fails to cure the fistula as it does not remove the primary cause.

Table VII.—THE MORTALITY IN PATIENTS WITH DIVERTICULAR DISEASE

Time of Death after Operation (weeks)	*No. of Cases*	*Cause*	
1	7	Pulmonary embolus	2
		Coronary thrombosis	3
		Cerebrovascular accident	1
		Bronchopneumonia	1
2	2	Peritonitis	
4	1	Cardiac failure	
	10 (28 per cent)		

One patient died at 3 months from superadded carcinoma of the colon. Twenty-two cases were symptom-free for more than 5 years. There were no cases of recurrent fistula formation.

With regard to preliminary colostomy the interval previously accepted (many months in some cases) seems unreasonably long, and it could be argued that in this era of careful bowel preparation and chemotherapy it is unnecessary even in the presence of bowel obstruction. Moreover, the mimicry of neoplasm by diverticulitis, and vice versa, is well known, and the possibility of both conditions being present can rarely be ruled out at laparotomy. In favour of preliminary colostomy is the fact that fistula formation means peridiverticultis with abscess formation, and at laparotomy a formidable inflammatory mass involving the large bowel, small bowel, and bladder is sometimes found which precludes immediate resection.

It would seem reasonable that where the patient's general condition is good and there is no significant large-bowel obstruction, all cases should be prepared in the usual way for a single-stage procedure, and if at all possible the sigmoid colon should be excised with end-to-end anastomosis. This usually results in a small defect in the bladder which may be closed in layers. A relieving transverse colostomy may be performed at the conclusion, and this can be closed in a few weeks. Where the inflammatory mass makes resection too hazardous a procedure, a defunctioning transverse colostomy for 2 or 3 months prior to definitive surgery may be effective in reducing the size of the mass. However, in recent years we have not had to resort to this preliminary colostomy, and primary anterior resection *without* relieving colostomy is increasingly used.

In the very old and infirm these major procedures are sometimes not justified, in which case the symptoms may be considerably reduced by the use of chemotherapy. The risk of postoperative complications in this group of patients with diverticular disease is not inconsiderable (*Table VII*), and an overall mortality of 28 per cent occurred (cf. Kellogg, 1938, 25 per cent; Mayo and Blunt, 1950, 6·5 per cent).

VESICO-ILEAL FISTULA (REGIONAL ILEITIS)

Of the 7 cases of Crohn's disease (*Table V*), 5 were treated by a single-stage right partial or full hemicolectomy with excision of 50 cm. of terminal ileum and repair of the bladder defect. This procedure would agree with Williams (1954) and Lockhart-Mummery (1958), who stated that a cure of the fistula would follow excision of the fistulous track together with the diseased ileum. One of our cases was very similar to a case described by Robinson (1953). At laparotomy an inflammatory mass involving the bladder, terminal ileum, and caecum was found and ileotransverse colostomy was performed. After a stormy convalescence the sequel was one of steady improvement, and cystoscopy performed on two occasions subsequently showed healing of the fistula. The mass in the right iliac fossa has resolved slowly and at a 5-year follow-up the patient was symptom-free.

The remaining case was known to have Crohn's disease and he presented with urinary symptoms, having had an ileotransverse colostomy some years previously. At laparotomy a fistula between an enormous bowel mass and the bladder was treated by simple repair and omental interposition. He remains well after 6 months.

The possible high recurrence rate of Crohn's disease and recurrent fistula formation as suggested by Pollock (1958) has not been borne out in this series. There has been no recurrent fistula formation; 3 cases are alive and well after 10 years.

It is worthy of note that in vesico-intestinal fistulae, no matter what their aetiology, there was a high incidence of bladder calculi (approximately 14 per cent). This is probably related to the foreign material in the bladder and also to the presence of *B. proteus* urinary infection which was present in most of those patients with calculi.

Acknowledgements.—We would like to thank our urological colleagues and the general surgeons at the two hospitals for the inclusion of their cases in this survey.

ABDOMINAL TUBERCULOSIS

BY A. GUNN AND N. C. KEDDIE

MANCHESTER ROYAL INFIRMARY

SUMMARY

Twelve cases of abdominal tuberculosis are presented. They illustrate the great variability in the clinical features of this condition, making diagnosis extremely difficult. In particular, we draw attention to the problem of tuberculosis of the reticulo-endothelial system in the abdomen. Biopsy and culture are essential at laparotomy if a correct diagnosis is to be made.

DESPITE a great reduction in the incidence of tuberculosis in Britain it remains a persistent problem due, in part, to the presence of an immigrant population. However, clinical awareness has probably declined with the disease so that although tuberculosis is not uncommon it causes certain diagnostic difficulties. In abdominal tuberculosis in particular we have found that the clinical features suggest advanced malignancy until histological evidence has shown otherwise. A review of all the forms of abdominal tuberculosis (excluding tuberculosis of the genito-urinary system) admitted to the Manchester Royal Infirmary during the 5-year period 1965–9 revealed 12 cases. These cases are most readily divided into tuberculosis of the intestinal tract, of the peritoneum, and of the reticulo-endothelial system.

The diagnosis of tuberculosis was based on the criteria of (1) typical tuberculous granulomata with caseation, (2) the demonstration of acid-fast bacilli within the diseased tissues, or (3) the isolation of *Mycobacterium tuberculosis* by culture or guinea-pig inoculation.

The present series is reported in the hope that the diagnosis of abdominal tuberculosis will be considered more frequently and, in particular, to stress the great importance of biopsy and culture of tissue in cases which macroscopically are typical of abdominal carcinomatosis.

Table I.—DETAILS OF THE CASES OF INTESTINAL TUBERCULOSIS IN THE PRESENT SERIES

CASE NO.	AGE AND SEX	NATIONALITY	SITE	PREVIOUS HISTORY	CHEST RADIOGRAPH	CLINICAL DIAGNOSIS	BASIS OF DIAGNOSIS OF TUBERCULOSIS	TREATMENT	RESULT
1	26 M.	Pakistani	Ascending colon	None	Normal	Carcinoma of colon	Tuberculous caseation	Right hemicolectomy. Anti-tuberculous drugs for 5 mth.	Well 5 yr. later
2	40 F.	English	Ileum, jejunum, and ascending colon	None	Bilateral cavitation	Carcinoma or Crohn's disease of colon	Tuberculous caseation. *Mycobacterium tuberculosis* cultured	Anti-tuberculous drugs still continuing	Well 1 yr later
3	65 M.	English	Sigmoid colonic carcinomatous ulcer	None	Inflammatory changes in right upper lobe	Carcinoma of colon	Tuberculous caseation. Acid-fast bacilli present	Resection of sigmoid colon. Antituberculous drugs	Died 10 d. after resection from tuberculous bronchopneumonia
4	23 F.	Nigerian	Ileum	None	Normal	Tuberculosis	*Mycobacterium tuberculosis* cultured from loin abscess	Resection of ileum. Antituberculous drugs	Well 3 yr. later

Table II.—DETAILS OF THE CASES OF TUBERCULOSIS OF THE PERITONEUM IN THE PRESENT SERIES

CASE NO.	AGE AND SEX	NATIONALITY	TYPE	PREVIOUS HISTORY	CHEST RADIOGRAPH	CLINICAL DIAGNOSIS	BASIS OF DIAGNOSIS OF TUBERCULOSIS	TREATMENT	RESULT
5	64 F.	English	Ascitic with a palpable mass	None	Calcified lesion of right upper lobe	Carcinoma of colon	Tuberculous caseation. Acid-fast bacilli	Anti-tuberculous drugs	Alive 2 yr. later with persistent diarrhoea
6	16 F.	English	Turbid ascites with fibrinous adhesions	None	Effusion of left base	Crohn's disease	Tuberculous caseation	Anti-tuberculous drugs	Well 2 yr. later
7	18 M.	English	Plastic peritonitis	Enlarged hilar gland 2 yr. previously	Normal	Intestinal obstruction. ? tuberculosis	Tuberculous caseation. *Mycobacterium tuberculosis* cultured	Anti-tuberculous drugs	Well 1 yr. later
8	29 M.	Pakistani	Plastic peritonitis	Tuberculous peritonitis 5 yr. previously. On drugs for 15 months	Normal	Tuberculous peritonitis	*Mycobacterium tuberculosis* cultured 5 yr. previously	Resection of 30 cm. of intestine; division of adhesions. Anti-tuberculous drugs	No trace
9	35 F.	English	Ascitic	Miliary tuberculosis when 10 yr. old	Scattered calcification	? Gall-stones. ? Carcinoma	Tuberculous caseation. Acid-fast bacilli	Anti-tuberculous drugs	Well 18 mth. later

GENERAL FEATURES

The main features of the cases reviewed are shown in *Tables I, II*, and *III*, but some case histories are given in detail later in the text.

Non-specific features such as rapid loss of weight (present in 4 out of the 12 patients), malaise, a raised erythrocyte sedimentation rate, and unexplained pyrexia are all factors which should raise a suspicion of tuberculosis. Usually, however, these features make the clinician suspect malignancy. Thus 7 of our 12 patients were thought clinically to have a malignant tumour and even at operation the macroscopic features of tuberculosis were mistaken for malignancy in 5 patients.

The age range of the patients was 6 to 64 years, but it should be noted that children are not usually admitted to the Manchester Royal Infirmary except as an emergency such as a road accident. Five patients

(42 per cent) were from overseas and there was an equal number of males and females.

A chest radiograph was normal in 5 of the 12 cases. Definite evidence of active pulmonary tuberculosis was only present in 3 cases. None of our cases of reticulo-endothelial tuberculosis (*Table III*) showed evidence of active lung disease.

INTESTINAL TUBERCULOSIS (*Table I*)

Two of these patients had well-recognized forms of tuberculosis, 1 suffering from primary hypertrophic ileocaecal tuberculosis (*Case* 1) and 1 from ulcerative intestinal tuberculosis with active pulmonary disease (*Case* 2). Even so, the diagnosis was only made in these patients after histological examination of the affected tissues. In *Case* 3 tuberculosis was found in association with a carcinoma of the sigmoid colon. It seems probable that tuberculous infection followed malignant ulceration of the colon. Although histology of the ileal strictures in *Case* 4 showed non-specific inflammatory changes, the presence of tuberculous pus tracking from the retroperitoneal area makes tuberculosis the likely diagnosis.

Case 1.—A 26-year-old male Pakistani was admitted to hospital complaining of a pain in the right hypochondrium with vomiting, shivering attacks, and sweating for 3 months; during this period he had lost 19 kg. in weight. Examination revealed an ill-looking man with no lymphadenopathy, but a fixed mass was present in the right hypochondrium; haemoglobin, white cell count, and liver-function tests were normal, but an occult blood test was positive. A barium-enema examination showed a filling defect in the ascending colon and laparotomy revealed a mass in the ascending colon involving the caecum and ileum with enlarged mesenteric nodes. A right hemicolectomy was performed with an end-to-side ileocolic anastomosis. Histology showed a deep 2-cm. ulcer with tuberculous granulomata involving the ascending colon and caecum; there was caseation of the mesenteric lymph-nodes and acid-fast bacilli were demonstrated. Culture was not performed as the mass was thought to be either a carcinoma or Crohn's disease.

The patient made an uneventful postoperative recovery and was placed on streptomycin, para-aminosalicylic acid, and iso-nicotinic acid hydrazide, which the patient probably discontinued 5 months after the operation. However, he was fit and well 5 years after the operation.

Case 2.—A 40-year-old English woman was seen in the out-patients' department with a 4-month history of passing four or five loose motions daily with associated lower abdominal discomfort, malaise, and the loss of 12·7 kg. in weight. She was emaciated with a temperature of 37·4 C. and a fixed mass in the right iliac fossa. She did not complain of a cough. Her serum albumin was 3 g. per cent; globulin, 4·3 g. per cent; alkaline phosphatase, 21 K.A. units; and haemoglobin, 58 per cent. A barium-enema examination showed a filling defect of the ascending colon which was thought to be due to a carcinoma or Crohn's disease although it did, in fact, show features indicative of tuberculosis (*Fig.* 1). The patient's condition was so poor that she was soon admitted to hospital and after a blood transfusion a laparotomy was performed. She was found to have twelve inflammatory segments, each 2 cm. in length, scattered through the small intestine with a large inflammatory mass in the ascending colon. One of the diseased ileal segments was excised for biopsy, continuity being restored by an end-to-end anastomosis; an enlarged lymph-node was removed for culture. Histology of the excised small intestine showed typical tuberculous granulomata without caseation but acid-fast bacilli were present.

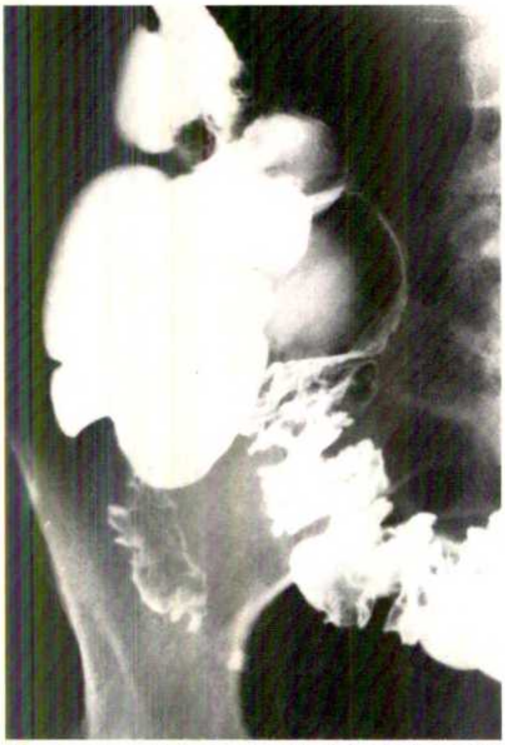

FIG. 1.—*Case* 2. Barium-enema radiograph, showing an obtuse ileocaecal angle and apparent disappearance of the caecum. A stricture is present in the ascending colon.

Table III.—DETAILS OF THE CASES OF TUBERCULOSIS OF THE RETICULO-ENDOTHELIAL SYSTEM IN THE PRESENT SERIES

CASE No.	AGE AND SEX	NATIONALITY	SITE	PREVIOUS HISTORY	CHEST RADIOGRAPH	CLINICAL DIAGNOSIS	BASIS OF DIAGNOSIS OF TUBERCULOSIS	TREATMENT	RESULT
10	52 F.	Indian	External iliac lymph-node	None	Fibrosis right upper lobe	Secondary carcinoma or reticulosis	Tuberculous caseation. Acid-fast bacilli	Excision of lymph-node	Well 2 yr. later
11	6 M.	English	Spleen	None	Normal	Ruptured spleen	Tuberculous caseation	Splenectomy	Well 5 yr. later
12	53 M.	West Indian	Mesenteric and coeliac lymph-nodes	Pulmonary tuberculosis 1 yr. previously	Fibrosis right upper lobe	Carcinomatosis	Tuberculous caseation	Anti-tuberculous drugs	Well 1 yr. later

Culture of the excised lymph-node later confirmed the presence of *Mycobacterium tuberculosis*. A postoperative chest radiograph showed advanced bilateral lung disease with cavitation.

The patient was treated with streptomycin, para-aminosalicylic acid, and iso-nicotinic acid hydrazide, but because of her diarrhoea rifampicin and ethambutol were substituted for the para-aminosalicylic acid. The streptomycin was discontinued after 5 months, but she was still taking oral anti-tuberculous drugs 1 year later when she was clinically well and had gained 5·4 kg. in weight.

Case 3.—A 65-year-old English man was admitted as an emergency with a 7-day history of constipation, vomiting, and generalized abdominal pain. He had apparently been well previously, although he had been investigated 2 years earlier for a suspected carcinoma of the colon with a negative barium-enema examination and sigmoidoscopy. On admission the patient was dehydrated, his temperature was 36·2° C., and his abdomen was distended. A plain radiograph of the abdomen confirmed the diagnosis of intestinal obstruction. Laparotomy revealed a stenosing carcinoma of the sigmoid colon and a loop transverse colostomy was performed. A chest radiograph showed diffuse inflammatory changes of the right upper and middle lobes of the lungs and culture of his sputum produced a growth of *Haemophilis influenza* and *Pneumococcus*; he was therefore treated with intramuscular ampicillin. His general condition improved and 10 days later a resection of his sigmoid colon was performed and continuity restored by means of an end-to-end anastomosis. Histology of the excised specimen showed a well-differentiated adenocarcinoma of the colon with a metastatic deposit in an adjacent lymph-node. There were also several tuberculous granulomata with central caseation immediately deep to the colonic tumour and within several of the paracolic lymph-nodes. Acid-fast bacilli were present in the granulomata.

Because of the histological findings and later the discovery of acid-fast bacilli in his sputum, the patient was treated with streptomycin, para-aminosalicylic acid, and iso-nicotinic acid hydrazide. His general condition deteriorated, however, paralytic ileus and atrial fibrillation supervened, and he died 1 week after his second operation. Post-mortem examination showed no evidence of residual carcinoma or tuberculosis in the abdomen, but there was a tuberculous bronchopneumonia affecting mainly the right upper and middle lobes.

Case 4.—A 23-year-old Nigerian woman presented with malaise and an abscess in her left renal area. There were no other abnormal physical findings; a chest radiograph, haemoglobin, and white cell count were normal. Her Heaf test was positive grade III, her E.S.R. was 16, and a radiograph of the lumbosacral spine showed no definite evidence of tuberculous involvement of the vertebra. The abscess was aspirated and 6 weeks later *Mycobacterium tuberculosis* was isolated on culture. Eight weeks after the aspiration of the abscess, the abscess was explored and traced to the retroperitoneal area but there was no communication with the vertebra. After drainage, the wound was closed and the patient was nursed on a plaster bed and treatment with streptomycin, para-aminosalicylic acid, and iso-nicotinic acid hydrazide was begun. Four weeks later she developed signs of intestinal obstruction and at laparotomy three discrete strictures were demonstrated in a 30-cm. length of ileum. This piece of ileum was resected and continuity restored by means of an end-to-end anastomosis. Histology of the strictures showed epithelial ulceration and non-specific inflammatory changes.

Following this, the patient made a good postoperative recovery and all anti-tuberculous treatment was stopped after a period of 18 months. She was well and symptom-free 3 years after the last operation.

TUBERCULOUS PERITONITIS

These 5 cases presented considerable diagnostic problems and preoperative investigations were of little value. None of these was easily classified into the usually described forms of tuberculous peritonitis. Malignancy was suspected in 2 patients preoperatively and at laparotomy; the correct diagnosis was made from a biopsy. The importance of biopsy of peritoneal deposits is illustrated in *Case* 9.

Case 9.—A 35-year-old English woman was admitted to hospital with a 1-year history of epigastric and lower sternal pain occurring once a week and lasting for periods of between 10 minutes and 4 hours. There was no vomiting and the pain was not related to meals. The pain had been very severe on two occasions and the patient had lost 11·7 kg. in weight. She had had miliary tuberculosis when she was 10 years old and had been in hospital for 18 months. There were no abnormal findings on physical examination, her white cell count was 11,800, but the haemoglobin, liver-function tests, urea and electrolytes, barium-meal examination, and a cholecystogram were all normal. A chest radiograph showed scattered areas of calcification in both lung fields.

A laparotomy was performed, when the patient was found to have fibrinous adhesions around the gall-bladder and in the pelvis. There were 2-mm. nodules scattered throughout the peritoneum and in the omentum which were thought to be due to carcinomatosis. An omental biopsy was taken and this was shown to contain tuberculous granulomata with central caseation and acid-fast bacilli were demonstrated.

The patient was treated with streptomycin, para-aminosalicylic acid, and iso-nicotinic acid hydrazide. She made a good recovery and was symptom-free 18 months later.

TUBERCULOSIS OF THE RETICULO-ENDOTHELIAL SYSTEM

These were patients in whom tuberculosis of part of the reticulo-endothelial system was demonstrated without evidence of tuberculosis elsewhere in the abdomen. In *Cases* 10 and 11 the tuberculosis was discrete, affecting an external iliac lymph-node and the spleen respectively. In *Case* 12 there was diffuse involvement of the mesenteric and retroperitoneal lymph-nodes, presenting a difficult diagnostic problem.

Case 12.—A 53-year-old Jamaican man was admitted to hospital with a 7-week history of ill-defined pain in the right side of the abdomen with anorexia. He had recently noted increasing dyspnoea with exercise. One year previously he had been treated with anti-tuberculous drugs as an in-patient for 4 months because of active pulmonary tuberculosis. He had discontinued the anti-tuberculous drugs after 9 months (i.e., 3 months prior to admission).

On examination the patient looked reasonably well, but there was some abdominal swelling and tenderness in the right side of the abdomen. His haemoglobin, electrolytes, Wassermann reaction, barium-enema examination, and cholecystogram were all normal. His serum albumin was 4·4 g. per 100 ml. and the globulin, 5·4 g. per 100 ml. A chest radiograph showed evidence of healed tuberculosis of the right upper lobe of the lungs and pleural calcification of the right lateral chest wall. His white cell count was 3600 with 47 per cent lymphocytes.

Laparotomy revealed a uniformly pale liver. There were grossly enlarged lymph-nodes, 4–5 cm. in diameter, in the mesentery, around the duodenum, and along the lesser curve of the stomach. There were no lesions of the stomach or the large or small intestines. Milky fluid was aspirated from one of the mesenteric lymph-nodes for culture and one was excised for biopsy. Histology of the lymph-nodes showed typical tuberculous granulomata with central caseation; there were no acid-fast bacilli and culture for *Mycobacterium tuberculosis* proved negative.

The patient was treated with streptomycin, para-aminosalicylic acid, and iso-nicotinic acid hydrazide. He made a good recovery and was fit and well 1 year later, when he was still taking the oral therapy.

DISCUSSION

A number of recent papers have focused attention on tuberculosis of the intestinal tract (Campbell, 1961; Howell and Knapton, 1964; Anscombe, Keddie, and Schofield, 1967) and of the peritoneum (Johnston and Sanford, 1961; Faulkner, 1964; Dowling, 1968). Little has been written about tuberculosis of the reticulo-endothelial system within the abdomen.

Tuberculosis of the intestine is usually divided into ulcerative, hypertrophic, and ulcerohypertrophic. It may occur anywhere from the stomach (Palmer, 1950) to the rectum (Hawley, Wolfe, and Fullerton, 1968), but the ileocaecal area is the most common site affected (Abrams and Holden, 1964).

In ulcerative tuberculosis the clinical picture is often dominated by the pulmonary tuberculosis, but the abdominal complaints of diarrhoea, abdominal pain, loss of weight, and sometimes an abdominal mass may predominate. In the present *Case* 2 there were no respiratory symptoms of note despite gross radiographic changes. Treatment of these patients is usually by chemotherapy, but it must be remembered that complications requiring surgical intervention, such as adhesions or perforation, can still occur after anti-tuberculous therapy has been started (Sweetman and Wise, 1959).

Patients with hypertrophic ileocaecal tuberculosis usually complain of abdominal pain, change in bowel habit, weight-loss, and general deterioration in health (Anscombe and others, 1967). The finding of an abdominal mass together with the radiological demonstration of a stricture in the caecum or ascending colon makes the diagnosis of Crohn's disease or carcinoma likely. The chest radiograph is often normal (Anand, 1956).

It should be noted that there are typical features of tuberculosis visible on the barium-enema examination. These are a shortened ascending colon with a stricture and an obtuse angle at the ileocaecal junction (Aird, 1957a). Treatment is usually by right hemicolectomy (Anand, 1956; Anscombe and others, 1967), but it would seem wise to give chemotherapy if there is widespread involvement of the peritoneum or of the mesenteric glands. There is little evidence on this point. Histology of the intestinal lesions is often equivocal, but the mesenteric lymph-glands nearly always show caseation (Anand, 1956). Routine culture of the mesenteric glands in equivocal intestinal lesions is a recommended practice.

The association of tuberculosis with carcinoma of the intestine is rare, but tuberculosis has been reported in association with carcinoma of the stomach (Tanner and Swynnerton, 1956). The present *Case* 3 demonstrated tuberculosis in association with carcinoma of the sigmoid colon. Barson and Kirk (1970) have reported this case previously and we agree with their conclusion that tuberculous infection was probably secondary to the carcinoma.

The histological diagnosis of an ileal stricture is often difficult and the picture may be one of non-specific inflammation. Crohn's disease may then be the favoured diagnosis, but evidence of tuberculosis in the mesenteric or retroperitoneal glands indicates tuberculous infection, as in the present *Case* 4.

Tuberculous peritonitis may be acute or chronic in onset, but is usually divided into ascitic or plastic forms. In addition, there is a purulent or caseating peritonitis. Like other authors (Faulkner, 1964) we did not find the differentiation of the varying forms of peritonitis easy. The patients usually present with abdominal swelling or discomfort and pyrexia (as in 3 out of 5 patients in our series). Johnston and Sanford (1961) drew attention to rigors in 4 out of 7 patients in their series. If ascites is present and paracentesis performed, examination of the fluid may be helpful. Thus 3 out of the 6 fluids examined in Johnston and Sanford's (1961) series showed acid-fast bacilli or yielded *Mycobacterium tuberculosis* on culture. A high protein content of the ascitic fluid (> 3 g. per 100 ml.) with a specific gravity of over 1016 is in favour of tuberculous infection (Dowling, 1968). However, the diagnosis is usually by means of laparotomy and biopsy. The appearance of the tubercles on the peritoneum and omentum can easily be mistaken for carcinomatous deposits, and thus biopsy is mandatory (*Case* 9).

Whatever the site of entry of the tuberculous organism, the disease may rarely be found apparently confined to one part of the reticulo-endothelial system of the abdomen.

Case 10 had a large tuberculous external iliac lymph-node presenting as a mass in the right iliac fossa. Barium-enema, gynaecological, and urinary-tract investigations and radiographs of the spine and pelvis were normal.

Tuberculous mesenteric adenitis in children has been recognized for many years (Aird, 1957b, Maingot, 1970) but it is less widely appreciated that this disease may occur in adults. Quattlebaum (1960) reported 5 cases of tuberculosis of the mesenteric and retroperitoneal lymph-glands. The nodes were very large, often palpable on abdominal examination, usually affecting the pancreaticoduodenal and coeliac areas, and sometimes causing duodenal obstruction. Retroperitoneal tuberculous lymph-nodes may also obstruct the ureter (Mitty and Faegenburg, 1964).

The clinical picture in these patients may be very confusing. Gerace, Weed, and Nichols (1959) found that laparotomy in patients with a fever of unknown origin revealed that 7 per cent had tuberculosis as the cause of their fever, and this is often the only way to make the diagnosis in these patients (e.g., *Case* 12).

Primary tuberculosis of the spleen (Aird, 1957c) has received little attention but it seems likely that this occurred in *Case* 11. The spleen was removed as an emergency following a road accident and at that time there was no evidence of abnormality amongst the other intra-abdominal organs. Usually, however, these patients present with malaise and a tender, palpable spleen. Recently, 2 cases of primary tuberculosis of the spleen have been reported by McGowan (1965).

ACID-FUNDIC SELECTIVE VAGOTOMY OF THE STOMACH WITHOUT DRAINAGE IN THE TREATMENT OF DUODENAL ULCER: TECHNIQUE AND RESULTS*

By LUIGI IMPERATI, COSTANZO NATALE, and FRANCESCO MARINACCIO

SURGICAL DEPARTMENT, UNITED HOSPITALS OF FOGGIA, ITALY

SUMMARY

Out of 415 patients with duodenal ulcer undergoing vagotomy in the past 6 years, 198 truncal vagotomies (T.V.) and 217 selective vagotomies (S.V.) were performed. Of the 217 S.V.s, 134 cases had a total selective vagotomy of the stomach (preserving the pyloroduodenal nervous peduncle), and in 83 cases a proximal selective vagotomy was performed (preserving also the antral branches of the two principal nerves of the gastric lesser curve or Latarjet nerves). The authors prefer the name 'acid-fundic selective vagotomy (A.F.S.V.) of the stomach' for the latter procedure.

In 89 of the patients having S.V. no gastric drainage procedure was performed; in 27 of these a total S.V. had been performed and in 62 cases an A.F.S.V.

In patients undergoing S.V. without gastric drainage the clinical results and gastric emptying were fairly good in the cases with a total S.V. (follow-up time, 12 months), and very good in the cases with an A.F.S.V. (follow-up time, 6 months). Basal acid output (B.A.O.) and maximal (pentagastrin-stimulated) acid output (M.A.O.) were evaluated in those patients undergoing A.F.S.V. before and 10 days after operation. B.A.O. was reduced by 80·5 per cent and M.A.O. by 68·5 per cent. An insulin test performed 3 months after operation was negative in 80 per cent of cases (complete vagotomy); in the other cases the vagotomy was adequate.

Clinical results, although after only a short follow-up, suggest that the procedure can be considered as the treatment of choice in most patients with an uncomplicated duodenal ulcer (76 per cent in our series). Gastric drainage is required only in cases of stenosing duodenal ulcer with delayed gastric emptying. Pyloroplasty is also mandatory in the treatment of bleeding ulcer and of perforated ulcer (if the suture is stenosing).

TOTAL selective vagotomy inhibits acid secretion and antral motility. To prevent gastric stasis it is necessary to perform a pyloroplasty. This method has complications (leakage) and side-effects (dumping syndrome, duodenal regurgitation, diarrhoea) which are mainly the result of a lack of duodenal regulation of gastric emptying, as McKelvey (1970) has recently demonstrated.

By preserving the pyloroduodenal peduncle (arising from the hepatic plexus of the anterior vagal trunk) Burge and Frohn (1969) have been able to perform a number of total selective vagotomies without drainage.

Our first results after total selective vagotomy without drainage were fairly satisfactory in some selected cases; in other cases delayed gastric emptying followed (Imperati, Natale, and Marinaccio, 1970).

More encouraging results have been obtained by confining the denervation to the acid- and pepsin-secreting area so that the distal 5–7 cm. of the stomach were left innervated. This procedure has been called 'vagal denervation of parietal cell mass' (Griffith and Harkins, 1957), 'proximal selective vagotomy' (Holle, 1967), or 'highly selective vagotomy' (Johnston and Wilkinson, 1970); we prefer the term 'acid-fundic selective vagotomy of the stomach' (*Fig.* 1). This operation, preserving the normal motility and emptying of the stomach, can be performed without gastric drainage in all uncomplicated duodenal ulcer patients.

MATERIALS AND METHODS

Four hundred and fifteen consecutive duodenal ulcer patients (January 1965–March, 1971) have had a vagotomy procedure; 198 had a truncal subdiaphragmatic vagotomy and 217 had selective vagotomy (*Table I*). In 83 cases the selective vagotomy was limited to the acid-fundic area.

---

* Based on a paper presented to the Fourth World Congress of Gastro-enterology at Copenhagen on 17 July, 1970, and a paper presented to the First World Congress of Digestive Surgery at San Remo on 22 May, 1971.

In 89 patients selective vagotomy was performed without gastric drainage; 27 of these had been treated by total selective vagotomy and 62 by acid-fundic selective vagotomy (*Table II*). Gastric drainage was not performed in patients with a gastric emptying time of 4 hours or less with no evidence of pyloroduodenal stenosis at operation.

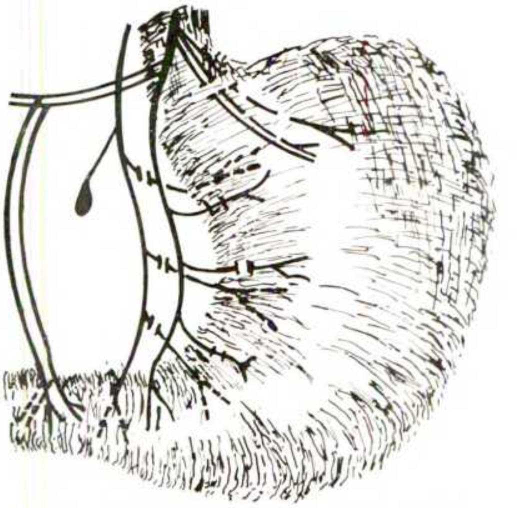

FIG. 1.—Diagram of the acid-fundic selective vagotomy.

Table I.—TYPE OF VAGOTOMY PERFORMED

Type of Vagotomy		*No. of Patients*

Table II.—GASTRIC DRAINAGE IN PATIENTS UNDERGOING VAGOTOMY FOR DUODENAL ULCER

TYPE OF VAGOTOMY	GASTRIC DRAINAGE	NO GASTRIC DRAINAGE	TOTAL	MORTALITY
Total selective	107	27 (2)	134	1
Acid-fundic selective	21	62 (7)	83	0
Total	128	89 (9)	217	1

Number of perforated duodenal ulcers is shown in parentheses.

Nine of the patients treated by selective vagotomy had a perforated ulcer of the anterior wall of the duodenum; a simple suture of the perforation was sufficient in these cases. The technique of total selective vagotomy has been described elsewhere (Natale, Marinaccio, and Pellegrino, 1969).

Operative Technique of A.F.S.V.—

Step 1.—The anterior nerve of Latarjet is demonstrated in the lesser omentum 1–2 cm. from the lesser curve up to its terminal branches to the antrum 6–7 cm. from the pylorus. The lesser curve is then separated from the lesser omentum leaving intact the nerve of Latarjet and its terminal branches on the antrum (*Fig.* 2); the dissection is begun near the incisura (*see arrow, Fig.* 2) and is continued upwards to the cardia; nerve-fibres arising from the nerve of Latarjet and blood-vessels are divided close to the stomach. The dissection is then continued to the cardia; the gastric fundus and the cardia are mobilized so that all the anterior nerve-fibres to the stomach are divided.

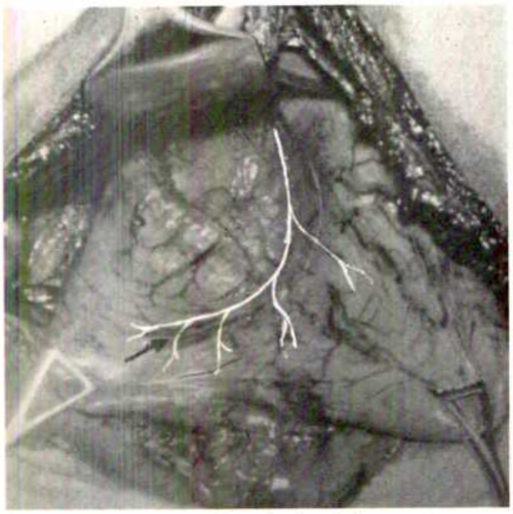

FIG. 2.—The course and distribution of the anterior nerve of Latarjet. The dissection begins at the point indicated with an arrow, leaving the antrum innervated.

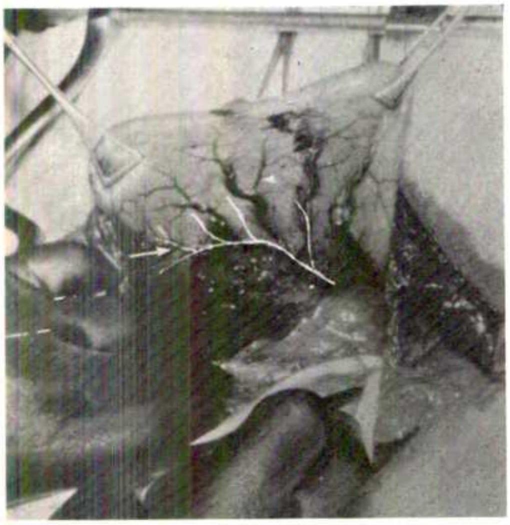

FIG. 3.—The course and distribution of the posterior nerve of Latarjet (the gastrocolic ligamant has been opened and the lesser sac penetrated). The dissection begins at the point indicated with an arrow.

Step 2.—The gastrocolic ligament is opened and the lesser sac is penetrated. The posterior walls of the stomach and of the lesser omentum are visualized and the posterior nerve of Latarjet demonstrated; its terminal branches to the antrum are preserved (*Fig.* 3).

The dissection begins near the incisura (*see arrow, Fig.* 3) and proceeds upwards. The lesser omentum is thus detached from the lesser curve. Finally, the cardia and the abdominal oesophagus are denervated.

RESULTS

1. Clinical Results.—The postoperative course of the patients who were treated by acid-fundic selective vagotomy has been very satisfactory. There was no mortality. The ulcer pain disappeared immediately after operation. Intravenous infusions were performed only during the first 24–36 hours. The patients had a liquid diet on the second and third postoperative days, and on the fourth day they were started on a solid diet. A small number (4·8 per cent) of patients had delayed gastric emptying (more than 300 ml. of resting juice after an overnight fast). In contrast delayed gastric emptying was present in 11·1 per cent of patients treated by total selective vagotomy without drainage (*Table III*).

Table III.—DELAYED GASTRIC EMPTYING AFTER SELECTIVE VAGOTOMY WITHOUT DRAINAGE (TUBE SUCTION)

Type of Vagotomy	*Patients with Delayed Gastric Emptying* (per cent)
Total selective	11·1
Acid-fundic selective	4·8

Long-term Results (3–10 months after surgery).—Eating tolerance (*Table IV*) was very good in 86·49 per cent and good in 13·51 per cent of the cases. Body-weight (*Table V*) had increased in most of the cases (86·49 per cent), was steady in 10·81 per cent, and had decreased in 2·70 per cent. The dumping syndrome (*Table VI*) did not occur in the patients who had undergone selective vagotomy without gastric drainage, but was present in 5·5 per cent of the patients who had had a gastric drainage operation.

Table IV.—EATING TOLERANCE 3–10 MONTHS AFTER ACID-FUNDIC SELECTIVE VAGOTOMY WITHOUT DRAINAGE

Eating Tolerance	*Percentage of Patients*
Very good (4/4)	86·49
Fairly good (3/4)	13·51
Poor (1/2)	0

Table V.—BODY-WEIGHT 3–10 MONTHS AFTER ACID-FUNDIC SELECTIVE VAGOTOMY WITHOUT DRAINAGE

Body-weight	*Percentage of Patients*
Increased	86·49
Steady	10·81
Decreased	2·70

Table VI.—PRESENCE OF THE DUMPING SYNDROME 3–10 MONTHS AFTER SELECTIVE VAGOTOMY

Gastric Drainage	*Percentage of Patients*
With gastric drainage	5·5
Without gastric drainage	0

According to Visick criteria the results in our series are as follows: grade 1 (very good), 86·49 per cent; grade 2 (good), 10·81 per cent; grade 3 (fairly good), 2·70 per cent (*Table VII*).

2. Gastric Secretion.—Gastric secretion was studied prior to surgery in all the patients. The tests were performed after an overnight fast. Gastric content was aspirated by means of a nasogastric tube, and some gastric juice was titrated with *N*/10 sodium hydroxide using phenol red as an indicator. The following data were evaluated: 1-hour basal acid output (B.A.O.); maximal acid output (M.A.O.) after pentagastrin stimulation (6 μg. per kg. body-weight i.m.) for 1 hour following the initial 30 minutes.

Average values obtained were: B.A.O., 8·8 mEq. per hour; M.A.O., 36·5 mEq. per hour. The B.A.O. and M.A.O. were re-evaluated 10 days after acid-fundic selective vagotomy of the stomach. At that time average values were 1·8 mEq. per hour for the B.A.O., and 11·4 mEq. per hour for the M.A.O. The reduction in B.A.O. was 80·5 per cent and in M.A.O. 68·5 per cent (*Table VIII*).

Table VII.—VISICK'S GRADES 3–10 MONTHS AFTER ACID-FUNDIC SELECTIVE VAGOTOMY WITHOUT DRAINAGE

Visick's Grade	*Percentage of Patients*
1	86·49
2	10·81
3	2·70
4	0

Table VIII.—ACID SECRETION BEFORE AND AFTER ACID-FUNDIC SELECTIVE VAGOTOMY

ACID SECRETION INDEX	ACID SECRETION		
	Before Operation (mEq. per hour)	10 Days after Operation (mEq. per hour)	Reduction (per cent)
B.A.O.	8·8	1·8	80·5
M.A.O.	36·5	11·4	68·5

Table IX.—INSULIN TEST (HOLLANDER) 3–10 MONTHS AFTER ACID-FUNDIC SELECTIVE VAGOTOMY

Test	*Percentage of Patients*
Negative	80

Early positive	0

Table X.—GASTRIC EMPTYING 3–10 MONTHS AFTER ACID-FUNDIC SELECTIVE VAGOTOMY WITHOUT DRAINAGE

Gastric Emptying	*Percentage of Patients*
Within 4 hours	92·0
Within 6 hours	5·3
After 6 hours	2·7

3. Completeness of Vagotomy: Insulin Test.—To establish the completeness of vagotomy insulin tests were performed 4 months after surgery in the patients treated by acid-fundic selective vagotomy. Twelve 15-minute collections of gastric juice were made, 4 before and 8 after insulin administration (0·2 U. per kg.).

The secretory response to insulin was evaluated according to the Hollander criteria (Kallehauge and Amdrup, 1969); the vagotomy was considered complete if the insulin test was negative, adequate if the test was positive in the second hour (late positive test), and incomplete if the test was positive in the first hour (early positive test). In this series the test was negative in 80 per cent of the cases and late positive in 20 per cent (*Table IX*).

4. Gastric Emptying: Radiological Findings.—After acid-fundic selective vagotomy without gastric drainage radiographic examination 5 months after surgery (*Table X*) showed complete emptying of the stomach within 4 hours in 92 per cent of the patients, within 6 hours in 5·3 per cent, and after 6 hours in 2·7 per cent. These results were far better than those after total selective vagotomy without gastric drainage.

CONCLUSIONS

The clinical and secretory results in the present series support the following conclusions:—

1. Acid-fundic selective vagotomy achieves a complete denervation of the parietal cell mass and reduces basal and stimulated acid gastric secretion to the same extent as total selective (or truncal) vagotomy.
2. Acid-fundic selective vagotomy, preserving the vagal branches of the antrum, does not affect gastric emptying and makes gastric drainage unnecessary.

The clinical results, although after only a short follow-up, suggest that the procedure can be considered as the treatment of choice in most patients with an uncomplicated duodenal ulcer (76 per cent in our series). The gastric drainage procedure is required only in cases of stenosing duodenal ulcer with delayed gastric emptying. Pyloroplasty is also mandatory in the treatment of bleeding ulcer and of perforated ulcer (if the suture is stenosing).

Acknowledgements.—We are indebted to our anaesthetists, Dr. R. Aloi and Dr. A. Talia, to the staff nurses of the operating theatre, and to the sisters and nurses of the wards for their help.

A RANDOMIZED PROSPECTIVE TRIAL COMPARING THREE ESTABLISHED METHODS OF GASTRIC DECOMPRESSION AFTER VAGOTOMY

BY D. F. MILLER, J. R. MASON, J. McARTHUR, AND I. GORDON

VICTORIA INFIRMARY, GLASGOW

SUMMARY

One hundred and thirty-two patients who were about to undergo vagotomy and drainage were randomly allocated nasogastric tubes, gastrostomy tubes, or no decompression postoperatively. Significantly fewer patients with no decompression developed respiratory infections postoperatively. The role of smoking in the production of postoperative chest complications was again confirmed. Neither the choice of decompression nor its absence appeared to affect postoperative electrolyte control. Postoperative dysphagia was more common in the group with a nasogastric tube. Wound infections were commoner in the gastrostomy group. While most patients with gastrostomies expressed a preference for this type of decompression a proportion of those with nasogastric tubes expressed a preference for a gastrostomy.

IT is not generally agreed that gastric decompression is required after vagotomy with drainage, nor indeed do those who feel decompression to be necessary agree on the method of choice. Soon after the introduction of the nasogastric tube came reports of complications due to irritation, pressure, and disturbed function of the cardia. These have previously been summarized by Farris and Smith (1956).

Gastrostomy was suggested as a means of decompression over 30 years ago by Horsley (1939) and seemed to have several advantages in general use. Nasopharyngeal pressure and irritation were removed and there was no interference with function of the cardia. It was inevitable, however, that complications of gastrostomy should be reported, ranging from fistula formation to peritonitis. Barnes and Williams (1967) found that wound infections could be a problem particularly when the gastrostomy was sited near the main wound. When the gastrostomy was used for feeding purposes as well as for decompression deep venous thrombosis was noted and a curiously high incidence of dysphagia was recorded (Hamer, Wellwood, and Cox, 1969).

A retrospective review of 174 patients who had had a gastrostomy performed in the Victoria Infirmary, Glasgow, did not confirm this high incidence of dysphagia. Only 2 cases (1·2 per cent) were found. Four patients (2·3 per cent) were found to have developed deep venous thrombosis, 60 (34·5 per cent) had respiratory infections, and 34 (19 per cent) had identifiable electrolyte disturbances. No case of fistula formation was encountered. Although retrospective studies have been performed comparing gastrostomy and nasogastric decompression (Grant, Elliot, and Frederick, 1962; Hamer and others, 1969) no randomized prospective trial comparing nasogastric tubes, gastrostomies, and no decompression has been reported. The following study was therefore undertaken.

MATERIALS AND METHODS

A consecutive series of 132 patients who underwent vagotomy between August, 1969, and December, 1970, was studied prospectively. There were 100 males and 32 females with ages ranging from 16 to 74 years (mean 44·5 years). A duodenal ulcer was present in 127 cases, including 10 patients who were operated on because of bleeding, and 4 who had a perforated ulcer. The remaining 5 patients had a gastric ulcer which was excised by wedge resection in 3 cases and biopsied in 2.

Table I.—DISTRIBUTION OF COMPLICATIONS BETWEEN THE THREE GROUPS OF PATIENTS

COMPLICATIONS	TOTAL		NASOGASTRIC GROUP	GASTROSTOMY GROUP	NO TUBE GROUP
	No.	Per cent			
Electrolyte depletion	47	36	16	14	17
Chest infection	57	43	24*	21	12*
Wound infection	17	13	6	9*	2*
Dysphagia	9	6·9	6*	2	1*
Total No. of patients in each group	132		47	43	43

* Significant difference (*see Table III*).

Vagotomy was performed with a gastro-enterostomy in 103 patients and with a Heineke-Mikulicz pyloroplasty in 29. Four patients had, in addition, a hiatus hernia which was repaired during the operation.

The patients were divided into three groups by random selection based on the month of their birth. In the first group of 47 patients a nasogastric tube passed before operation was kept in place for 48 hours postoperatively. In the second group of 43 patients in place of the nasogastric tube a temporary gastrostomy was established using a Foley catheter which was removed after 8 days. The stomach was not fixed in any way to the parietal peritoneum. The remaining 42 patients were treated without decompression. A nasogastric tube could be passed whenever clinically indicated in this last group, but was required, because of paralytic ileus, by only 1 patient from the second to the ninth postoperative days.

Intravenous fluids were continued for a minimum of 48 hours after operation in all the cases. Electrolyte estimations were made before operation and twice in the first 4 days postoperatively. The patients were observed for evidence of chest or wound infection, a pyrexia of 37·3° C. or over, deep venous thrombosis, or pulmonary embolism. Before discharge from the ward the patients who had had nasogastric or gastrostomy tubes were asked to complete a questionnaire regarding the symptoms caused by the drainage tube. All the patients were asked both on discharge and 1–2 months after operation if they had experienced any postoperative dysphagia.

RESULTS (*Tables I, II, III*)

Electrolyte Depletion.—The serum-sodium level fell in several of the patients after operation and was accompanied by a less pronounced fall in serum chloride and potassium. For the purpose of comparison of the different groups a serum-sodium level of 133 mEq./l. or less was taken as evidence of sodium depletion. This was found in 47 of the 132 patients (34·6 per cent); 16 were in the nasogastric group, 14 in the gastrostomy group, and 17 among those with no drainage tube. As the differences between these groups are not significant the choice of drainage tube does not appear to affect the electrolyte depletion.

Table II.—PATIENTS' REACTIONS TO METHOD OF DECOMPRESSION

METHOD OF DECOMPRESSION	TOTAL	SYMPTOMS		CHOICE	
		Bearable	Distressing	Same	Change
Nasogastric tube	47	14	33	28*	19
Gastrostomy tube	43	36	7	40*	3

* Significant difference (*see Table III*).

Table III.—STATISTICAL ANALYSIS OF THE RESULTS

COMPARISON	χ^2	*P*
Chest infection	4·66	< 0·05 > 0·025
Wound infection	4·93	< 0·05 > 0·025
Dysphagia	5·84	< 0·025 > 0·0125
Patients' choice	13·60	< 0·001

Chest Infection.—Clinical signs of a chest infection with either a pyrexia of 37·3° C. or over, or a positive sputum culture, or radiological evidence were present in 57 of the 132 patients (43 per cent). Of these, 24 had had a nasogastric tube, 21 a gastrostomy tube, and 12 were in the group with no drainage tube. The difference in the rate of chest infection between the nasogastric group and those with no tube is statistically significant.

The number of patients who smoked cigarettes was 98 (74 per cent); 64 smoked 20 or more per day. Of the 57 patients with chest infection, 51 (89·4 per cent) were smokers and only 6 (10·6 per cent) were non-smokers. This is a significant difference confirming that smoking is a factor in producing postoperative chest infection.

Wound Infection.—Wound infection occurred in 6 patients of the nasogastric group, 9 of the gastrostomy group, and 2 of those without a tube, giving a total of 17 (12·9 per cent). There is a statistically significant difference between the rates of infection in the gastrostomy group and in the group with no tube.

Dysphagia.—Two patients who had had repair of a hiatus hernia complained of mild dysphagia as soon as oral feeding was commenced after operation. This temporary dysphagia appeared to be due to the operative procedure. Of the remaining 130 patients, 9 (6·9 per cent) developed post-vagotomy dysphagia

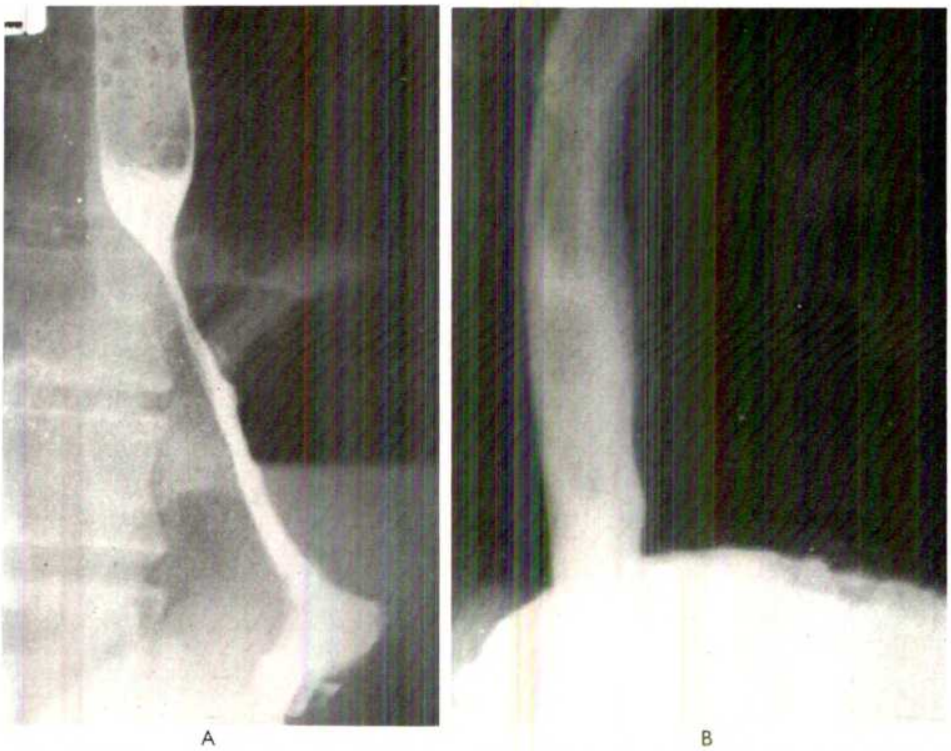

FIG. 1.—A, Barium-swallow film of a patient with troublesome dysphagia 4 weeks following vagotomy. B, Final appearance 4 months later.

between 12 and 28 days (mean 17 days) postoperatively. In 8 of the patients this lasted from a few days to 4 weeks until it settled spontaneously. The symptoms were distressing but varied in severity. In most cases the dysphagia occurred only with solid food, and in 1 case it was intermittent. These patients were symptom-free when seen at the outpatients' clinic and no treatment was required. The ninth patient developed more troublesome dysphagia and was readmitted 4 weeks after operation complaining of pain when swallowing food. A barium-swallow examination revealed a smooth stricture of the lower end of the oesophagus (*Fig.* 1 A) and on oesophagoscopy inflammation of the mucosa was seen at the site of the stricture. After bouginage the symptoms improved and eventually settled completely. A second barium swallow a few months later showed a normal oesophagus (*Fig.* 1 B).

Six of the 9 patients with dysphagia had had nasogastric intubation, while 2 came from the gastrostomy group and 1 had had no drainage tube. Pyloroplasty was the operative procedure in 4 of the 9 patients.

Other Complications.—There were no deaths in the series and none of the 132 patients developed clinical evidence of deep venous thrombosis or pulmonary embolism. Wound rupture occurred in 2 patients and 4 developed an incisional hernia. Two of the gastrostomy group were readmitted with pyrexia, possibly due to intraperitoneal infection, which settled with antibiotic therapy. In 2 patients a gastro-enterostomy was converted to a pyloroplasty because of obstruction at the stoma.

The Patients' Opinion of the Drainage Tube (*Table II*).—In the nasogastric group 14 of the 47 patients found the symptoms caused by the tube 'bearable', while the remaining 33 found them 'unpleasant' or 'distressing'. Nineteen patients in this group thought a gastrostomy would have been preferable if a choice were possible.

Of those with a gastrostomy tube, 36 of the 43 patients described the symptoms as 'bearable', and 40 would choose a gastrostomy again, only 3 electing to change to a nasogastric tube.

DISCUSSION

It is to be expected that the free drainage provided by a gastrostomy might lead to electrolyte depletion, and gastrostomy tubes have been devised with feeding limbs to allow gastric secretion to be returned to the duodenum (Kay, 1964). In our retrospective analysis we found only 19 per cent with depleted electrolytes. This was obviously a low percentage probably because of lack of information. Particular care, therefore, was taken in this prospective study to estimate electrolytes at the specified intervals. It is interesting that not only were the percentages of electrolyte deficiency in the gastrostomy and nasogastric tube patients the same, as found by Hamer and others (1969), but that a similar proportion of patients with no decompression should develop electrolyte abnormalities.

Grant and others (1962) stated that a gastrostomy tube reduces the incidence of chest infections, and this is advanced as a good theoretical indication for gastrostomy. The present trial offers good evidence that the choice of decompression does not influence the occurrence of postoperative chest infections. The low chest-infection rate in patients with no decompression is interesting and gives further weight to the suggestion that no decompression at all should be used until there is established evidence of paralytic ileus (Gunn, 1970). The effect of smoking is marked and underlines another hazard of this habit. As the period of the trial covered a whole year the seasonal variations in respiratory infections should have balanced.

It is not surprising that with such a potential source of infection nearby wound sepsis should occur after gastrostomy. We experienced a higher incidence of wound infection, even with gastrostomies placed well away from the main incision. Two patients developed evidence of peritoneal irritation following gastrostomy. Nevertheless, we do not feel that the wall of the stomach should be sutured to parietal peritoneum. Several patients from our retrospective series either underwent further surgery or came to post-mortem examination from other causes when it was noted that there was very little trace of the transomental gastrostomy. Furthermore, anchoring the stomach to the abdominal wall may carry the risk of future traumatic perforation (Grant and others, 1962).

As part of the present study the patients were questioned carefully about dysphagia both in hospital and after discharge. We found 9 patients (6·9 per cent) who developed dysphagia that could be attributed to their vagotomy. Six of these patients had had a nasogastric tube passed. The other 3 at no time had a nasogastric tube passed. The aetiology of the dysphagia, which usually appears 7–14 days after vagotomy, is uncertain. Three varieties have been described based on clinical signs and symptoms:—

1. *Dysphagia without Pain.*—The mucosa of the oesophagus appears normal on oesophagoscopy and a barium swallow reveals narrowing at its terminal part. There is thought to be a neural factor in its production following vagal section, particularly by the transthoracic route. Most of our cases were of this type.

2. *Dysphagia with Oesophagitis.*—In this group pain is associated with the dysphagia. Oesophagoscopy shows inflammation of the lower oesophagus and a barium swallow shows narrowing at the lower end of the oesophagus. *Fig.* 1 shows the barium-swallow film of the 1 patient in our series with marked dysphagia who appeared to fall into this group.

3. *Peri-oesophageal Cuff.*—The dysphagia in this group is more marked than group 1. Oesophagoscopy shows normal mucosa but with an appearance of extrinsic pressure. Barium swallow confirms the narrowing. In severe cases operation may be required to divide the cuff (Bruce and Small, 1956).

Whether these varieties are separate entities is open to doubt. They could all be features of a single process. The mildest form would be a little local oedema and damage to oesophageal muscle, and in the severe forms an organized fibrous cuff develops as a progression of the same progress. The occurrence of oesophagitis in some of the patients could well be related to nasogastric intubation. One possible factor could be that a diligent search for vagal fibres traumatizes the oesophagus against the nasogastric tube. Indeed we were impressed by the ease of performing vagotomy with no tube in place during the trial.

It is generally agreed that nasogastric tubes are uncomfortable. It seemed reasonable to seek the patients' opinion, particularly to determine if gastrostomies were better tolerated. There is no doubt that patients do find a gastrostomy more comfortable.

Acknowledgements.—We are grateful to the surgeons of the Victoria Infirmary, Glasgow, for their co-operation in the trial, to Dr. Glen of the Biochemistry Department for help with the statistical analysis, and to the Medical Illustration Department of the Victoria Infirmary for *Fig.* 1.

INFLAMMATORY ANEURYSMS OF THE ABDOMINAL AORTA

BY D. I. WALKER,* K. BLOOR, G. WILLIAMS, AND I. GILLIE
DEPARTMENTS OF SURGERY AND PATHOLOGY, UNIVERSITY OF MANCHESTER

SUMMARY

Two hundred and seventeen patients presenting with abdominal aneurysms in the Department of Surgery at the Manchester Royal Infirmary between the years 1958–69 were surveyed retrospectively.

One hundred and eighty-seven of the patients underwent operation for resection of their aneurysms; of these, 19 (10 per cent) showed excessive thickening of the aneurysm walls and perianeurysmal adhesions at operation.

Subsequent histological examination of the walls of these unusual aneurysms showed extensive active chronic inflammatory changes, including plasma-cell infiltration.

This group of patients whose aneurysms we describe as 'inflammatory' presented with different clinical features in comparison with the atherosclerotic group.

Retrospective investigation has not yet revealed any aetiological factors. We feel that 'inflammatory' aneurysms are a discrete entity with significant differences from atherosclerotic aneurysms and previously described arteritis.

Two hundred and seventeen patients presented with abdominal aortic aneurysms at the University Department of Surgery at the Manchester Royal Infirmary over the period 1958–69 and of these, 187 underwent operative treatment with the intention of resection of their aneurysms.

One hundred and sixty-eight patients were found to have aneurysms of the atherosclerotic type. In the remaining 19 cases the aneurysms were unusually thick walled and surrounded by extensive fibrous adhesions which made operative procedures much more difficult. On 2 occasions aneurysms described at operation as 'surrounded by dense fibrous tissue' and 'densely adherent', respectively, were encountered before this investigation was undertaken. These 2 cases were probably of the 'inflammatory' type, but owing to the lack of histological verification have not been included in the series. Specimens of the aneurysm walls from this group of 19 cases were subjected to detailed histological examination and bacterial culture, the case records of all 19 patients were reviewed, and haematological, biochemical, and immunological investigations were carried out on the surviving patients.

Despite their striking operative appearance and significant incidence these aortic lesions, as far as we are aware, have not been previously described.

OPERATIVE APPEARANCE

In common with most abdominal aortic aneurysms the 'inflammatory' aneurysms are usually confined to the abdominal aorta between the renal arteries and aortic bifurcation; on only 1 occasion has there been involvement of the renal arteries.

The inflammatory aneurysm has a thick, firm, smooth wall which is shiny white in appearance although there is an obvious increase in the vascularity of the wall with multiple small vessels traversing it. The adjacent dense fibrosis is marked and may involve adjoining tissues and structures. In 1 case fibrosis was particularly marked in the tissues around the common iliac vessels, involving the ureters but not the vessels themselves. Resection of the aneurysm was not performed in this particular case because of the density of the fibrosis. This patient died 28 days after his laparotomy and autopsy showed bilateral hydronephrosis and hydro-ureter due to fibrosis in the retroperitoneal tissue.

On section the wall of the aneurysm is thickened up to 1·5 cm. and has a characteristic fleshy appearance with an increase in the vascularity. The dense fibrosis makes dissection of the adjacent structures, such as the sigmoid colon and duodenum, difficult. This may be particularly marked around the accompanying veins and separation of the inferior vena cava and left common iliac veins may be hazardous.

PATHOLOGY

Formalin-fixed tissue representing resected portions of the aneurysm walls was examined as paraffin sections after staining with haemalum and eosin, Victoria blue/Van Gieson for elastic tissue, the M.S.B. method of Lendrum, Fraser, Slidders, and Henderson (1962), the periodic acid-Schiff, and Mallory's phostungstic acid-haematoxylin techniques.

Sections from most specimens were also examined for bacteria and fungi. Frozen sections of fixed material were examined for neutral fat after Sudan IV staining and by polarized light for possible refractile content.

PATHOLOGICAL RESULTS

Macroscopic Appearances.—Specimens representing full-thickness strips or portions of aneurysm walls measured up to 7 cm. in length. Their most striking feature was the increased wall thickness which ranged from 0·5 to 1·5 cm. in cross-section.

Microscopic Appearances.—Thrombus was present on the luminal surface in all the cases, and significant atheromatous infiltrations were present in 6 and these showed disruption of their internal elastic laminae, occasionally with calcification.

---

* Requests for reprints to be sent to Mr. D. I. Walker, Department of Surgery, Manchester Royal Infirmary, Manchester M13 9WL.

The media showed loss of smooth muscle, extensive loss or fragmentation of elastic fibres, variable inflammatory infiltration, and collagenization. In contrast with the usual atherosclerotic aneurysm the adventitial coats of all the specimens were markedly thickened (*Fig.* 1). In some instances medial and adventitial coats were fused to form a continuous fibro-inflammatory sheath densely infiltrated with lymphocytes, plasma cells, and histiocytes including occasional giant-cell forms and small granulomata. The inflammatory infiltrates varied in density and distribution: some as lymphoid aggregates or follicles (*Fig.* 2), and others as perivascular infiltrates with a high plasma-cell content around numerous adventitial vessels (*Fig.* 3) or diffused throughout the entire adventitial layer (*Fig.* 4). In 4 cases fibrin thrombi were present in the small penetrating vessels of the thickened adventitia (*Fig.* 5), and in 2 cases focal necrosis with polymorphonuclear infiltrations was present. The excess connective tissue was almost entirely collagenous; elastic fibres were absent or represented by trace fibres only. Transected nerves were prominent in the fibrous mass, and occasional penetrating lumbar arteries were either thrombosed and recanalized or occluded by endarteritis. Variable

CLINICAL FEATURES

None of the patients in the 'inflammatory' group showed evidence of aneurysm formation in vessels other than their abdominal aorta; none had a family history of arterial disease or other significant illness.

The clinical findings of the patients with 'inflammatory' and atheromatous aneurysms differed.

Age-range.—The 'inflammatory' aneurysms tended to occur in a younger age-group with an age-range of 42–71 years (average age, 62 years), as opposed to the atherosclerotic group where ages ranged from 55 to 86 years (average age, 72 years).

Incidence of Rupture.—The incidence of rupture in the two groups of aneurysms differed. Three of the 19 patients (15 per cent) of the 'inflammatory' group presented after rupture of their aneurysms, whereas in the atherosclerotic group rupture had occurred in 65 patients (40 per cent).

Sex.—Two of the patients with inflammatory aneurysms were females, an incidence of 10 per cent which also applied to this series as a whole and which conforms to the 1 : 9 female to male ratio for atherosclerotic aneurysms (DeBakey, Crawford, Cooley, Morris, Royster, and Abbott, 1964).

Peripheral Arterial State.—None of the patients with inflammatory aneurysms complained of intermittent claudication and a full complement of peripheral pulses was noted in 15 of the 19 cases. No record was made in 3 patients and 1 was noted to have absent popliteal and foot pulses. These findings suggest the absence of gross occlusive arterial disease. In the atherosclerotic group 16 (15·5 per cent) of those presenting without rupture complained primarily of intermittent claudication. Furthermore, 72 (70 per cent) were noted to have one or more peripheral pulses absent preoperatively.

Aortograms were not performed on any of the cases as we feel that this procedure is not necessary and may in fact be hazardous.

Hypertension.—Patients with a diastolic blood-pressure of more than 100 mm. Hg or a systolic blood-pressure of more than 170 mm. Hg were considered to be hypertensive. With these criteria hypertension was noted in only 3 of the 16 cases who presented without rupture of their aneurysms, an incidence of 19 per cent. In the series as a whole hypertension was noted in 65 (63·1 per cent) of the patients who had had a preoperative record made. This of course excludes the majority of the ruptured aneurysms.

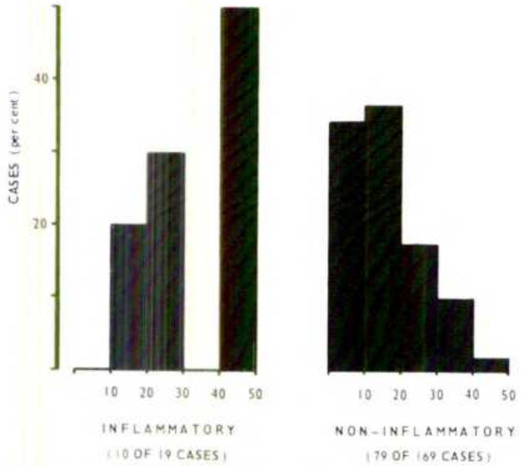

FIG. 6.—Comparative histogram of the preoperative E.S.R. in inflammatory and non-inflammatory cases.

Presentation.—In the 'inflammatory' group there were no unusual presenting features. Five patients presented with pulsatile abdominal masses, 4 with backache, and 4 with abdominal pain. One patient had duodenal obstruction and previous backache and 2 were asymptomatic.

The 3 remaining cases presented with ruptured aneurysms; of these, 2 had suffered backache, the third having been symptom-free.

Length of History.—This varied between 1 and 12 months. The patients showed no associated pattern of illness and were indeed surprisingly well considering the nature of their aortic lesions.

CLINICAL INVESTIGATIONS AND COURSE

Erythrocyte Sedimentation Rate.—Estimation of the preoperative erythrocyte sedimentation rate (E.S.R.) was performed by the Wintrobe method (Wintrobe and Landsberg, 1935) in 10 of the 19 cases (*Table I*); all were either at the upper limit of normal or above for their respective ages (Olbrich, 1948). In 5 cases the preoperative E.S.R. was above 40 mm. in the first hour, anaemia not being present in any. In contrast, the preoperative E.S.R. estimated in 79 of the 168 non-inflammatory cases was more than 20 mm. in the first hour in 23 cases (29 per cent) and below this rate in 56 (71 per cent).

Table I.—Preoperative E.S.R. in 10 Cases with 'Inflammatory' Aneurysms

Age and Sex of Patient	*E.S.R.* (mm. in first hr.)
67 M.	15
66 M.	19
66 M.	21
71 F.	21
60 M.	22
65 M.	41
64 F.	42
57 M.	43
69 M.	44
63 M.	46

In only 3 patients in this group was the E.S.R. above 40 mm.

A comparative histogram of the two groups (*Fig.* 6) shows that whilst patients with inflammatory aneurysms tend to have a raised E.S.R., those of the non-inflammatory group fall into lower values.

Calcification.—In the 'inflammatory' group calcification was noted on straight radiographs of the abdomen in 14 cases (87·5 per cent) and 2 (12·5 per cent) showed no evidence of calcification; 3 did not have a preoperative radiograph In the non-inflammatory group 119 patients had preoperative abdominal radiographs taken; 86 (71 per cent) showed evidence of calcification whereas 33 (29 per cent) did not. Thus there is no significant difference in the incidence of calcification between the two groups.

Operative Mortality.—One patient died during operation from hypotension, having ruptured his aneurysm preoperatively. There were 5 other postoperative deaths: 1 from pulmonary embolism at 12 days, 2 from graft thromboses associated with retroperitoneal abscess at 28 days and 40 days, respectively, 1 from cardiac failure at 10 days, and 1, previously mentioned, who had only a laparotomy and died at 28 days from causes not determined by post-mortem examination.

Postoperative Complications.—The only significant complication would appear to be the incidence of graft thrombosis associated with abscess formation. There has been 1 late death at 5 months from this cause in addition to the 2 in the immediate postoperative period. The abscess formation in 1 case was associated with perforation of the small bowel after attempts had been made to free small-bowel adhesions from the wall of the prosthesis 5 days after its insertion. No abnormality of the bowel was found in the other 2 cases. This abscess formation has not been seen in atherosclerotic aneurysms although graft thrombosis has occurred.

Wound dehiscence occurred in only 1 of the 17 cases who lived for longer than 14 days, an incidence (5·9 per cent) comparable to the series as a whole.

Late Mortality.—One patient died at 20 months of a myocardial infarct, and 1 at 2½ years of a cerebrovascular accident.

Table II.—Retrospective Investigations carried out in 11 Patients with 'Inflammatory' Aneurysms

Age and Sex	Pre-operative E.S.R.	Retrospective Tests

64 F.	42	6
69 M.	44	12

RETROSPECTIVE INVESTIGATIONS

Retrospective investigations were performed in all 11 survivors of the 19 patients at intervals varying from 4 months to 4 years after operation (*Table II*).

Erythrocyte Sedimentation Rate.—All the patients eventually reached the normal range (*Table II*). In 1 case this took several months to occur. This man's E.S.R. was 44 mm. preoperatively; 3 months after operation it was 47 mm.; 6 months postoperatively the value was 28 mm.; and after 12 months it had fallen to 12 mm. Comparison of preoperative and postoperative E.S.R. was available in 6 cases only (*Table III*). A postoperative E.S.R of 31 mm. (preoperative 44 mm.) was obtained from 1 patient who developed a retroperitoneal abscess which subsequently proved fatal.

Other Investigations.—The cardiolipin Wassermann reaction, Reiter protein complement fixation, and treponemal haemagglutination tests were negative in all 11 cases.

In view of the number of plasma cells in the inflammatory infiltrates we investigated the serum proteins both quantitatively and qualitatively (*Table II*). No abnormality was detected.

Qualitative and quantitative immunoglobulin assessments showed no abnormality. Quantitative immunoglobulin IgA, IgG, and IgM levels were all within normal ranges, viz., 50-400, 800–1800, and 50–200 mg. per 100 ml. respectively. Investigations for antinuclear factors were also negative (*Table II*).

Allowing for age and sex, all the serum cholesterol values were in the normal range, and the rheumatoid factor as defined by the sensitized sheep-cell and F 11 latex tests was negative in all cases.

DISCUSSION

We have previously noted the similarity in the extent of the 'inflammatory' aneurysms and the atherosclerotic aneurysms. This is, however, the only point of similarity.

From the surgical viewpoint the most striking difference between the two groups of patients was the gross appearance of their aneurysms. In the 'inflammatory' group the thickened aneurysm walls with their fleshy appearance and adjacent dense fibrosis were characteristic and striking. This fibrosis often made dissection at operation very difficult and the lumbar veins and arteries were liable to damage during mobilization of the upper end of the aneurysm. Similarly, the common iliac veins and inferior vena cava were solidly attached to the aneurysm wall and separation of them was particularly hazardous.

In addition, the duodenum may be so adherent to the anterior wall of the aneurysm that the plane of cleavage is completely obliterated. In 1 instance this was so marked as to have caused duodenal obstruction. Once mobilization of the proximal and distal ends of the aneurysm has been completed successfully the remainder of the operation carries no further special hazards, and indeed the anastomoses may be easier to perform as the adjacent aorta is relatively free from atheroma in comparison to the atherosclerotic aneurysm.

The aetiology of the 'inflammatory' aneurysm remains obscure. Atherosclerosis remains the most common cause of abdominal aortic aneurysm with an age-range between the fourth and the tenth decades with the highest incidence in the seventh decade (DeBakey and others, 1964). Other causes are rare, although Marquis, Richardson, Ritchie, and Wigle (1968) reported an aneurysm found at autopsy as due to 'idiopathic medial aortopathy' (*Case* 4), and other aortic aneurysms of uncertain aetiology have been reported by Abrahams and Cockshott (1962).

Specific causes of aortitis have long been known. Syphilis is still the commonest cause (Gore, 1960), involving mainly the thoracic vessel although the abdominal portion may also be affected. Aortitis has been described in rheumatic fever (Klotz, 1912; Reid, 1957; Heggtveit, Hennigar, and Morrione, 1963), rheumatoid disease, and ankylosing spondylitis (Schilder, Harvey, and Hufnagel, 1956; Ansell, Bywaters, and Doniach, 1958). In the present series serological tests for syphilis were uniformly negative and there was no evidence of a systematized collagen disorder.

Non-specific aortitis is rare. Cases of Takayashu's (pulseless) disease or of an allied aortitis have been described in countries other than Japan; for example, by Danaraj, Wong, and Thomas (1963) in Singapore, by Abrahams and Cockshott (1962) in Nigeria, and by Isaacson (1961) in South Africa. In these instances children or young adults were affected and secondary renal hypertension from involvement of a renal artery in the inflammatory process was common. Renovascular hypertension has also been reported in the aortitis syndrome in Japan (Committee Report, 1968).

In the present series of 19 patients with abdominal aortic aneurysms, 17 were males aged between 48 and 71 years; this contrasts with the male : female ratio of 1 : 7 in Takayashu's syndrome in a younger age-group (Committee Report, 1968), although in Western countries patients with aortic arch syndrome are often middle-aged or elderly (Thurbeck and Currens, 1959), and the disease is of mixed aetiology, involving atheroma and thrombosis, syphilis (Ross and McKusick, 1953), or idiopathic thrombosis (Lessof and Glynn, 1959).

We have referred to the present series of aneurysms as 'inflammatory' in type but this implies no specific aetiology or pathogenesis. From the pathological viewpoint the unusual feature was the grossly thickened aneurysmal walls resulting from active chronic inflammation and collagenization of the adventitial and medial coats. If these thick-walled aneurysms are of atherosclerotic origin they show an unusual form of a lesion which usually presents as a discrete, thin-walled fibrous sac or dilatation of the abdominal aorta. Adventitial cellular infiltration is a feature of atherosclerosis, particularly if complicated by recent thrombus (Schwartz and Mitchell, 1962), but the infiltrates seen are lymphocytic and homogeneous. The inflammatory response in the aneurysm described in this study was not only intense but heterogeneous, including polymorphonuclear leucocytes in areas of focal necrosis, lymphocytes in both follicular aggregates and diffuse infiltrates, large numbers of plasma cells, and occasional granulomata including giant-cell macrophages. Possibly this represents an exaggerated inflammatory response to fresh luminal thrombi which were present in all the specimens or to breakdown products of the thrombi permeating the aneurysm walls. The precise antigenic stimulus producing the intense phlogistic reaction is, however, unknown.

From the pathological viewpoint the condition of the aorta remote from the aneurysms is also relevant. To date 3 patients in this series have been autopsied. There has been no widespread aortic inflammation, the thoracic aorta showing moderate to severe atheroma but only insignificant inflammation of the media and no fibrosis of the adventitia. Degenerative medial changes with loss of elastic tissue were limited to an area immediately adjacent to the aneurysm.

In the absence of other significant disease processes one might assume that the raised E.S.R. is referable to the active inflammation within the aneurysm wall. However, this would not explain the postoperative drop in E.S.R. levels as the aneurysms were merely *incised and not excised in* preparation for the arterial graft, thus leaving most of the 'inflammatory' tissue in situ. Possibly surgical repair of the aneurysm is followed by reduction of the inflammatory process, but we have not yet had an opportunity of checking this by examination of further material.

In the first 9 months of 1970, 3 more cases of 'inflammatory' aneurysms have been seen; all had a raised E.S.R., 1 to a level of 87 mm. in the first hour.

It would appear, therefore, that the group of aortic aneurysms we have described differs from the more common arteriosclerotic form in both their clinical and structural characteristics.

Acknowledgements.—We would like to thank Dr. G. Taylor for investigating the serology of these patients, and the Department of Medical Illustration for their help.

FEMORAL ANEURYSMS

BY D. G. HARDY AND D. G. A. EADIE

THE LONDON HOSPITAL

SUMMARY

Femoral aneurysms are a relative rarity in clinical practice. A series of 15 such aneurysms treated in a variety of ways is presented. The method of treatment did not appear to affect the outcome. Where the aneurysm was found to be infected at operation treatment was not successful. An alternative method of arterial reconstruction by endo-aneurysmorrhaphy is presented.

ALTHOUGH femoral aneurysms are relatively infrequently seen, even in specialist vascular units, the growing numbers of arterial vascular reconstructive procedures and the increasing age of the population have resulted in a gradual increase in the incidence of both false and atherosclerotic aneurysms since the condition was first recognized some hundreds of years ago. Despite the fact that more sophisticated methods of treatment have become available, femoral aneurysms still have an appreciable morbidity and mortality from their complications and following surgical treatment. This paper describes a series of femoral aneurysms of mixed aetiology treated in a variety of ways over the past 9 years at the London Hospital.

CASE MATERIAL

Fifteen aneurysms were treated in 13 patients, who had an average age of 59 years, the oldest being 76 and the youngest 47. All were male. Ten of the aneurysms were on the left side and 5 on the right. The most frequent presenting complaint was of a palpable, pulsating, occasionally painful mass in the groin. Two cases presented with preoperative symptoms attributable to thrombotic or embolic episodes with acute limb ischaemia and 1 had a spontaneous rupture of the aneurysm.

There were 7 true aneurysms, resulting from atherosclerotic degeneration of the vessel wall, and 1 primary mycotic aneurysm. Of the 7 false aneurysms, 5 followed previous surgical intervention, and 3 of these were infected. These operations had taken place from 9 years to 9 days before the appearance of the false aneurysms. Two of the false aneurysms resulted from direct trauma to the vessel wall. Eleven of the aneurysms involved the common femoral artery, 3 the superficial femoral artery, and 1 the profunda femoris artery.

MANAGEMENT AND OUTCOME

Four of the 7 atherosclerotic aneurysms were treated by endo-aneurysmorrhaphy (*Table I*). The profunda femoris aneurysm was treated by excision and autogenous vein replacement. The atherosclerotic superficial femoral aneurysm was treated by proximal and distal ligation of the artery with excision of the aneurysm. One patient who had an abdominal aneurysm in addition to a left common femoral aneurysm was treated by excision of both aneurysms, with a Dacron graft replacement. The primary mycotic aneurysm of the common femoral artery was initially treated by an autogenous saphenous vein by-pass. This subsequently developed a false aneurysm from the proximal suture line and was replaced by a Dacron iliofemoral graft. This was initially successful but later occluded, but with limb survival.

Table I.—DETAILS OF THE CASES IN THE PRESENT SERIES

CASE	DATE	AGE (years)	DIAGNOSIS	TYPE OF ANEURYSM	SITE OF ANEURYSM	PREOPERATIVE SYMPTOMS	TREATMENT	OUTCOME
1	1969	47	Atheroma, 1969	True atherosclerotic	Left common femoral	Claudication left leg	Endo-aneurysmorrhaphy	No symptoms
2	1967	63	Atheroma, hypertension, multiple aneurysms, 1969	True atherosclerotic	Left common femoral	Painful swelling left groin. Embolism to left calf	Endo-aneurysmorrhaphy	No symptoms
3	1965	59	Atheroma, ? arteritis, 1965	True atherosclerotic	Right common femoral	Painful swelling right groin. Claudication right leg	Endo-aneurysmorrhaphy	No symptoms
4	1970	70	Atheroma, 1969	True atherosclerotic	Left common femoral	Painful swelling left groin. Claudication left leg	Endo-aneurysmorrhaphy	No symptoms
5	1967	51	Atheroma, hypertension, 1967	True atherosclerotic	Right profunda femoris	Pulsating mass right groin	Excision and autogenous saphenous vein replacement	No symptoms
6	1962	70	Atheroma, 1962	True atherosclerotic	Right superficial femoral	Pulsating mass right groin	Ligation and excision	No symptoms
7	1969	66	Atheroma and abdominal aortic aneurysm	True atherosclerotic	Left common femoral	Pulsating mass left groin	Dacron aortofemoral graft	No symptoms
8	1970	59	Bilateral femoropopliteal grafts; left, March 1969; right, Dec., 1969	False mycotic anastomotic disruption	Right common femoral	Painful mass right groin and haemorrhage from groin	Simple closure of defect	Claudicating
9	1965	59	Right and left iliofemoral endarterectomies 7 years	False anastomotic disruption	Left common femoral	Pulsating mass claudicating	Revision arterioplasty	Claudicating
10	1968	59	Left superficial femoral endarterectomy 1 month previously	False mycotic anastomotic disruption	Left superficial femoral	Painful pulsating mass	Excision and saphenous vein replacement	Claudicating
11	1968	67	Atheroma—aortofemoral bifurcating graft, 1959	False anastomotic disruption	Left common femoral	Claudication	Iliofemoral Dacron by-pass	No symptoms
12	1967 and 1968	51	Primary atherosclerotic mycotic aneurysm, 1967. Subsequent false mycotic aneurysm, 1968	Primary mycotic False mycotic anastomotic disruption	Left common femoral Left common femoral	Painful pulsating mass and thrombosis left common femoral artery	Excision and saphenous vein replacement followed by Dacron iliofemoral by-pass	Claudicating
13	1965	49	Stab wound 9 days prior to appearance of aneurysm	False traumatic	Right superficial femoral	Painful pulsating mass right groin	Excision and saphenous vein replacement	No symptoms
14	1969	48	Mitral valve replacement and arterial puncture 1 month before aneurysm	False traumatic	Left common femoral	Pulsating mass	Evacuation and simple closure of defect	No symptoms

One of the 2 post-traumatic aneurysms was treated by lateral arterial repair, while the other was treated by excision of a segment of the damaged artery and replacement by an autogenous saphenous vein-graft.

Of the 5 false aneurysms resulting from prior surgical operations, the defect was found to occur at the site of the previous anastomosis or arterial repair in all cases. In these silk had been employed in 3 and Dacron suture material in 2 of the initial repairs. In only 1 of these cases had a Dacron graft been sutured end to side to the common femoral artery. All the false aneurysms which resulted from previous surgery were managed in different ways. One, following a femoropopliteal by-pass, was treated by simple closure, and another by a revision arterioplasty following a leak from a previous endarterectomy. Following an endarterectomy, 1 case developed an infected false aneurysm which was treated by an autogenous saphenous vein-graft. The fourth case had a second Dacron graft inserted more distally into the common femoral artery, and in the fifth case a long Dacron graft was used to circumvent the site of the previous infected false aneurysm.

There was no operative mortality and no limbs were lost. Of the 5 patients who had operations for false aneurysms resulting from previous arterial operations, 4 complained of intermittent claudication in the postoperative period, and 3 of these had been found at operation to be infected.

DISCUSSION

True postoperative aneurysms are comparatively rare in vascular practice and this group of 8 cases seen over a 9-year period agrees substantially with the numbers quoted in previous series (Tolstedt, Radke, and Bell, 1961; Bergan, Kaupp, and Trippel, 1969). Even in the largest reported series there were only 39 true atherosclerotic aneurysms out of a total of 150 peripheral aneurysms seen over an unstated period of time (Crawford, DeBakey, and Cooley, 1959). Multiple aneurysms are common in all the published reports and incidences ranging from 36 to 69 per cent are quoted (Pappas, Janes, Bernatz, and Schirger, 1964; Bergan and others, 1969). In the present small series only 2 patients had multiple aneurysms, 1 of these having no less than 4 aneurysms in the legs.

False aneurysms are also relatively rare, but this condition was much more common in the earlier published reports before it was realized that the use of absorbable sutures, woven grafts, and end-to-side anastomoses all contributed to the development of false aneurysms (Crawford, Edwards, DeBakey, Cooley, and Morris, 1961; Stoney, Albo, and Wylie, 1965; Sawyers, Jacobs, and Sutton, 1967; Spratt, Doran, and Baird, 1967).

Infection has also played a prominent part in the breakdown of graft anastomoses, and the incidence of such infected false aneurysms has been as much as one-third of the total numbers of the various reported series. By using non-absorbable sutures, knitted grafts, end-to-end anastomoses, and scrupulous aseptic technique it has, however, proved possible to reduce somewhat the incidence of infected false aneurysm formation, but 3 in the present series of 15 aneurysms resulted directly from dehiscence of an infected suture line.

Embolic episodes leading to peripheral gangrene are a well-recognized complication of untreated peripheral arterial aneurysms, and gangrene has been reported as occurring in over 50 per cent of patients in whom conservative treatment has been adopted (Crawford and others, 1959). No patient in these 15 cases suffered preoperative emboli resulting in limb death. Early treatment is, therefore, essential if this outcome is to be avoided.

Although the two standard methods of treatment by excision and either Dacron or autogenous vein replacement, or by-pass, were used, an alternative method of arterial reconstruction was used in 5 cases. This involved partial excision of the aneurysm with local endarterectomy and revision of the lumen to an appropriate size, the reconstruction of the artery being performed over a rubber catheter matched to fit the proximal vessel above the aneurysm. Although this procedure can be subjected to the criticism that under conditions of aneurysmal dilatation all the coats of the vessel wall are affected by the disease process, a substantial time has elapsed since these operations were performed and in no case has further arterial dilatation resulted. It is a simple surgical procedure under conditions where adequate substance remains following endarterectomy, and would appear to be preferable to the use of Dacron or an unsuitably small vein.

In 3 of the 4 cases in which treatment was not successful and the patients developed intermittent claudication postoperatively the aneurysms were infected preoperatively. This relationship between treatment, failure, and infection has been noted by others (Stoney and others, 1965; Sawyers and others, 1967; Spratt and others, 1967) and the presence of infection would seem to be an indication for 'radical and vigorous tratment, or complete avoidance of the infected area' (Sawyers and others, 1967) if treatment is to succeed.

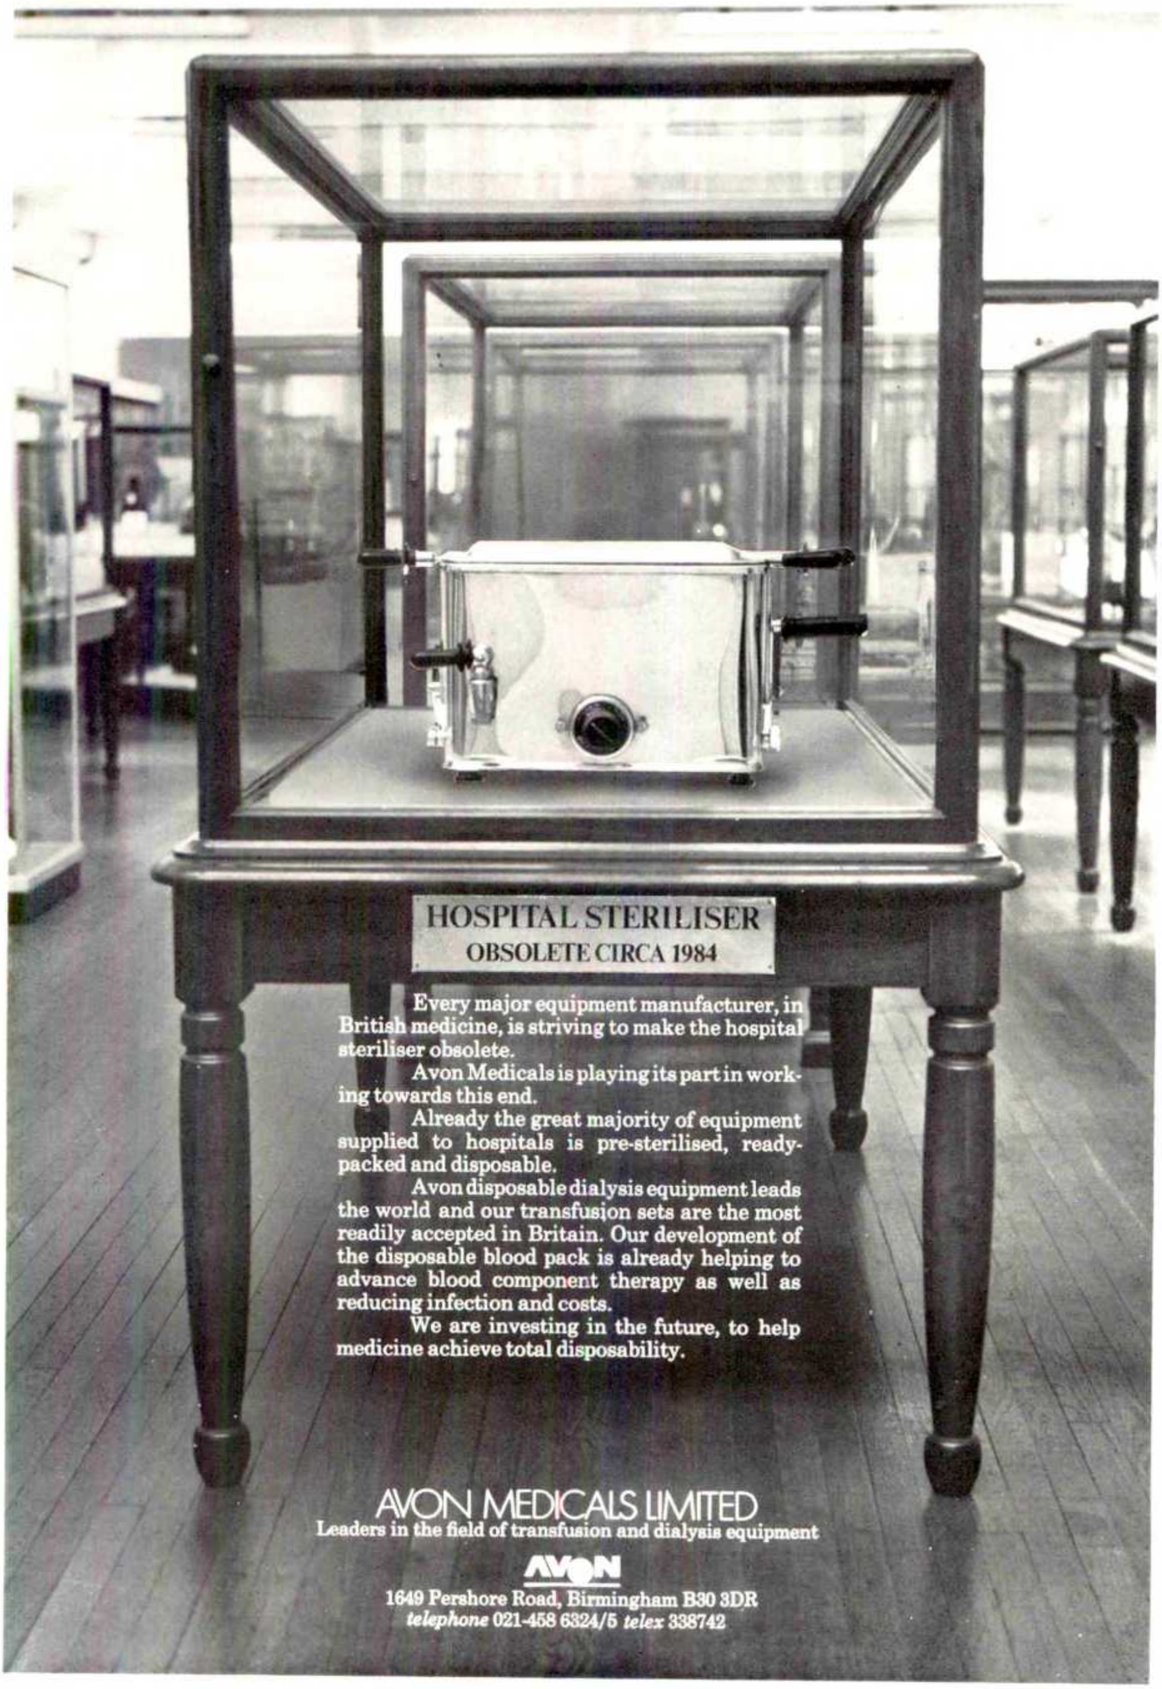
UBRETID®
distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, UBRETID will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.
Full details of UBRETID ampoules and tablets are available upon request.

BERK PHARMACEUTICALS LIMITED
GODALMING & SHALFORD, SURREY

® Regd. Trade Mark J.3959



Every major equipment manufacturer, in British medicine, is striving to make the hospital steriliser obsolete.

Avon Medicals is playing its part in working towards this end.

Already the great majority of equipment supplied to hospitals is pre-sterilised, ready-packed and disposable.

Avon disposable dialysis equipment leads the world and our transfusion sets are the most readily accepted in Britain. Our development of the disposable blood pack is already helping to advance blood component therapy as well as reducing infection and costs.

We are investing in the future, to help medicine achieve total disposability.

THE HISTOPATHOLOGY OF SMALL VESSELS FOLLOWING MICROVASCULAR REPAIR

BY THELMA J. BAXTER, B. McC. O'BRIEN, P. N. HENDERSON, AND R. C. BENNETT

DEPARTMENTS OF SURGERY (ST. VINCENT'S HOSPITAL) AND OPHTHALMOLOGY, UNIVERSITY OF MELBOURNE, AND THE PLASTIC SURGICAL UNIT, ST. VINCENT'S HOSPITAL

SUMMARY

1. The histopathological findings following microvascular repair of 105 arteries and 89 veins in English-strain rabbits are reported.

2. The importance of (*a*) the accurate apposition of the vessel walls and (*b*) the avoidance of excessive medial necrosis is stressed.

3. The process of subintimal hyperplasia is described and the importance of its role in the repair of small vessels is discussed. Previously, the new formation of elastin tissue has been considered pathognomonic of vascular disease.

4. The appreciably slower rate of repair in veins is also reported.

5. From these observations suggestions have been made with regard to improved technique of surgical repair.

SINCE 1967 various microvascular surgical techniques have been developed in the Departments of Surgery (St. Vincent's Hospital) and Ophthalmology of the University of Melbourne. As part of this programme femoral vessels of the rabbit and the dog have been sutured with the aid of a special operating microscope (O'Brien, 1970). Direct anastomoses of arteries and veins and reversed arterial and venous grafts have been undertaken. Precise details of the special microvascular techniques have been described previously (O'Brien, Henderson, Bennett, and Crock, 1970; O'Brien, Henderson, Baxter, and Miller, 1971). All the operative specimens were subsequently removed for examination. In the present paper our attention will be confined to reporting in detail the histopathological changes observed in the vessels of the rabbit following direct suture. The features of repair which occur during the healing process have been studied and an attempt has been made to delineate those factors which are important in determining the early and long-term patency of the vessels.

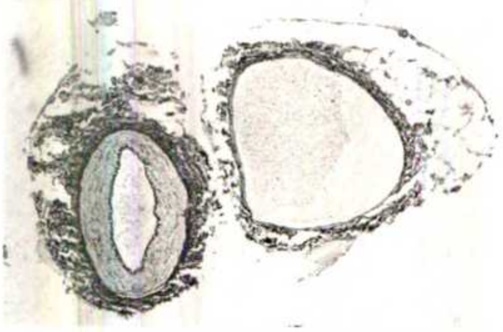

FIG. 1.—Transverse section of a normal femoral artery and vein of rabbit. Gomori aldehyde fuchsin (G.A.F.). (× 30.)

MATERIALS AND METHODS

This report is based upon histological examination of 105 arteries and 89 veins in English-strain rabbits, all of which had been repaired previously by direct suture. The vessels were measured with an ocular micrometer and their mean diameters were found to be 0·8 and 1·0 mm. respectively. The operative techniques and macroscopic assessment of the anastomoses of some of these vessels have already been reported (O'Brien and others, 1970). All the sutures used were of 0000000000 or metallized 28 μ nylon, interrupted, and inserted through the full thickness of the vessel wall. No attempt was made to strip the adventitia from the cut edges.

Excision biopsy of the anastomotic segments was performed at varying intervals following surgery until as late as the eighteenth postoperative week. The anastomoses were examined macroscopically and the histopathological features were studied by light and electron microscopy.

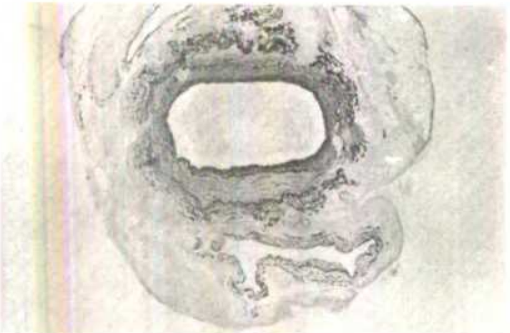

FIG. 2.—Transverse section of a patent artery and vein at the anastomosis, showing minimal subintimal hyperplasia in the artery. The vein is partly collapsed but patent, although the wall shows areas of necrosis (absence of internal elastic lamina and media) and a suture 'pull-through'. Biopsied 6 weeks after anastomosis. G.A.F. (× 30.)

The tissues were prepared by fixation in formol–saline (10 per cent) and serially sectioned (4 μ in thickness) proximal and distal to the lines of anastomosis. The sections were stained with haematoxylin and eosin, aldehyde fuchsin (Gomori, 1950), toluidine blue, and Verhoff Van Gieson.

Appropriate tissue was also selected for electron microscopy. The arterial segments were flushed with saline and fixed in 4 per cent buffered glutaraldehyde (approximately 4° C.) for 24 hours. Blocks of tissue from the level of the suture line and from regions proximal and distal to this were processed for transmission microscopy by post-fixing in chrome osmium (Dalton, 1955) and were embedded in Araldite. Sections were stained with lead citrate (Reynold, 1963) and uranyl acetate and viewed in a Siemens 1A electron microscope.

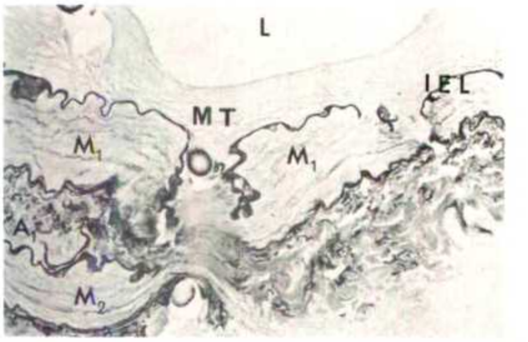

FIG. 3.—Transverse high-power section of an arterial wall at the anastomosis showing imperfect apposition of the cut vessel edges and the resultant tissue overlap. The media M_2 has been forced out of alinement with the media M_1 by excessive tension applied in tying of the suture. As a result the adventitia A_1 has been entrapped between the two layers of media M_1 and M_2. The necrotic tissue adjacent to the suture 'pull-through' is shown. The mural thrombus (MT) is seen between the lumen (L) and the ruptured internal elastic lamina (IEL). Biopsied 2 weeks after anastomosis. G.A.F. (× 240.)

RESULTS

Macroscopic Features.—Examination at the time of excision biopsy showed that 83 of 105 arteries (79 per cent) and 76 of the 89 veins (85 per cent) had remained patent. These findings were confirmed and an assessment of additional changes was made by microscopy.

Histopathological Features.—The histology of the normal femoral artery and vein of the rabbit is shown in *Fig.* 1. The following observations were made in both arteries and veins following suture. The arterial changes will be described first as these occurred earlier and to a more pronounced degree than those in the veins.

1. *Accuracy of Apposition of Cut Vessel Edges.*—In specimens with macroscopically patent anastomoses accurate apposition of all layers of the cut vessel edges had almost always been achieved (*Fig.* 2). However, even under these circumstances biopsies at 8–12 days showed coagulum between the opposing edges which was in continuity with a thin layer of mural thrombus which occupied the entire luminal perimeter. During the second week the thrombi underwent shrinkage and were invaded by smooth-muscle cells. Newly formed elastin fibrils and collagen fibres were also observed (*Fig.* 3). In addition during this period the luminal surfaces of the thrombi had become covered with endothelial cells.

Where accurate alinement of the cut vessel edges was not achieved more extensive thrombosis, either partial or complete, inevitably resulted. This was observed as early as 3 days postoperatively but may have occurred earlier. The mural tissue gaps were again filled by fibrinous coagulum which continued between the overlapping edges and became confluent with the luminal thrombus. Groups of fresh blood-cells were present in spaces which had developed within the luminal mass. After 7 days organization occurred by the ingrowth of small capillary loop from the adventitia at the cut edges and through suture perforations. Many fibroblasts were present throughout the thrombus and recanalization had commenced. However, when failure to achieve good apposition was accompanied by massive tissue disruption, especially when the media was extensively involved (*see below*), the resultant thrombus in the affected vessel segment failed to canalize for extensive periods, sometimes ranging from 8 to 18 weeks (*Figs.* 4, 5). In only 2 vessels, biopsied at 11 and 17 weeks respectively, were there small vessels containing medial tissue in their walls within the thrombi (*Fig.* 6).

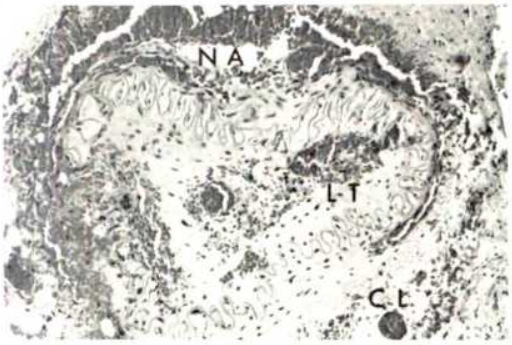

FIG. 4.—Transverse section of a thrombosed artery beyond the suture level showing blood-flow through spaces in the necrotic adventitia (NA) as well as through the luminal thrombus (LT). Small capillary loops (CL) are evident throughout the section. Biopsied 8 weeks after anastomosis. H. and E. (× 84.)

2. *Medial Disruption.*—The most important factors responsible for medial disruption were inaccurate apposition of the vessel edges (*Fig.* 3) and insertion of the sutures (*Fig.* 7). The number, placement, and tension of the sutures were all important as judged by the degree of tissue distortion. In some instances the sutures caused a scalloped or pinched effect in the wall (*Fig.* 8), whilst in others the suture pulled through the full thickness of the wall (*Fig.* 9). These necrotic pathways in the wall appeared to be due to excessive tension of the suture and frequently were associated with the failure of effective apposition of the cut edges.

The resultant associated cellular changes appeared to be of considerable significance in determining the degree of medial distortion. In the initial stages (up to 7 days) following vessel repair the sutures were surrounded by populations of cells of differing density in individual specimens, but consisting mainly of plump fibroblasts, smooth-muscle cells, and macrophages. These cells soon became less numerous, and after 14 days most of the sutures were surrounded by an area of hyaline necrosis (*Fig.* 9). However, in some specimens even at 4–8 weeks the cellularity was still more prominent than the associated necrosis. The amount of necrosis was greatest where there was suture crowding (*Fig.* 9) or where an excessive number of sutures had been inserted (*Fig.* 7). Under these circumstances the necrotic areas often became confluent and involved large areas of the vessel wall.

The extent of this mechanical disruption of the media largely determined its subsequent viability.

3. *Subintimal Hyperplasia.*—The degree of viability of the media appeared to be a critical factor in determining the success of the anastomoses (*Fig.* 2). Because the interrupted sutures traversed the full thickness of the wall at the anastomotic site the media was always penetrated and the continuity of the internal elastic lamina was invariably interrupted. Effective repair or reconstitution of these two components was only achieved by a hyperplastic response of the medial constituents, which response will be referred to as 'subintimal hyperplasia' (*Figs.* 2, 7, 10).

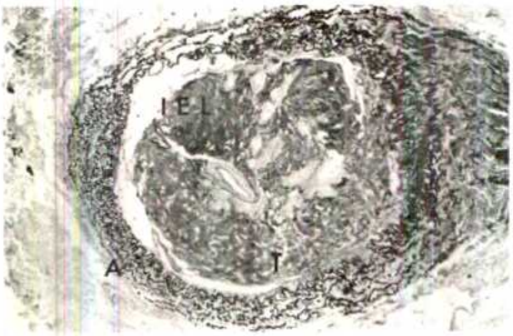

FIG. 5.—Transverse section of a thrombosed artery beyond the anastomotic site, showing small capillary loops and a developing vessel within a central thrombus (T). Small remnants of the old internal elastic lamina (IEL) are seen here. The original media is non-existent. The remaining tissue is adventitia (A) with its multilayered external elastic lamina. Biopsied 18 weeks after anastomosis. G.A.F. (× 72.)

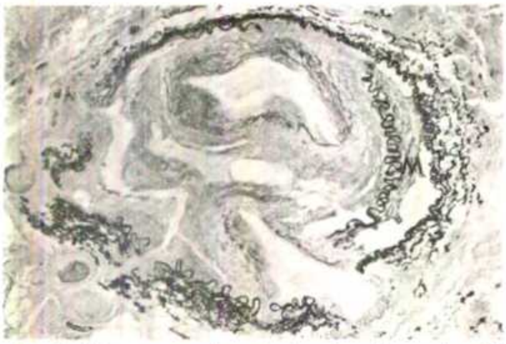

FIG. 6.—Transverse section of a thrombosed artery in which there is incorrect apposition of the cut vessel edges. Only a small amount of viable media (M) is present. Small vessels are forming within the thrombosed areas and the elastin fibrils of their developing media are clearly seen. Biopsied 17 weeks after anastomosis. G.A.F. (× 72.)

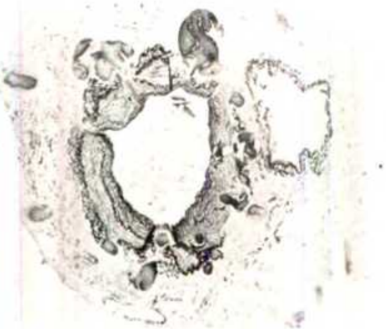

FIG. 7.—Transverse section of a patent artery and vein at the anastomosis showing uneven spacing of sutures in the artery as well as the 'pinched' appearance resulting from excessive suture tension. Subintimal hyperplasia is prominent. The vein, although patent, is collapsed and has a partly necrotic and broken wall. Biopsied 6 weeks after anastomosis. G.A.F. (× 30.)

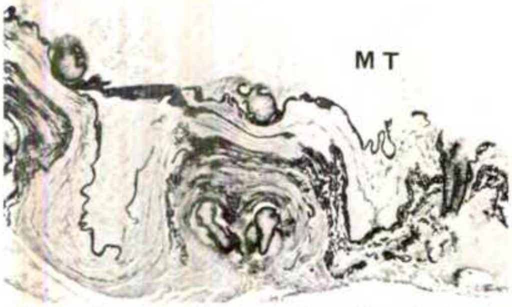

FIG. 8.—Transverse high-power section of the wall of a patent artery at the anastomosis, showing a mural thrombus (MT) and disruption of the arterial wall by the insertion of sutures, the tension of which has resulted in a 'scalloped' effect. Biopsied 1 week after anastomosis. G.A.F. (× 240.)

The speed and effectiveness of this restoration were directly dependent on the amount of surviving media following anastomosis. If at least one-third of the media was not viable the hyperplasia did not occur and invariably the vessel segment became thrombosed (*Fig.* 5). In the arteries which had thrombosed completely at the suture line viable media was not present and subintimal hyperplasia was never observed. On rare occasions, however, examination approximately 300 μ on either side of the thrombosed region showed subintimal hyperplasia in the patent segments where the media was not significantly damaged.

As early as 1 week in a patent vessel with a circumferential mural thrombus the luminal edge was already covered by immature endothelial cells. Medial cells, fibroblasts, elastin fibrils, and collagen fibres were present in the mural thrombus, the cells entering via the breaks in the internal elastic lamina. The cell population then consisted of longitudinally orientated smooth-muscle cells and fibroblasts. Fine elastin fibrils were recognizable with the Gomori stain (*Fig.* 3). Electron microscopy showed that the elastin elements first appeared as isolated clumps or as long microfibrils, 100–150 Å in diameter, in close proximity to smooth-muscle cells. Between 2 and 4 weeks the smooth-muscle cells gradually became more numerous than the fibroblasts and the elastin fibrils stained progressively more densely. The cells and fibrils spread circumferentially as well as along the vessel for varying distances (from 250 to 320 μ) to either side of the suture level. Simultaneously the fibrils became more concentrated immediately beneath the endothelium.

From 4 to 6 weeks the fibrils had usually reached a sufficient density to form a new internal elastic lamina. This was confirmed by electron microscopy which showed that the elastin clumps had coalesced to form elastic lamellae surrounded by typical peripheral microfibrils (*Fig.* 11). The new internal elastic membrane varied from 2 to 2·5 μ in width. The remnants of the original broken internal elastic membrane were always clearly visible (*Fig.* 7) and newly formed fibrils were more numerous where the breaks were widest.

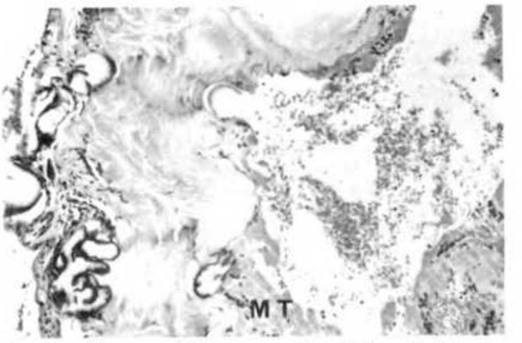

FIG. 9.—Transverse high-power section of the wall of a patent artery at the anastomosis, showing a mural thrombus (MT) as well as the suture crowding. As a result the hyaline areas of necrosis associated with the sutures have become confluent. Note the suture 'pull-through'. Biopsied 1 week after anastomosis. H. and E. (× 240.)

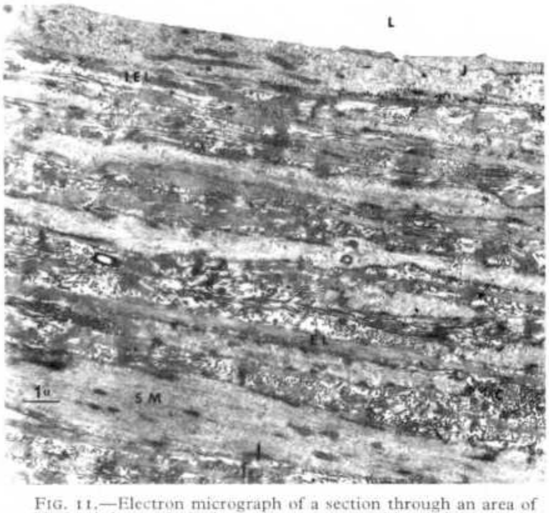

FIG. 11.—Electron micrograph of a section through an area of subintimal hyperplasia in a patent artery, biopsied 17 weeks after anastomosis. Beneath the lumen (L) is the endothelium with a tight junction (J) and several layers of longitudinally orientated smooth-muscle cells (SM), and newly formed elastic lamellae (EL), and collagen (C). A new internal elastic lamina (IEL) is seen deep to the endothelium.

In some vessels subintimal hyperplasia was not evenly distributed around the circumference and showed a higher concentration of the medial components at points where the disruption of the internal elastic lamina was greatest. Hyperplasia was occasionally more disorderly, forming papillary projections which encroached on the lumen, greatly reducing its internal diameter (*Fig.* 12.) Occasionally these papillae resulted in an interlacing meshwork so that the lumen of the vessel was divided into three or four separate channels, without any evidence of pre-existent thrombosis.

4. *Adventitial Damage.*—In addition to the trauma produced by the division of the artery prior to anastomosis, adventitial damage was caused by the insertion of sutures and the use of arterial clamps. No histological evidence was observed to suggest that adventitia was pulled into the lumen between the cut edges or along suture tracks.

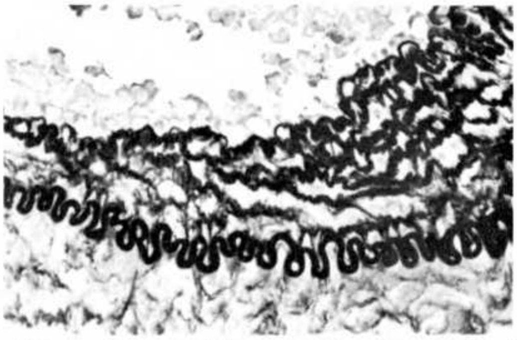

FIG. 10.—Transverse high-power section of an arterial wall, showing the high content of elastin in the subintimal hyperplasia and the 'condensation' of the fibrils at the luminal edge to form a new internal elastic lamina. This artery was sutured without cutting in order to observe the effect of sutures alone on the arterial wall. Biopsied 13 weeks after the placement of the sutures. G.A.F. (× 600.)

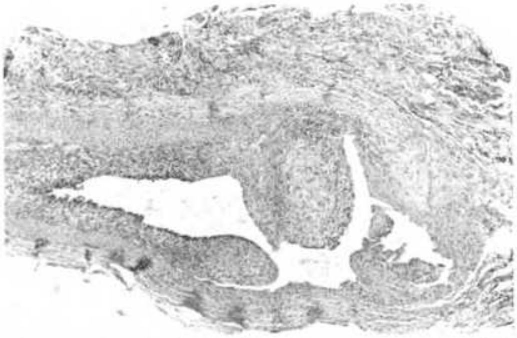

FIG. 12.—Longitudinal section of a patent artery beyond the anastomosis, showing disordered subintimal hyperplasia. This has resulted in papillary projections with considerable reduction of the lumen. Biopsied 2 weeks after anastomosis. H. and E. (× 48.)

To determine the effect of clamping on the vessel wall one artery was clamped for 1 hour without cutting and biopsied 1 week later. This vessel showed some degree of adventitial disruption and necrosis, and a small portion of the internal elastic lamina was reduplicated (*Fig.* 13), though the media appeared undamaged. At 7 days small capillary loops and many fibroblasts were observed entering the damaged adventitia to organize the necrotic areas. In the anastomosed arteries biopsies at 4–8 weeks usually showed the organization to be complete. However, where the damaged areas were extensive repair was often considerably slower.

Veins.—On the whole, repair following venous anastomosis proceeded along similar lines to that of arterial repair, with the same four factors being of prime importance. However, certain differences have been noted. These included:—

1. Accuracy of apposition of the vessel edges seemed to be more important with veins than with

arteries. Thrombosed veins which were biopsied after an interval of 1 week showed failure to achieve good apposition in every specimen.

2. Although the venous wall frequently appeared to be almost completely necrotic the vessel remained patent (*Fig.* 7).

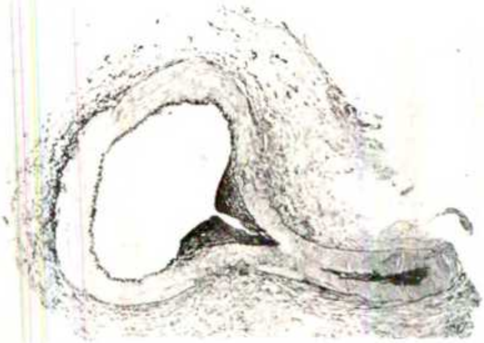

FIG. 13.—Transverse section of an artery (cut obliquely at one end) biopsied 1 week after clamping alone for 1 hour. Note the extensive adventitial damage and the subintimal hyperplasia where the internal elastic lamina has been disrupted. G.A.F. (× 48.)

3. Most veins exhibited some degree of narrowing. However, this did not appear to affect to any significant degree their ultimate patency (*Fig.* 2).

4. The rate of repair was appreciably slower. Endothelization of the mural thrombi was not evident until 4–6 weeks. Subintimal hyperplasia occurred subsequent to this time but was much less prominent than in arteries, consistent with the relatively small medial component in vein walls.

DISCUSSION

Although successful anastomosis of large blood-vessels has been possible for many years it is only recently that serious attempts have been made to overcome the problems associated with the repair of small vessels, particularly those with diameters in the region of 1 mm. Early work in this field was performed using relatively simple techniques and unsophisticated equipment (Seidenberg, Hurwitt, and Carton, 1958; Jacobson and Suarez, 1960). More recently a number of workers have become keenly interested in microvascular surgery because of the wide range of surgical applications which are made possible by the development of successful techniques (Krizek, Tani, Desprez, and Kiehn, 1965; Buncke, Daniller, Schulz, and Chase, 1967). More sophisticated equipment has been developed to provide for better magnification (O'Brien, 1970), suture material (O'Brien, Henderson, and Crock, 1970), and operative aids (Henderson, O'Brien, and Parel, 1970; Henderson, Pericic, and O'Brien, 1970). However, despite these advances if anastomoses of fine-bore vessels are to prove successful careful consideration must be given to the following points:—

1. The nature of the changes in the vessel walls subsequent to a technically successful anastomosis and the relevance of these changes to stenosis and occlusion.

2. The prevention of thrombosis produced by the action of platelets and related factors.

It has been the aim of this investigation to study the first of these important points by a careful histopathological examination of the sutured vessels. A number of pertinent factors have emerged.

It has been shown that the first requirement for successful anastomosis is correct apposition of the cut vessel edges. Repair then proceeds with the organization of both the coagulum between the cut vessel edges and the mural thrombi. Concurrently the thrombotic surfaces are endothelized by the proliferation of the intimal cells.

Organization is dependent upon medial activity and the findings demonstrate that minimal medial damage is the most important single entity concerned in successful vessel repair. It can be seen from the sequence of the histopathological processes that even with the most careful surgical techniques the vessel tissues suffer appreciable disruption.

It is worth re-emphasizing that correct apposition of the cut vessel edges is one of the most important factors in the prevention of thrombosis during the first week following anastomosis. Mural thrombi which cover the cut vessel edges are minimal where tissue overlap is avoided. Inaccurate apposition is more frequently associated with thrombosis in veins than in arteries, and this finding is probably related to the relative delicacy of the vein wall. The placing of the sutures and the tension with which they are tied must certainly be important factors in successful apposition.

In this series endothelium had commenced to grow over the luminal edges of the mural thrombi in the arteries at 8–12 days, but was not seen earlier than 4 weeks in the venous anastomoses. Other accounts of endothelial restoration during arterial repair vary considerably both with respect to rapidity and cellular origin. Times generally varied between 24 hours (Buck, 1961) and 2 weeks (Murray, Schrodt, and Berg, 1966). However, Poole, Sanders, and Florey (1958) reported that intimal lesions in the rabbit aorta were still not completely healed after 33 weeks. The two principal suggestions as to the origin of the new endothelial cells are (*a*) the intimal surface is restored by growth of the undamaged endothelial cells at the edges of the lesion, spreading into and covering the denuded area (Poole, Sanders, and Florey, 1959), and (*b*) the continuity of the luminal cells is restored by circulating mononuclear cells (Ghani and Tibbs, 1962). Alternative propositions are based on the fact that these early lining cells closely resemble macrophages (Buck, 1961) or smooth-muscle cells (Nomura, 1970). Zweifach (1959) adds further confusion to the problem by suggesting that cells possess diverse potentialities which vary with their particular location in the vascular system. In the present material the new endothelium appeared to arise and spread from the multiplication of the endothelial cells adjacent to the cut edges.

We regard the media as the most important mural component in the repair of small vessels. The medial reaction is comprised of hyperplasia of the cells and the production of elastin fibrils which reconstitute an internal elastic lamina. These processes are essential for successful repair. The term 'subintimal hyperplasia' is preferred to distinguish the process from any response which is of intimal or endothelial origin.

The hyperplasia is certainly medial in origin and when the formation of the new internal elastic lamina is complete both the cellular and the extracellular components are restored to a position beneath the intima.

At the end of 1 week the hyperplasia was well established, medial cells and elastin fibrils being conspicuous in the mural thrombi. These hyperplastic cells migrate through breaks in the internal elastic membrane and subsequently produce delicate elastin fibrils. The fibrils become more closely apposed and 'condense' beneath the endothelium, finally resulting in the production of a new elastic lamina. This medial response is proportional to the degree of tissue damage, provided always that medial disruption is not excessive. Hyperplasia was maximal where the discontinuity of the internal elastic lamina was greatest. These cells have been described as altered smooth-muscle cells, and by Buck (1961) as 'smooth-muscle cells which had undergone varying degrees of dedifferentiation'. Previous workers have reported the cellular proliferation as commencing at 10–14 days (Buck, 1961; Murray and others, 1966; Davies, Woolf, and Bradley, 1969), but only Buck referred to the production of elastin during this period.

Bunting (1939) put forward the view that if developing connective tissue was constantly subjected to 'alterations of tension and relaxation' elastic tissue formation would result. He based this conclusion on the dense elastic tissue observed in scars following myocardial infarction and in pleural adhesions. The work of Williams (1970) supported this concept. Following intimal damage of rabbit aortae Friedman and Byers (1965) observed that while transverse lacerations produced marked hyperplasia, longitudinal lacerations produced relatively slight cellular response. Bjorkerud (1969) attributed this difference to the fact that transverse lacerations were subjected to greater haemodynamic stress.

Murray and others (1966) were appreciative of the role of smooth-muscle cells in the reparative process, but the importance of elastin production appears to have been overlooked because previously new elastin production had been associated exclusively with vascular disease. Dible (1966) correctly observed that the term 'splitting' of the original internal elastic lamina inaccurately described the 'hypertrophied elastotic intima' because this was actually composed of newly formed elastica.

Our studies show subintimal hyperplasia to be part of the repair process and indeed that its occurrence is unavoidable. Furthermore, considerable disruption of the internal elastic lamina and media leads to excessive hyperplasia, which may result in either stenosis or subdivision of the vessel lumen. It is, therefore, obviously desirable to limit this response by avoidance of excessive damage to the above structures. This is best achieved by gentle handling, fine needles and suture material, restricting the number of sutures, and the careful adjustment of tension when the sutures are tied. The nature and strength of the arterial clamps are also of obvious importance and the time of their application should be limited.

These objectives are most likely to be achieved with adequate magnification and appropriate instrumentation.

Acknowledgements.—We are indebted to Dr. B. Oakes of the Anatomy Department, Monash University, for the valuable information resulting from his electron microscopic examination of some of the material. Gratitude is expressed to the following members of the Pathology Department, University of Melbourne: Professor G. S. Christie for advice in the early days of incertitude, to the late Mr. J. Blake and Mr. D. Cahill for their untiring technical assistance, and to Mr. J. Smith for the photography. We are also most appreciative of the skilled, patient, and very willing assistance of the staff of the Surgical Research Theatre, St. Vincent's Hospital, Melbourne.

We gratefully acknowledge the financial assistance from the following bodies which enabled this work to be undertaken and further developments in this field to proceed: National Health and Medical Research Council of Australia, Ian Potter Foundation, Felton Bequest, Buckland Foundation, William Angliss Charitable Fund, St. Vincent's Hospital, and St. Vincent's School of Medical Research.

THE INCIDENCE OF RIGHT INGUINAL HERNIA FOLLOWING APPENDICECTOMY

By PETER LEECH, GORDON WADDELL, and ROBERT G. MAIN
SURGICAL UNIT, ROYAL INFIRMARY, FALKIRK

SUMMARY

A retrospective study of 549 patients who had undergone repair of an inguinal hernia is presented. It is noted that appendicectomy does not predispose to the development of a right inguinal hernia.

It has long been a clinical impression that the muscle-splitting incision in the right iliac fossa, commonly used for appendicectomy, renders the patient prone to develop an inguinal hernia on the right side (Aird, 1958) as a consequence of nerve and muscle damage weakening the inguinal canal. The purpose of the present study was to examine this relationship and to produce some statistical evidence either to refute or to confirm this hypothesis.

MATERIALS AND METHODS

The case records of 549 patients who had undergone inguinal hernia repair at Falkirk and District Royal Infirmary during the period 1967–9 were examined, referring particularly to a past history of appendicectomy performed through a right iliac fossa muscle-splitting incision or the presence of an appendicectomy scar.

Table I.—Incidence of Inguinal Hernia following Appendicectomy

	Right Side	*Left Side*
Total No. of inguinal hernia cases	301	248
No. with a previous appendicectomy	27	28
Percentage incidence ± 1 standard deviation	8·9 ± 1·7	11·2 ± 2·1

Among those who had undergone appendicectomy the number of cases coming to right inguinal hernia repair was noted, and as a control series the patients undergoing left inguinal hernia repair were documented. Cases being submitted to bilateral hernia repair were included in both the test and the control groups. No attempt was made to distinguish between direct and indirect herniae. Congenital herniae were discounted.

RESULTS

The results are summarized in *Table I.*

DISCUSSION

Lichtenstein and Isoe (1951) reviewed 576 patients with an inguinal hernia and found that a right-sided lesion was approximately twice as common following appendicectomy as was a hernia on the left side—clearly a significant relationship.

Cox (1961), describing a series of 252 cases of inguinal hernia, found that 12·4 per cent of right-sided hernia sufferers had previously undergone appendicectomy, compared with only 7·1 per cent of cases on the left side. In a statistical exercise, however, he concludes that these results do not support a relationship between right inguinal hernia and appendicectomy.

Scott (1960), in a study of 196 cases of inguinal hernia repair, was unable to establish a cause-and-effect relationship.

In the current study there was no statistical difference between the number of post-appendicectomy cases coming to right inguinal hernia repair and the number undergoing left-sided repair.

Clearly the limitation of a retrospective study of this nature is the inability to differentiate accurately between an uncomplicated appendicectomy and one which involves sepsis, drainage of the peritoneal cavity, and prolonged wound healing.

Taking the current study in combination with those of Scott (1960) and Cox (1961) it appears that there has been no evidence published since the review in 1951 of Lichtenstein and Isoe to support the belief that right inguinal hernia is a complication of appendicectomy.

It remains to explain why this relationship, noted by eminent observers in the past, has not held true. One possible explanation is that the advent of antibiotics has made appendicectomy a less infected procedure with quicker wound healing and fewer local long-term complications.

VENTILATION IN AN ARTIFICALLY PRODUCED GAS CAVITY UNDER BASAL CONDITIONS

By LADE WOSORNU*

DEPARTMENT OF EXPERIMENTAL SURGERY, ROYAL POSTGRADUATE MEDICAL SCHOOL, HAMMERSMITH HOSPITAL, LONDON

SUMMARY

The left hemithoraxes of 150 SPF rats were transformed into stable skin-lined gas cavities which were opened to the exterior. Fifty-nine of 75 rats so exposed survived with the natural, unilateral lung receiving air from the trachea, and the skin-lined hemithorax (an artificially produced gas cavity) receiving air independently from a thoracostomy.

In the test rats the mean arterial *p*H, Po_2, and Pco_2 were 7·355 ± 0·17, 77·03 ± 2·56 mm. Hg, and 38·41 ± 2·41 mm. Hg respectively. The values were similar to those obtained for unoperated rats (7·349 ± 0·015, 80·18 ± 2·77 mm. Hg, and 38·24 ± 0·94 mm. Hg). Although the skin-lined hemithorax was functionally an open-ventilated gas cavity, its mean tidal volume (0·93 ± 0·07 ml.) and its mean minute-ventilation (271·6 ± 24·4 ml. per kg. per minute) were about half of normal.

In the test rats the mean rate of respiration and the mean tidal volume were 98·5 ± 4·3 per minute and 1·68 ± 0·04 ml. as compared with 76·1 ± 5·3 per minute and 1·94 ± 0·12 ml. in the unoperated rats. The differences were significant. However, the difference between the mean minute-ventilation (tidal volume × rate of respiration) in the two groups was not significant. The values obtained were 506·1 ± 36·2 ml. per kg. per minute (test rats) and 407·0 ± 50·4 ml. per kg. per minute (unoperated rats). This suggested further that under basal conditions the test rats achieved adequate ventilation by means of a compensatory rise in the rate of respiration.

BODELL, Head, Head, and Formolo (1965) have shown that it is feasible to implant prosthetic lungs, but their experiments were short-lived. Peirce (1966, 1967) described an implantable prosthetic lung which permanently occupied the pleural cavity and received its gas as air from the trachea as a result of natural breathing. Such a concept, however, presents many unsolved problems and the experiments described here have been performed in an attempt to provide possible solutions to two of them.

First, there was the difficulty of making the pleural cavity equal to the task of housing a functioning foreign body such as an implantable prosthetic lung. As a possible solution an experimental model has been produced in which the left hemithorax of SPF rats was lined with skin-grafts and opened to the exterior (Wosornu and Melrose, 1971).

Secondly, the route by which the prosthetic lung could receive air remained to be established. Peirce (1966) had suggested that the prosthetic lung might receive air from the trachea. However, such an arrangement would pose difficulties related to the different compliances and airway resistance of the natural lung and the contralateral implanted lung. Hugh-Jones, Macarthur, Cullum, Mason, Crosbie, Hutchison, Winterton, Smith, Mason, and Smith (1971) have emphasized the imbalance between the distribution of gas and blood as an important cause of early respiratory failure in lung transplantation.

It was thought that these difficulties could be circumvented if the two halves of the thorax were so partitioned that they functioned as separate ventilating chambers with the normal unilateral lung receiving air from the trachea and the prosthetic lung receiving air from a separate opening directly through the chest wall.

The experiments described here sought to explore and to quantify such a possibility. Ventilation in the skin-lined hemithorax in rats was measured and compared with ventilation in the unilateral lung on the opposite side. The arterial *p*H, Po_2, and Pco_2 of the test rats were also measured and compared with those of unoperated rats.

MATERIALS AND METHODS

Male albino SPF rats (purchased from Carworth, Huntingdon, England) were used. Their mean initial weight was 240 ± 30 g. They were kept under standard laboratory conditions in large cages which housed 5 rats each. A total of 150 rats had successful intrapleural skin-grafting; 132 survived the next 4 weeks or more. In 75 of these rats the skin-lined hemithorax was opened to the exterior and sutured to the skin. In this way an open artificially produced gas cavity was obtained in which the left hemithorax had been transformed into a skin-lined cavity bearing a skin-to-skin stoma directly through the chest wall. Fifty-nine of the 75 rats thus exposed survived. Details of the technique employed to prepare the experimental model have been described elsewhere (Wosornu, 1972).

OBSERVATIONS ON THE SKIN-LINED HEMITHORAX 24 HOURS AFTER THE CREATION OF THE PERMANENT STOMA

1. **Radiographic Demonstration.**—The rats were screened radiographically after the creation of the permanent stoma. (It was observed that there was no paradoxical respiration.) Chest radiographs were taken. Forty consecutive preparations were studied as follows:—

2. **Arterial *p*H, Po_2, and Pco_2** were measured with a Radiometer Type BMS/3. Blood-samples were obtained from the exposed abdominal aorta of 10 test rats and 10 unoperated SPF rats as controls. The rats were anaesthetized with intraperitoneal sodium pentobarbitone (2 mg. per 100 g.), and 2–3 ml. of blood were withdrawn slowly with a heparinized

---

* Present address: Ghana Medical School, P.O. Box 4236, Accra.

syringe, care being taken to exclude air-bubbles; the estimations were made immediately afterwards.

3. Measurements of Ventilation.—The minute-ventilation in the unilateral lung and in the skin-lined hemithorax was measured separately. Thirty test rats (mean weight 356·8 ± 20·1 g.) and 12 unoperated SPF rats (mean weight 394·3 ± 40·4 g.) as controls were used. A miniature Krogh spirometer filled with room air was employed; the maximum capacity of the air chamber was 25 ml. The output signal from the spirometer, a displacement transducer, was passed through a transducer converter into a direct current amplifier (Type SE 905) and recorded on an ultra-violet recorder (Type SE 3005).

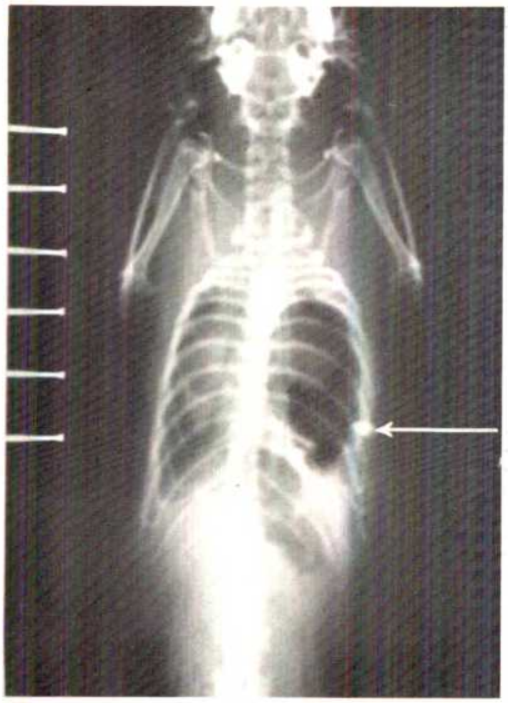

FIG. 1.—Radiograph of a test rat. The left hemithorax has been lined fully with skin-grafts and opened to the exterior to give the artificially produced gas cavity shown by the arrow. The markers, 1 cm. apart, were placed on the right-hand side.

TRACHEOSTOMY

The rats were anaesthetized with intraperitoneal pentobarbitone (2 mg. per 100 g.). A vertical midline skin incision was made in front of the neck, the trachea was exposed, delivered into the wound, and cannulated with a 3-cm. metal cannula (14 gauge) which was tied firmly in position. The stoma in the chest wall was fitted with a 3-cm. nylon connexion piece (internal diameter = 3·5 mm.); tissue glue was employed to obtain an airtight fit.

Before the tidal air was recorded the rats were allowed about 5 minutes to adapt to the tracheal cannula. The tidal air of the skin-lined hemithorax was recorded first. Recordings from the tracheal cannula were made continuously for about 45 seconds only because the system was closed and contained no agent to remove carbon dioxide. Three separate readings were made and the mean was accepted as the tidal air and rate of respiration.

RESULTS

Fig. 1 shows the radiograph of a test rat. The means of the arterial *p*H, Po_2, and Pco_2 of the test rats were similar to those of the unoperated rats (*Table I*).

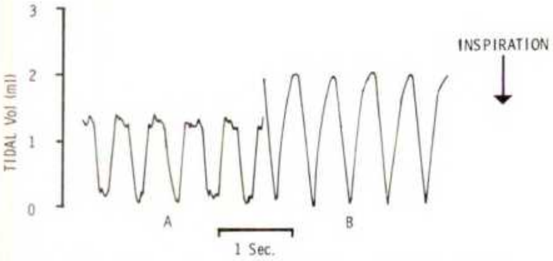

FIG. 2.—Tidal volumes recorded after the skin-lined pleural cavity had been opened to the atmosphere for 24 hours. A, Tracing from stoma in the chest wall. The stoma was created 4 weeks after intrapleural skin-grafting. B, Tracing from trachea of the same rat (280 g.).

Table I.—COMPARISON BETWEEN ARTERIAL *p*H, Po_2, AND Pco_2 IN UNOPERATED RATS AND IN TEST RATS

	*p*H	Po_2 (mm. Hg)	Pco_2 (mm. Hg)
Unoperated rats (10)	7·349 ± 0·015	80·18 ± 2·77	38·24 ± 0·94
Test rats (10)	7·355 ± 0·17	77·03 ± 2·65	38·41 ± 2·41
Statistical analyses (d.f. = 18)			
t	0·258	0·822	0·066
P	0·799†	0·433†	0·948†

† Not significant.

Values in the tables are given as the mean ± S.E.

Table II.—COMPARISON BETWEEN VENTILATION IN THE NATURAL UNILATERAL LUNG AND IN THE SKIN-LINED HEMITHORAX

	TIDAL VOLUME (ml.)	MINUTE-VENTILATION (ml. per kg. per minute)
Natural unilateral lung	1·68 ± 0·04	506·1 ± 36·2
Skin-lined hemithorax	0·93 ± 0·06	271·6 ± 24·4
Statistical analyses (d.f. = 29)		
t	10·6	8·98
P	< 0·001*	< 0·001*

* Significant.

$N = 30$; mean body-weight = 356·8 g.; mean rate of respiration = 98·5 per minute.

Functionally the skin-lined hemithorax was an open ventilated gas cavity (*Fig.* 2). The two ventilation variables measured were tidal volume and rate of respiration, and from the results the minute-ventilation per kg. body-weight was calculated. The three sets of values obtained were compared as follows: ventilation in the skin-lined hemithorax was compared with that in the natural unilateral lung, which in turn was compared with the ventilation of the unoperated rats.

In the test rats the mean tidal volume in the normal unilateral lung was 1·7 ± 0·04 ml. as compared with 0·9 ± 0·07 ml. in the skin-lined hemithorax. The respective minute-ventilations (tidal volume × rate of respiration) were 506·1 ± 36·2 and 271·6 ± 24·4 ml. per kg. per minute; the differences were significant (*Table II*).

Table III.—COMPARISON BETWEEN VENTILATION IN UNOPERATED RATS AND IN THE NATURAL UNILATERAL LUNG OF THE TEST RATS

	RATE OF RESPIRATION (per minute)	TIDAL VOLUME (ml.)	WEIGHT (g.)	MINUTE-VENTILATION (ml. per kg. per minute)
Unoperated rats (12)	76·1 ± 5·3	1·94 ± 0·12	394·3 ± 40·44	407·0 ± 50·4
Natural unilateral lung in test rats (30)	98·5 ± 4·3	1·68 ± 0·04	356·8 ± 20·11	506·1 ± 36·2
Statistical analyses (d.f. 40)				
t	2·96	2·59	0·923	1·51
P	0·005*	0·013*	0·361†	0·139†

* Significant. † Not significant.

The rate of respiration in the unoperated rats was 76 per minute as compared with 98·5 per minute in the test rats, and their respective tidal volumes were 1·9 and 1·7 ml. The differences were significant (*Table III*). However, the minute-ventilation in the unoperated rats (407·0 ± 50·5 ml. per kg. per minute) was not significantly different from the value obtained for the normal unilateral lung in the test rats (506·1 ± 36·2 ml. per kg. per minute) (*Table III*).

DISCUSSION

It has been possible anatomically to exteriorize the pleural cavity by relining it with skin-grafts (Wosornu, 1972). The next thing to consider was the function of the artificial gas cavity thus obtained. All normally or pathologically occurring or artificially produced gas cavities in the body may be divided into four functional types: closed non-collapsible, closed collapsible, open non-ventilated, and open ventilated gas cavities (Piiper, 1965). For example, whereas the normal paranasal air sinuses are open non-ventilated gas cavities the normal lungs are open ventilated gas cavities.

In the rats with a skin-lined hemithorax the two halves of the chest functioned as separate, open, ventilated gas cavities in phase. The natural unilateral lung received air normally through the trachea and the skin-lined hemithorax received air from an independent opening directly through the chest wall. However, the tidal volume and minute-ventilation in the skin-lined hemithorax were about half of normal.

In this investigation the values obtained for the mean tidal volume (1·9 ml.) and the mean rate of respiration (76 per minute) for the unoperated rats agreed closely with the mean values reported by others (Crosfill and Widdicombe, 1961; King, 1966; Binns, Clark, and Healey, 1971; McIntyre, 1971). Therefore, the values obtained for the test rats might be compared with those for the unoperated rats, since the experimental conditions were identical.

The test rats breathed significantly more rapidly than the unoperated rats ($P < 0{\cdot}005$) and there was also a significant difference between their tidal volume ($P < 0{\cdot}01$). However, there was no significant difference between their minute-ventilations ($P = 0{\cdot}1$; *Table III*). This suggested that the test rats achieved adequate ventilation by means of a compensatory increase in the rate of respiration.

King and Bell (1966) found that the mean arterial oxygenation in 35 normal SPF rats was 89·3 ± 2·9 S.D. and they commented also on the difficulty in obtaining arterial blood-samples from unanaesthetized rats. In the present study the test rats maintained normal arterial *p*H, Po_2, and Pco_2, which is a further indication that, under basal conditions, their respiration was adequate.

Acknowledgements.—I am grateful to Professor D. G. Melrose for directing the project, to Mrs. J. Beckett, Mr. E. Williams, and Dr. B. J. B. Grant for technical assistance, to Dr. J. M. B. Hughes for lending his Krogh spirometer, and to Mr. Clark for the drawing.

POST-ANGIOGRAPHIC VERTEBRAL ARTERIOVENOUS FISTULAE

By VIRA SANGRUCHI,* EDWARD HITCHCOCK, AND A. A. DONALDSON

DEPARTMENT OF SURGICAL NEUROLOGY, WESTERN GENERAL HOSPITAL, EDINBURGH

SUMMARY

Four cases of arteriovenous fistula of the high cervical vertebral artery are presented as a complication of direct puncture of the vertebral artery using the lateral atlanto-occipital approach. One case is reported in detail. The management of such cases is discussed together with a brief review of the literature.

THE listed causes of arteriovenous fistula of the vertebral artery and veins are congenital or spontaneous (Ehrlich, Carley, and Kitrinos, 1938; Gooddy and Schechter, 1960; Svolos, Nomikis, and Tzouliadis, 1965; Markham, 1969), traumatic (Svolos and others, 1965), and as a complication of direct percutaneous puncture of the common carotid artery and the vertebral artery itself. This complication is very rare and has only been reported in a few cases. The literature reveals no previously reported case following vertebral artery puncture via the lateral atlanto-occipital route (Maslowski method) although Maslowski (1955) mentions this complication without providing details.

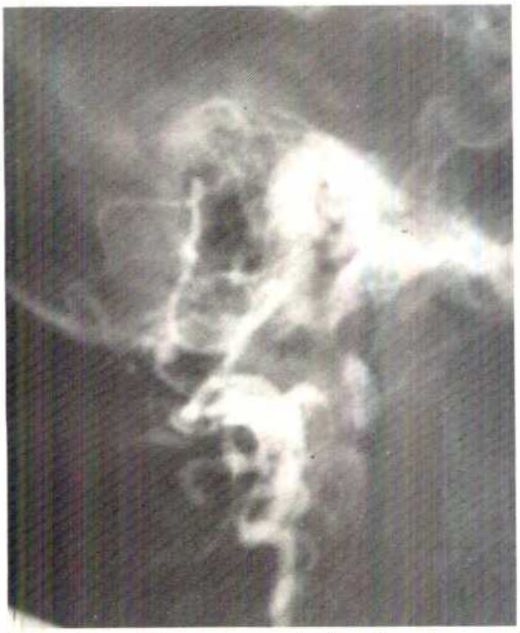

FIG. 1.—*Case* 1. The arteriovenous fistula of the right vertebral artery on 7 March, 1967.

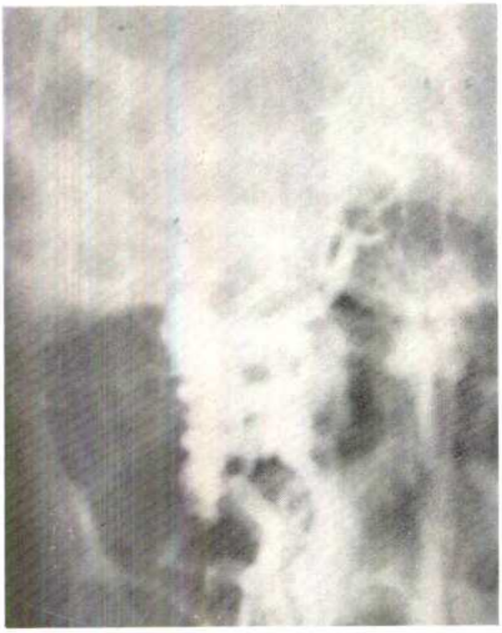

FIG. 2.—*Case* 1. The arteriovenous fistula of the right vertebral artery on 26 April, 1967, showing a larger venous drainage than before.

CASE REPORTS

Case 1.—The patient, a 42-year-old nurse, had been admitted previously with subarachnoid haemorrhage, and bilateral common carotid and bilateral vertebral angiography had revealed no definite lesion. Four weeks later she began to complain of noises in her head and was readmitted. A loud systolic bruit was audible over the right mastoid region. Percutaneous retrograde right brachial angiography on 7 March, 1967, showed an arteriovenous fistula of the right vertebral artery and the vertebral venous plexus in the region of the atlas at the site of puncture (*Fig.* 1). Following this procedure the noise became quieter and it was decided to defer surgery in the hope that the fistula would close by itself. A month later the patient returned complaining of dizziness and headache, whilst the noise in her head had been getting worse. Examination at that time showed no evidence of cardiac decompensation or enlargement, the pulse was 100 per minute and regular, and the blood-pressure was 120/80 mm. Hg. Neurological examination was normal apart from occasional nystagmus on looking to the right. There was a marked systolic bruit with a diastolic hum in the region of the mastoid. On 26 April a repeat percutaneous retrograde right brachial angiogram confirmed the existence of the fistula with, if anything, a larger venous drainage than before (*Fig.* 2). The bruit remained unchanged.

On 28 April, with the patient in the left lateral position, right side up, an incision was made just above and behind the right mastoid, curving somewhat transversely down to the midline in the region of C.V.2. A suboccipital craniotomy was performed with removal of the arch of the atlas. The vertebral artery was dissected completely free in its entire intradural and extradural course from the origin of the posterior inferior cerebral artery down to its emergence at the level of the foramen transversarium at C.V.2. The fistula could be seen joining a large conglomeration of veins overlying the vertebral artery at the arch of C.V.1 and at the old puncture site. The veins were all coagulated and stripped free of the artery, including the fistula.

---

* Requests for reprints should be addressed to: Vira Sangruchi, M.D., Central Hospital, Bangkok, Thailand.

Postoperatively the patient has been asymptomatic and in good general health. At the time of the last review 3 years and 4 months after operation she had no recurrence of the bruit.

A further 3 cases of traumatic vertebral arteriovenous fistula have been observed in a total of approximately 2000 vertebral angiographies by the lateral atlanto-occipital route.

In each of these cases the patient complained of a loud bruit synchronous with the pulse on the affected side. The bruit appeared some weeks following the angiography in each case.

In 2 cases (*Cases* 2 and 3) the causal arteriovenous fistula was demonstrated radiologically by further vertebral angiography carried out by percutaneous puncture of the vertebral artery by the anterior route. In 1 of these cases the patient declared on waking after anaesthesia that the noise in his head had ceased and the bruit heard before angiography could no longer be detected. The bruit did not return. In the second case the patient noted that his bruit was much lessened on waking after anaesthesia and this disappeared completely within a few days. The bruit could not be heard on auscultation after the repeat angiography.

In the third case (*Case* 4) the fistula was demonstrated by angiography carried out by catheterization of the vertebral artery from the femoral artery. The bruit was unchanged by the procedure. Operative closure of the fistula was not successful. Repeat vertebral angiography by the anterior route 2 weeks after exploration demonstrated the fistula, although poorly because of arterial spasm at the puncture site. Following this procedure the bruit disappeared.

DISCUSSION

The most satisfactory way of obtaining a good vertebral angiogram is still by direct percutaneous puncture of the artery (Taveras and Wood, 1964). Traumatic arteriovenous fistula following direct puncture of the artery might be expected in a large number of cases since the venous plexus lies anteriorly and laterally close to the second and third parts of the vertebral artery. Sugar, Holden, and Powell (1949) commented on this possibility but stated that, although theoretically the possibility of traumatic arteriovenous fistula existed, they had not observed such a complication. They postulated that in the presence of a normal coagulative mechanism, and with the use of a sharp needle, the puncture sites should close automatically and quickly. In the present *Case* 1 the right vertebral artery was punctured by the lateral atlanto-occipital route. Initially the test injection of saline caused severe arterial spasm and the artery had to be repunctured on several occasions; these special and unusual circumstances might be the reason for the development of a fistula in this case.

The main clinical presentation of an arteriovenous fistula of the vertebral artery is a bruit over the site of fistula. This differs from an intracranial arteriovenous fistula which presents with a bruit in about 23 per cent of cases (Moody and Poppen, 1970). Other symptoms and signs of vertebral insufficiency, as were seen in *Case* 1, may not occur.

Patients have been managed in many ways—conservatively (Maslowski, 1955; Gooddy and Schechter, 1960; Robles, 1968), by proximal ligation (Orlson, Baker, and Svien, 1963), by proximal and distal ligation (Elkins and Harris, 1946), and by exposure and ligation of the fistula (Chou and French, 1965). In the present *Case* 1 the fistula was successfully closed by direct exposure and coagulation. It is interesting that in 3 out of the 4 cases presented here the bruit disappeared after repeat angiography by the anterior route although in 1 of these, *Case* 4, indirect vertebral angiography did not affect the bruit. In *Case* 1 only indirect angiography (percutaneous retrograde brachial angiography) was used to demonstrate the fistula. Direct surgical closure of the fistula can be a formidable procedure and may not be successfully completed (*Case* 4). Vertebral angiography by the anterior route may be a simpler alternative.

Acknowledgement.—We are grateful to Mr. J. F. Shaw for permission to report *Case* 4.

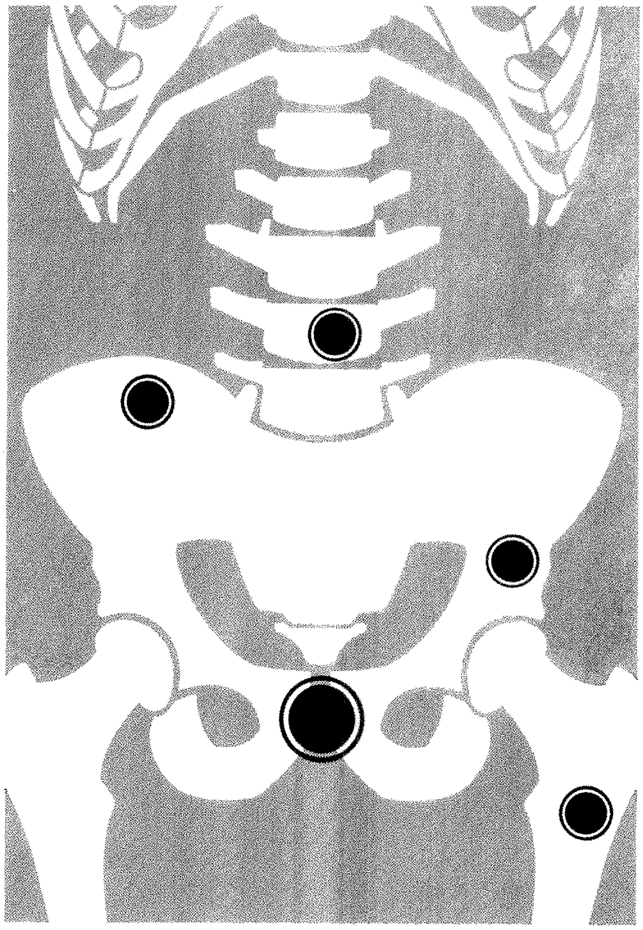
Honvan fosfestrol

Honvan is pharmacologically inert until dephosphorylated. It is selectively activated by tissues rich in acid phosphatase, notably the prostate, where it exerts a local cytotoxic action.

Regression of prostatic tumours and metastases is observed in most patients, including a majority of those unresponsive to standard oestrogen therapy.



Response is rapid. **Honvan** is a practical alternative to surgery in acute urinary retention caused by prostatic carcinoma.

Gastric tolerance of **Honvan** is good and side effects comparatively rare.

Honvan is available for both intravenous and oral administration.

a selective cytotoxic action

POSTOPERATIVE CHANGES IN BLOOD VISCOSITY AND THE INFLUENCE OF HAEMATOCRIT AND PLASMA-FIBRINOGEN

By J. V. HARVEY KEMBLE and J. A. HICKMAN

DEPARTMENT OF SURGICAL STUDIES, THE MIDDLESEX HOSPITAL, LONDON

SUMMARY

The blood of 25 patients undergoing surgery has been investigated for levels of whole-blood and plasma viscosity, haematocrit, and plasma-fibrinogen before and after operation.

The whole-blood viscosity diminished by between 14 and 23 per cent after operation. The haematocrit fell from a mean preoperative level of 42·3 per cent (S.D. ± 5·2) to a mean postoperative level of 36·3 per cent (S.D. ± 5·5). When the effect on viscosity of this reduction in haematocrit was removed the blood viscosity rose after operation by 9–14 per cent.

The level of plasma-fibrinogen rose from a mean preoperative level of 360 mg. per cent (S.D. ± 78) to a mean postoperative level of 714 mg. per cent (S.D. ± 155), an overall increase of 98 per cent. This postoperative rise in the plasma-fibrinogen concentration exerted an effect on the blood viscosity opposite to that of the haematocrit.

The deleterious effects of a rise in blood viscosity on tissue perfusion and oxygenation are outlined, and the relevance of the reported findings to the maintenance of an adequate microcirculation in the postoperative period is discussed. Attention is drawn to the benefits of a slight fall in haematocrit during this period.

In patients undergoing surgery it is becoming increasingly clear that the maintenance of an adequate flow of blood through the microvasculature is as vital to life as that through the heart and great vessels.

In the postoperative period there are rapid changes in the haematocrit and in the plasma-fibrinogen, two factors which affect viscosity (Godal, 1962; Litwin, 1968). This period therefore provides an ideal time in which to measure the effects of these factors on blood viscosity.

The rate of blood-flow depends partly on the blood viscosity. Many factors affect viscosity; the effect of flow-rate or shear rate* is shown in *Fig.* 1. Reemsta and Creech (1962), using fresh heparinized blood from dogs, showed that at a constant temperature blood viscosity increased with increasing haematocrit. This effect was most marked when the haematocrit rose above 40 per cent, when the increase in viscosity became exponential (Rand, Lacombe, Hunt, and Austin, 1964) (*Fig.* 2).

The purpose of the present study was to determine, solely within the range of change occurring in patients, the alterations which occur in blood viscosity following operation, and to relate these to alterations in haematocrit and in plasma-fibrinogen.

MATERIALS AND METHODS

Blood-samples were taken by venepuncture from 25 patients (16 male and 9 female) undergoing major operations; these were mostly abdominal, such as prostatectomy, colectomy, abdominoperineal resection, and cholecystectomy. Samples were collected between 9 and 10 a.m. on the day before operation and on subsequent postoperative days up to the tenth day.

Blood was drawn into disposable plastic syringes through a No. 1 needle and was immediately transferred into plastic tubes containing 24 mg. E.D.T.A. (Stayne Laboratories).

Haematocrits were determined by the Hawksley microhaematocrit method. Blood for reconstitution to a haematocrit of 47 per cent was centrifuged at 700 *g* for 20 minutes and the plasma was pipetted off. Packed cells and plasma were then mixed in the proportion of 1 : 1, and the resultant haematocrit of 47 per cent was confirmed by the microhaematocrit method. Preliminary experiments confirmed that no alteration in viscosity readings resulted from centrifugation of the blood-samples.

Viscosity of whole blood, of blood reconstituted to a haematocrit of 47 per cent, and of plasma was determined using a Wells Brookfield viscometer, Model LVT, at six shear rates—5·75, 11·5, 23, 46, 115, and 230 sec.$^{-1}$ (Wells, Denton, and Merrill, 1961). The temperature was maintained constant at 37° C. by a Radiometer Thermostat VTS 13 waterbath. The viscometer measures torque developed in the fluid between a rotating cone and a plate. The torque produced is a function of the shear stress. The fluid, 1·2 ml., to be investigated was introduced between the cone and the plate. Provided that the quantity introduced did not exceed 0·4 ml. either side of this value, no alteration was produced in the viscometer readings. Shearing was started at 230 sec.$^{-1}$ and the readings were taken when the needle reading stabilized, usually within 3 minutes. An average of two readings was taken at each shear rate.

Plasma-fibrinogen Concentration.—Plasma-fibrinogen concentration was estimated using a gravimetric method (Hickman, 1971). Duplicate 1-ml. samples of plasma were added to plastic test-tubes containing 2 ml. of phosphate saline buffer,

---

* Shear rate expresses how fast one plane or film of blood moves against its adjacent plane. It is expressed in cm. per second divided by unit distance between the films (in cm.), i.e., 1/sec. or sec.$^{-1}$.

Shear stress is the tangential force per unit area applied to a fluid plane to cause it to slide over its adjacent plane, thus producing flow. It is measured in dyn per cm.^{2}

Viscosity is defined as shear stress divided by shear rate in dyn per cm.^{2} or poise (P). 1 P = 100 cP.

*p*H 6, and 40 NIH units of thrombin (Leo Pharmaceuticals Ltd., Denmark). The samples were allowed to stand at room temperature for a minimum of 2 hours and the clot was then extracted using a steel needle (Regoeczi, 1967). After successive washes for 30-minute periods in 0·9 per cent saline and distilled water, the clot was removed from the needle using pointed forceps and placed in acetone for a further 30 minutes. The acetone was then drained from the clot, which was baked in a constant temperature oven at 90° C. for 15 hours. Clots were weighed immediately after removal from the oven using a Mettler, type H16, spring balance.

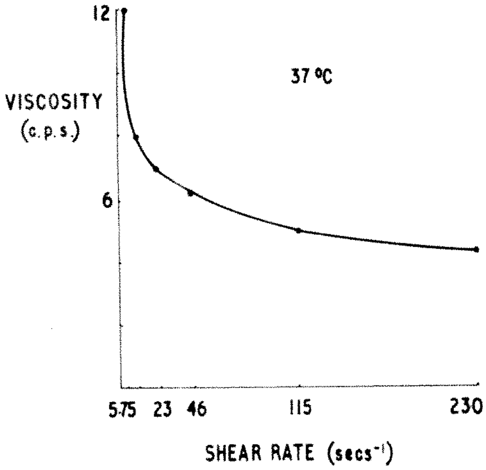

FIG. 1.—The relationship between shear rate and blood viscosity.

Table I.—THE PERCENTAGE DECREASE IN WHOLE-BLOOD VISCOSITY OCCURRING AFTER OPERATION MEASURED AT DIFFERENT SHEAR RATES

Shear Rate (sec.$^{-1}$)	*Percentage Decrease in Viscosity after Operation*
5·75	19·0
11·5	18·7
23·0	16·4
46·0	15·8
115·0	23·3
230·0	14·4

The mean fall in haematocrit after operation was 14·2 per cent.

Using this method, the mean percentage error in 80 such duplicate samples selected at random was 2·07 per cent (S.D. ± 1·85), and the mean value obtained in a study of 70 healthy young adults aged 20–35 years was 264 mg. per 100 ml. of plasma (S.D. ± 43·89).

RESULTS

The haematocrit fell from a preoperative mean of 42·3 per cent (S.D. ± 5·2) to a postoperative mean of 36·3 per cent (S.D. ± 5·5). This was significant ($P < 0{\cdot}001$).

The level of plasma-fibrinogen rose from a preoperative mean of 360 mg. per cent (S.D. ± 78) to a postoperative mean of 714 mg. per cent (S.D. ± 155). The peak of this rise varied from the first to the tenth postoperative days, but occurred most frequently on the third, fourth, or fifth day.

Whole-blood viscosity not corrected to constant haematocrit diminished after operation compared with the preoperative level. The decrease was between 14·4 and 23·3 per cent (varying with shear rate) after operation. At all shear rates the fall from preoperative to postoperative levels was significant ($P < 0{\cdot}005$). The percentage at each shear rate is shown in *Table I.*

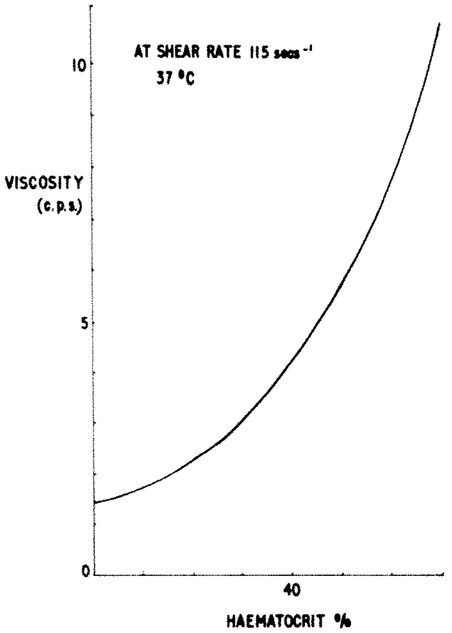

FIG. 2.—The relationship between the viscosity of whole blood and the haematocrit. Increase in the haematocrit above 40 per cent produced a marked increase in the blood viscosity.

Table II.—THE PERCENTAGE INCREASE IN VISCOSITY AFTER OPERATION WHEN THE HAEMATOCRIT IS MAINTAINED AT 47 PER CENT

Shear Rate (sec.$^{-1}$)	*Percentage Decrease in Viscosity after Operation*
5·75	13·7
11·5	13·8
23·0	11·5
46·0	10·7
115·0	11·2
230·0	9·4

The plasma-fibrinogen rose during this period by a mean of 98·3 per cent.

Whole-blood viscosity measured at a constant haematocrit of 47 per cent rose after operation compared with the preoperative level. This increase was significant at all shear rates ($P < 0{\cdot}001$). The increase varied from 9·4 to 13·8 per cent (varying with shear rate). The figures are shown in *Table II.*

When whole-blood viscosity was correlated at each shear rate with the haematocrit it was found that a rise in the haematocrit was associated with a rise in viscosity, and further that the correlation was significant (*Table III*).

When the effect of changes in the haematocrit was excluded by measuring blood viscosity at a constant haematocrit it was found that all shear rates changes in blood viscosity correlated with the change in plasma-fibrinogen and again this correlation was significant (*Table IV*). The results are shown graphically in *Fig.* 3.

Plasma-samples were investigated for the determination of their fibrinogen content and viscosity at shear rates of 230, 115, and 46 sec.$^{-1}$ Measuring the viscosity of each plasma-sample at these three shear rates did not alter the viscosity by more than 0·1 cP. This confirmed the Newtonian behaviour of plasma. There was a close correlation between plasma viscosity and plasma-fibrinogen ($P < 0·001$).

Table III.—THE CORRELATION BETWEEN THE BLOOD VISCOSITY AND THE HAEMATOCRIT AT THE DIFFERENT SHEAR RATES

SHEAR RATE (sec.$^{-1}$)	CORRELATION COEFFICIENT	SIGNIFICANCE
5·75	0·3461	$P < 0·01$
11·5	0·4870	$P < 0·001$
23·0	0·4687	$P < 0·001$
46·0	0·4234	$P < 0·001$
115·0	0·5201	$P < 0·001$
230·0	0·5471	$P < 0·001$

Table IV.—THE CORRELATION AT A CONSTANT HAEMATOCRIT (47 PER CENT) BETWEEN BLOOD VISCOSITY AND PLASMA-FIBRINOGEN AT DIFFERENT SHEAR RATES

Shear Rate (sec.$^{-1}$)	*Correlation Coefficient*
5·75	0·4022
11·5	0·5064
23·0	0·4184
46·0	0·4098
115·0	0·3369
230·0	0·4027

All these correlations are significant ($P < 0·001$).

The increase in the plasma viscosity from a preoperative mean of 1·5 cP to a postoperative mean of 1·7 cP failed to reach significance.

DISCUSSION

The range of shear rates used in this study probably includes the shear rates which are found in the main arteries, arterioles, and veins. Shear rate is a function of the flow rate and the radius of the vessel. The shear rate at the wall of the aorta has been estimated at 100 sec.$^{-1}$, and in an 'end-arteriole' of the order of 10 sec.$^{-1}$ (Wells and Merrill, 1962).

An increase in the fibrinogen concentration increases the blood viscosity because fibrinogen induces the aggregation of red cells (Rosenblum, 1969). Other plasma proteins have very little or no effect on viscosity except in the presence of fibrinogen, with which they act synergistically (Merrill, Filliland, Lee, and Salzman, 1966). Fibrinogen is a long fibrillar molecule with a length : width ratio of 15 : 1, and with a net change most dissimilar to that of the red cell. At concentrations of fibrinogen of 500–800 mg. per cent erythrocyte aggregation is marked. Albumin, on the other hand, with a length : width ratio of 3 : 1 and a highly electronegative charge inhibits aggregation (Ditzel, 1959; Wells, Gawronski, Cox, and Perera, 1964).

If the viscosity of defibrinated blood is determined there is very little change in viscosity with change in shear rate, such blood behaving virtually in a Newtonian fashion. Further, as shown in this study, plasma does behave in a Newtonian fashion. The non-Newtonian characteristics of whole blood are due therefore to the presence of both red cells and fibrinogen, and changes in their concentration in the blood are the main factors which influence blood viscosity. The postoperative period is characterized by changes in both these factors, so that any change in blood viscosity in this period will be the resultant of the two factors. The results of the investigations reported here allow the effect of changes in the concentrations of red cells (i.e., the haematocrit) to be separated from that of changes in the concentration of fibrinogen, and show that after operation a fall in the haematocrit counteracts the effect of the rise in fibrinogen, resulting usually in a slight fall in the viscosity of the blood.

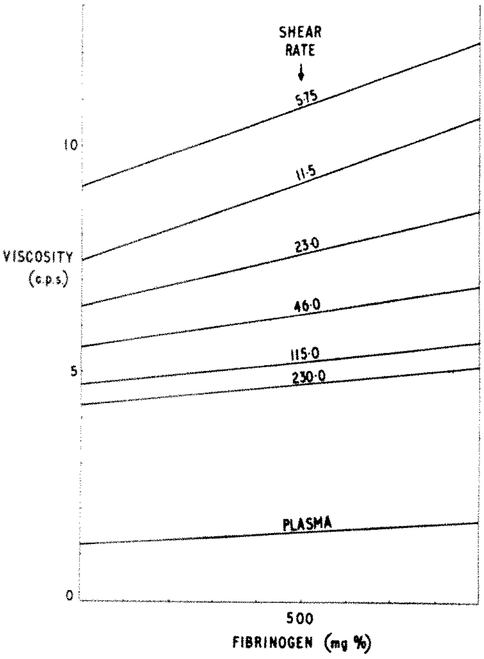

FIG. 3.—When blood-samples were measured at a constant haematocrit increase in the fibrinogen concentration was associated with an increase in the viscosity, the changes being greatest at lower shear rates.

Godal (1962) showed, as confirmed in this study, that after operation an increase in the level of fibrinogen in the plasma to as much as double or treble its preoperative value is normal. If the haematocrit remained constant throughout this period an increase in the blood viscosity of the order of 11 per cent would occur; if the haematocrit should also rise, as for instance as the result of an acute extracellular fluid deficit, the effect of this would be synergistic, with a further rise in blood viscosity and adverse effects on tissue perfusion and oxygenation.

Seligman, Frank, and Fine (1946) have shown, in studies on dogs, that increased blood viscosity aggravates haemorrhagic shock by reducing blood-flow. When the blood viscosity is high, the cardiac output becomes critically low at blood-pressures higher than those observed in haemorrhagic shock in which the blood viscosity is normal. Repogle, Kundler, and Cross (1965) have also shown that the cardiac output falls as the haematocrit and blood viscosity increase. In addition, the systemic peripheral resistance rises as the viscosity rises (Halmagyi, Starzecki, and Horner, 1965). Case, Berglund, and Sarnoff (1955) have demonstrated that while keeping the left ventricular work load of the vagotomized canine heart constant an increase in haematocrit from 32 to 55 per cent results in a decrease in the left coronary artery blood-flow from 193 to 83 ml. per minute. The same increase in haematocrit results in an increase in the coronary resistance from 0·6 to 1·7 mm. Hg per ml. per minute.

In the dog the consumption of oxygen by the tissues increases as the haematocrit increases up to a haematocrit value of 42 per cent, and then falls as the haematocrit continues to rise. At haematocrits of less than 42 per cent the increasing oxygen carriage of the blood more than compensates for the increasing blood viscosity (and hence decreasing cardiac output), but at values greater than 42 per cent the viscosity factor becomes the more significant (Crowell, Ford, and Lewis, 1959).

Any rise in blood viscosity which occurs as a result of the increase in plasma-fibrinogen postoperatively therefore tends to reduce cardiac output, reduce coronary blood-flow, and increase coronary and systemic peripheral resistance. It may also increase the liability to deep-vein thrombosis. In the postoperative period a modest drop in the packed-cell volume to offset this effect is beneficial to the patient, for the detrimental effect of the reduced oxygen carriage in the blood is more than offset by the improved circulatory effects.

MALIGNANT MELANOMATA: AN AID TO PREOPERATIVE DIAGNOSIS

BY RONA M. MACKIE

UNIVERSITY DEPARTMENT OF DERMATOLOGY, WESTERN INFIRMARY, GLASGOW

SUMMARY

The use of the Zeiss operation microscope in the preoperative diagnosis of malignant melanomata has given an overall accuracy rate of 85 per cent. The method is quickly and simply carried out, and is without risk to the patient and the operator. The machine is portable and can therefore be used at the bedside in a patient who is not ambulant. Only a normal domestic power supply is required. The use of this machine in the assessment of such cases is therefore advocated.

THE clinical diagnosis of an advanced malignant melanoma (the malignant tumour arising from the melanocyte cells of the epidermis) seldom offers a diagnostic problem. In the early case, however, clinical diagnosis can be difficult, and as the patient's greatest hope of a cure lies in the early treatment of the lesion by wide excision and skin-grafting it is a problem of considerable significance. On the one hand lies the risk of failing to diagnose a malignant melanoma and delaying definitive treatment, and on the other there is the possibility of wrongly labelling a benign pigmented naevus as malignant and instituting unnecessary extensive surgery.

Published figures in the literature lend support to the need for assistance in this diagnosis; Sverdlow (1952), reporting on 27 histologically proved malignant melanomata, states that only 16 (57 per cent) had been accurately diagnosed preoperatively, and Becker (1954), reporting on 151 specimens which were subsequently confirmed as malignant melanomata, states that 72 (48 per cent) were received at the laboratory with the correct clinical diagnosis.

It is in view of these figures that a study has been carried out over the past 5 years with the aim of evaluating the use of the Zeiss operation microscope for surface examination of suspected malignant melanomata at low magnifications. It was anticipated that surface features of malignant melanomata could be identified in this way, and could offer a guide to the surgeon in his preoperative assessment of the lesion.

MATERIALS AND METHODS

The machine used for this study was the Zeiss operation microscope (*Fig.* 1). This is a binocular microscope with a 35-mm. camera mounted on a side-arm. The magnifications obtainable are × 6, × 10, × 16, × 25, and × 40. The lesions referred for assessment are first washed thoroughly and then covered with a light oil to increase the epidermal translucency. Olive oil has been found to be satisfactory for this purpose. As it has been shown that melanocytes are not stimulated to mitotic activity by skin stripping with adhesive tape (Lessard, Wolff, and Winklemann, 1968) this procedure is used in lesions with a thick epidermal layer.

Every lesion is examined at all available magnifications and then photographed using Kodachrome II colour film and flash illumination. The most satisfactory magnifications for photography are × 10 and × 16, as above this magnification small movements such as transmitted abdominal pulsation become troublesome. All the lesions included in this report were removed surgically and the histology of each lesion was studied.

RESULTS

The accuracy of this method of assessment is shown in *Table I*. It can be seen that a total of 72 histologically confirmed malignant melanomata have been studied and that the preoperative accuracy rate was 85 per cent. The surface features which were commonly found to be present in these lesions and which proved a pointer to the diagnosis were, first, extensive variation in colour and in pigment density within any one lesion. Thus, although a blue naevus may have a characteristically blue-black appearance the colour is uniform, whereas a malignant melanoma may at one point have pigment very similar to that of the naevus but other areas may show dark- or light-brown areas of pigmentation and also areas of erythema. Another important feature has been found to be the relative distribution of pigment within the lesion, as a malignant melanoma frequently shows dark pigment deposits at its lateral margins whereas the tendency in benign pigmented naevi is for the lesion to show peripheral pigment loss with the greatest density of pigment centrally. Malignant melanomata frequently have dilated and abnormal capillaries clearly visible on the surface of the lesion and such capillaries have never been observed in a benign junctional or compound naevus. A feature which has been noted to be present in a high proportion of lesions showing junctional activity as a component of their histological features, namely malignant melanomata and junctional and compound naevi, is the presence of a very regular, delicate, superficial pigmentary pattern, not unlike a spider's web. This pattern would appear to indicate areas of active melanocyte proliferation, and although by itself this feature is not diagnostic for malignant melanoma its presence in conjunction with marked pigment variation, peripheral pigment increase, or dilated capillaries is virtually diagnostic of malignant melanoma as none of these other features has been observed in junctional or compound naevi.

Table I.—ACCURACY OF PREOPERATIVE ASSESSMENT USING SKIN MICROSCOPY AS CONFIRMED BY SUBSEQUENT HISTOLOGICAL EXAMINATION

TYPE OF LESION	NO. CORRECTLY DIAGNOSED	NO. INCORRECTLY DIAGNOSED	PERCENTAGE ACCURACY
Malignant melanomata	61	11	85
Junctional naevi	29	3	91
Compound naevi	92	13	91
Blue naevi	7	1	87
Basal-cell papillomata	34	8	81
Angiomata	12	2	86
Multifocal basal-cell carcinomata	7	3	70

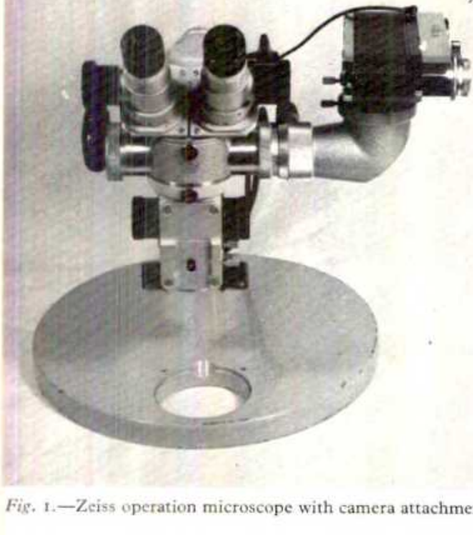

Fig. 1.—Zeiss operation microscope with camera attachment.

The amelanotic melanoma is commonly felt to be an extremely difficult diagnostic problem, but in the present series only 2 lesions, both in the subungual area, were found to be completely devoid of melanin pigmentation. This observation is in keeping with Olsen's (1966) comment, based on a series of 500 cases of malignant melanoma, that truly achromatic malignant melanomata are rare and that in the majority of cases labelled as amelanotic lesions one can observe a rim of melanin pigment at the lateral limit of the lesion.

DISCUSSION

The differential diagnosis of a malignant melanoma commonly includes other benign tumours of melanocyte origin such as junctional, compound, and blue naevi. Vascular lesions such as cavernous haemangiomata may on occasion have a very deeply pigmented surface and have also to be considered. Pigmented basal-cell papillomata and pigmented basal carcinomata of the adenocystic type may also at times give rise to confusion. *Table I* shows the accuracy of skin microscopy for differentiating these lesions preoperatively. The detailed magnified surface appearance of these lesions is reported elsewhere (MacKie, 1971).

Other methods of assisting preoperative assessment of malignant melanomata have been advocated in the past, but none has as yet won general acceptance. In 1955 Bauer and Steffen advocated the use of intravenous radioactive phosphorus using the isotope ^{32}P. This was based on their finding that the radioactive uptake over the malignant melanoma was 3·85 times higher than that over contralateral normal skin. Brauer, Kopf, Witten, Berman, and Cave (1960) also used this technique for studying 145 lesions and found 20 per cent false-positive and 37 per cent false-negative results. A comparison of the radioactive uptake over benign pigmented skin tumours is not included in this series and this method would not appear to be one which could be quickly or routinely undertaken in a busy ward or out-patients' department.

In 1962 Venkei and Bakos advocated the use of thermo-differentiation in the diagnosis of malignant melanoma. This suggestion was based on their findings that the skin temperature over a primary malignant melanoma is 1° C. or more higher than that over contralateral normal skin. In this series of 80 cases of histologically proved malignant melanomata 61 (76 per cent) gave positive results. Again a comparison with benign pigmented skin tumours is not included. A disadvantage of this method is the fact that consistent skin temperatures are extremely difficult to obtain, and usually require several hours' adaptation in a thermostatically controlled room.

The most recent method for preoperative assessment of pigmented lesions was advocated in 1968 by Andreev, who suggested incisional biopsy of the suspected malignant melanoma under cover of a dose of radiation to the tumour of 4000–5000 rad. In view of the work of Olsen (1967), who has shown that the natural progression of malignant melanoma treated by radiation is initial regression followed by early and widespread metastases, the wisdom of this procedure would seem to be debatable.

The use of frozen section in cases where clinical doubt as to the histological nature of the lesion exists is much debated. The chief problem is that only one portion of the lesion is sampled which may well show only active junctional change whereas an area only 1 or 2 mm. distant may show definite malignant activity. This fact is the reason for the many discrepancies which exist between the frozen-section report on a pigmented lesion and the report based on paraffin sections. The technique of frozen section in suspected malignant melanomata requires careful attention as the cells are easily distorted and the differentiation between junctional activity and early malignant change can thus be made extremely difficult (Rook, Wilkinson, and Ebling, 1968).

HAEMANGIOMATA OF SKELETAL MUSCLE

By I. L. C. FERGUSSON

WESTMINSTER HOSPITAL, LONDON

SUMMARY

Two cases of skeletal muscle haemangiomata are described.

All previous cases of this condition are reviewed and a brief account is given of the important facets of aetiology, diagnosis, and treatment.

Wherever a soft-tissue swelling presents in the region of skeletal muscle the possible diagnosis of a haemangioma should be considered and may frequently be confirmed pre-operatively with the aid of radiography.

Local excision remains the treatment of choice wherever possible.

Two new cases of haemangiomata arising in muscle are described. They fall into the rare group of skeletal muscle haemangiomata which provide interesting problems of diagnosis. The present cases are discussed in the light of previously reported cases with special reference to aetiology, diagnosis, and management.

CASE REPORTS

Case 1.—The patient, a 28-year-old married woman, was admitted to Westminster Hospital in September, 1970, with a swelling of the right upper arm which had been progressively enlarging over the past year. She was a professional 'cellist and had attributed the swelling to muscle hypertrophy resulting from over-zealous practice. Apart from occasional aching in the upper arm she complained of no other symptoms and her general health was excellent. Photographs of the patient as a young girl revealed no visible swelling at that time.

Examination revealed a normal, healthy young woman with no cutaneous haemangiomata, although she was suffering from an acute episode of pityriasis rosea at the time of admission. The lump in the arm measured 7 × 3 cm., was firm, mobile, and separate from the vascular bundle, but appeared to arise from the biceps muscle (*Fig.* 1). There was no skin attachment and no palpable axillary lymph-nodes could be felt. Fluctuation could not be demonstrated and there was no bruit.

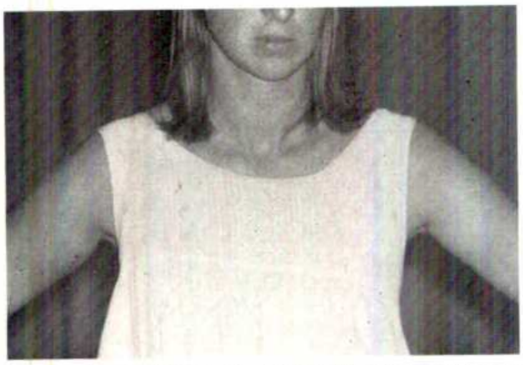

FIG. 1.—*Case* 1. Patient after biopsy but prior to definitive excision, showing site of tumour over right biceps brachii.

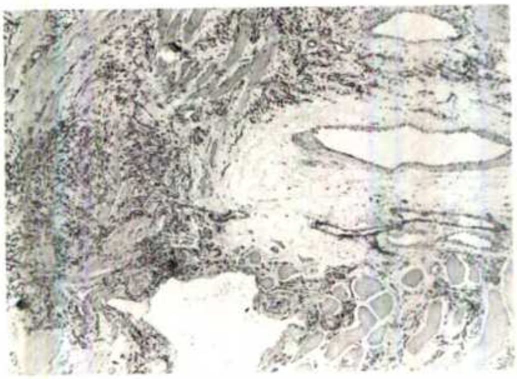

FIG. 3.—*Case* 1. Break up of muscle-bundles by blood-vessels of varying size. H. and E. (× 60.)

A radiograph of the chest and a full blood-count were normal. A preoperative diagnosis of fibrosarcoma was made, and the patient was given a single treatment of radiotherapy preoperatively, producing a centre dose of 1000 rad. At operation (18 Sept., 1970) an incision was made over the swelling and a highly vascular fibromuscular mass was found within the epimysium of the right biceps brachii. A biopsy was taken and the wound was closed. The biopsy report was as follows: 'The lesion is made up of vasoformative tissue of capillary type. In many areas the lesion consists of solid islands of endothelial cells devoid of lumina (*Fig.* 2). The vascular process is infiltrating through muscle-bundles (*Fig.* 3). The appearances are those of a vascular hamartoma and not a true neoplasm. Apparent growth of these lesions is said to be due to the opening up of vascular channels already present in a collapsed state. I have been able to match this case with one removed from the biceps of a young woman in 1964 at the Royal Marsden Hospital. In that case local excision was carried out and the patient had no further trouble.' With this information a right subclavian arteriogram was performed (*Fig.* 4). This showed a highly vascular lesion in the middle third of the upper arm on its medial aspect. It derived its blood-supply from a number of small branches of the brachial artery.

Further surgery was planned to remove the lesion. At operation on 25 Sept. a 10-cm. incision was made down the medial border of the upper arm, excising the biopsy scar. The tumour was seen to derive its blood-supply from obviously dilated branches of the brachial artery in the groove between the biceps and the coracobrachialis. There was no clear delineating plane between the tumour and biceps muscle-fibres. The musculocutaneous nerve was identified and preserved. The feeding vessels to the tumour were ligated, causing visible shrinkage of the mass. The tumour was excised together with superficial fibres of the biceps brachii which underlay it.

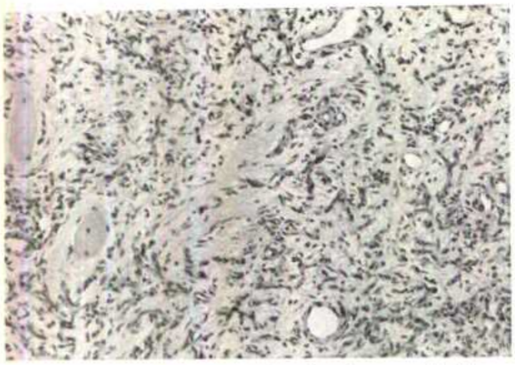

FIG. 2.—*Case* 1. Proliferating but largely uncanalized vasoformative tissue. H. and E. (× 62.)

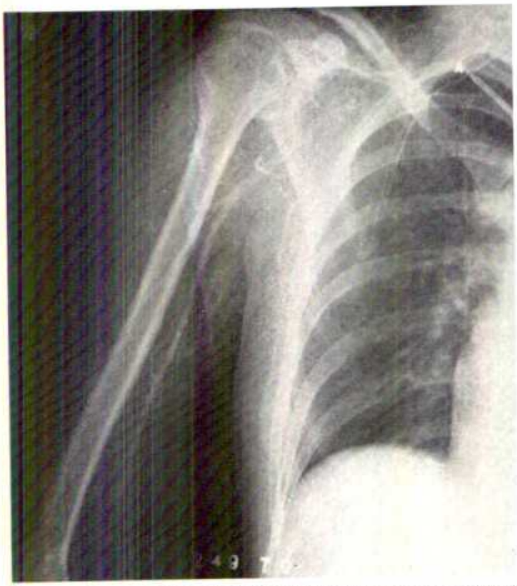

FIG. 4.—*Case* 1. Right subclavian arteriogram showing a highly vascular lesion over the medial aspect of the upper arm.

Postoperative recovery and healing were uneventful. The patient was last seen on 7 Jan., 1971, when the wound was well healed with slight keloid deformity. She had no residual motor or sensory deficit and was once again playing the 'cello professionally.

PATHOLOGY.—The macroscopic appearance was of a strip of biceps muscle measuring 11 × 3 cm. Within the muscle there was a small area of haemorrhage related to the biopsy. The surrounding muscle showed a speckled white appearance presumably due to the vascular component.

The microscopic appearance confirmed the diagnosis of vascular hamartoma. The histological appearances were modified in some areas by the biopsy, but there was no sign whatsoever of neoplasm of any kind. The muscle from the cut ends of the specimen was normal.

Case 2.—The patient, a 29-year-old fireman, was admitted to Westminster Hospital in February, 1971, with a large lump in the centre of his back. He had first noticed the lump 3 months previously, at which time he had felt a pain in the back on stretching forward. The lump had apparently become slightly smaller in the intervening 3 months. The patient was otherwise in good health with no past medical history apart from the excision of a branchial cyst 2 years previously.

Examination revealed a healthy man with no other palpable lumps and no cutaneous haemangiomata. The lump in the centre of his back was flat and tender. It measured 4 × 2·5 cm. and had an ill-defined border. There was no skin fixity but there was some deep attachment. Fluctuation could not be demonstrated and there was no bruit.

Radiographs of the chest and spine were normal, as was a full blood-count.

A provisional diagnosis of neurofibroma was made. At operation (23 Feb., 1941) an extensive ill-defined haemangiomatous mass was found extending from the latissimus dorsi muscle. Biopsies were taken and the incision was closed. A firm pressure dressing was applied. The post-operative course was uneventful.

PATHOLOGY.—Histological examination showed a cavernous haemangioma in which thrombosis had occurred in some of the vascular spaces. There was no evidence of neurofibromatosis.

DISCUSSION

Liston (1843) is generally accredited with the first description of a skeletal muscular haemangioma. His case was of a tumour of the popliteal space which was found to arise from the semimembranosus muscle. Since then excellent and comprehensive reviews have appeared on the subject, notably by Davis and Kitlowski (1930), Jenkins and Delaney (1932), Swallow, Eger, and Wagner (1944), Bonvallet (1950), Jones (1953), Bendeck and Lichtenberg (1957), Scott (1957), and La Sorte (1960).

Scott (1957) collected 393 histologically proved cases, to which may be added 9 cases collected by La Sorte (1960) and 16 cases collected by Stock (1953), but not included in previous reviews. Since then 9 further cases have been reported, including the present 2 (*Table I*), bringing the current total to 437 cases.

Most authors believe that these tumours are congenital in origin and they have frequently been described as vascular hamartomata. Most of them are discovered in childhood or adolescence, and over 85 per cent of the reported cases occurred in the first three decades of life. Willis (1960) reported a known congenital case. Scott (1957) described them as arising in abnormal embryonic sequestrations which retain their embryonic characteristics. Excessive muscle contraction and minor trauma probably play a part in stimulating blood-flow into pre-existing vascular malformations. The present *Case* 1 arose in the right arm of a professional 'cellist, and *Case* 2 on the back of a fireman.

The tumours show an almost equal sex incidence with a marginal preference for women. They mainly arise from a single muscle (66 per cent of the reported cases) although in some instances as many as five muscles have been involved (La Sorte, 1960). It seems likely that all races may be affected with reported cases in Asians, Americans, Europeans, and Indians. As already stated, the age of presentation is greatest in the under-30 age-group (85 per cent), with less than 5 per cent occurring after the age of 50.

	29 M.	Latissimus dorsi	Biopsy and compression bandage

Ninety-eight per cent of cases present with a soft-tissue swelling which has been apparent for between 1 month and 20 years. Sixty per cent of cases have associated pain from pressure on local nerves. The overlying skin was normal in 39 per cent of cases, but was frequently warm and bluish-red; ulceration of the overlying skin has been reported. The swelling is smooth and mobile in the transverse axis of the muscle-fibres. It may be any size and the dimensions in an individual tumour may vary. For instance, when situated in a limb muscle the swelling will become smaller with elevation of the limb, and greater if a proximal tourniquet is applied occluding the venous return. La Sorte (1960) reports a bruit in 1·8 per cent and pulsation in 3 per cent of cases. Functional impairment with deformity, limitation of movement, and muscle weakness are common when extensive muscle involvement has occurred.

Skeletal muscle haemangiomata are misdiagnosed in over 90 per cent of cases, although in the 9 recently reported cases (*Table I*) 4 had a correct preoperative diagnosis. The most common erroneous diagnoses are lipoma, fibrosarcoma, lymph-nodes, and hernia. Radiological evidence has proved useful in making a correct diagnosis. Soft-tissue films may show the appearance of dilated vessels, and also the presence of phleboliths which Wakeley described as characteristic in 1921. More recently, arteriograms have proved invaluable in many suspected cases. Aspiration of blood and biopsy are the most conclusive diagnostic tests.

In situ the tumours appear red with a bluish tinge; they may be spongy or firm, and some contain patchy calcification. They are more often diffuse than circumscribed and appear to infiltrate local muscle-bundles. They progressively enlarge locally but never metastasize. On excision the vascular part of the specimen tends to shrink to a small piece of ragged tissue. Microscopically, arterial, venous, capillary, and cavernous elements may be found infiltrating between muscle-fibres in various degrees of degeneration. Skeletal muscle haemangiomata accounted for 0·8 per cent of 1308 assorted haemangiomata reviewed by Watson and McCarthy (1940).

The treatment of choice is local excision of the tumour which may shell out or may necessitate excision of a cuff of the surrounding muscle. Where excision is impracticable because of extensive infiltration or the likelihood of risking permanent deformity, then radiotherapy may be beneficial.

Carbon-dioxide snow, of use in skin lesions, is quite unsatisfactory for the diffuse skeletal haemangiomata. Injection of sclerosant fluids has been tried by Stock (1953) without great success. Partial excision with the risk of recurrence is to be avoided wherever possible. In very rare cases of large painful tumours causing deformity or loss of function, amputation may be necessary.

Acknowledgements.—The author would like to thank Mr. Kingsley Robinson and Mr. Robert Cox for permission to publish these cases who were admitted under their care; Dr. Mackenzie for his pathological reports and photomicrographs; the Photographic and X-ray Departments of the Westminster Hospital for their co-operation; Miss Paula Warren and Miss Peggy Pearce for their help in preparing the typescript.

NASOGASTRIC TUBE MANAGEMENT

By LAURENCE TINCKLER
FORMERLY PROFESSOR OF SURGERY, UNIVERSITY OF SINGAPORE

Although the routine use of a nasogastric tube after abdominal operations is contentious (Earle, Metheny, and Lundmark, 1955) there are those who consider that tube decompression of the upper gastro-intestinal tract has contributed much to the relative safety of abdominal surgery (Wells and Tinckler, 1962).

The purpose of utilizing a nasogastric tube in postoperative management or for preoperative preparation of patients with intestinal obstruction is to evacuate fluid and gas from the upper gastro-intestinal tract; by so doing tension on recent suture lines is lessened, bowel distension is reduced with benefit to the vascularity and nutrition of the bowel wall, drag is reduced on vulnerable suture lines as in oesophagojejunal anastomosis, patients are relieved of a bloated feeling in the abdomen, and reduction of bowel distension eases strain on the patient's abdominal parietal wound.

Investigation of gastro-intestinal motility after abdominal operations has shown that while small-bowel tone and movement persist, gastric tone and motility either decrease or disappear for approximately 24–48 hours postoperatively, depending on the nature of the operation (Tinckler, 1960).

HISTORICAL REVIEW

In 1790 John Hunter, in a way one would expect of him, was one of the earliest to intubate the stomach (Hunter, 1841). His tube was a fresh eel skin drawn over a probang for introduction and was used for feeding a patient unable to swallow because of bulbar palsy.

Alexander Munro (1797) claimed that his father in 1767 used a flexible tube of coiled wire covered with leather to remove fluid and gas from cattle's stomachs in which there had been excessive fermentation.

A Philadelphia surgeon, Philip Physick, in 1800 advocated the use of a tube to wash out the stomach of poisoned patients.

Although Kussmaul (1869) revived clinical interest in stomach tubes, their development and routine application paralleled advances in abdominal surgery in this century.

The principal use which was made of gastro-duodenal tubes initially was the examination and analysis of gut secretions for diagnostic purposes. Later under the impetus of people like Wangensteen and Paine (1933) such tubes began to be more frequently applied for aspiration in the management of gastric and intestinal distension by decompression. Long before then, however, came isolated reports of utilizing gastroduodenal tubes for aspiration. Westerman in 1910 reported 15 cases of paralytic ileus due to peritonitis which were treated by siphon drainage of the stomach with a nasogastric tube, and Meyer (1926) used gastroduodenal tubes after gastric operations for aspiration and administration of fluids.

Matas (1924) advocated the use of siphon drainage of the stomach postoperatively whenever there was gastro-intestinal stasis.

Continuous suction aspiration of duodenal tubes originated with Ward of San Francisco (1925) but

Wangensteen (1932) popularized the application of this principle in the management of mechanical intestinal obstruction. Wangensteen and Paine (1933) showed that continuous suction was much more efficient than siphon drainage in decompressing the gastro-intestinal tract.

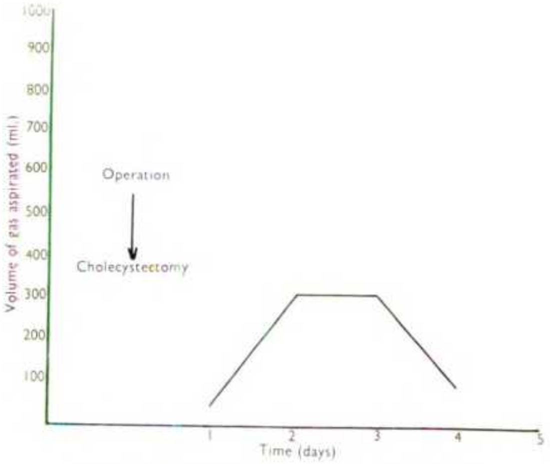

FIG. 2.—*Case* 1. Nasogastric tube gas collection.

NASOGASTRIC TUBE MANAGEMENT

The most commonly employed method of nasogastric tube management is to secure the tube in position with a turn of strapping applied to the patient's nose and to aspirate the tube at intervals.

The main advantage of adopting an intermittent aspiration policy is that it ensures that the patient is visited at prescribed intervals and the patency of the tube tested, giving an opportunity to flush the tube and adjust its position if it is found to be blocked or displaced.

It cannot be denied that the presence of a nasogastric tube causes the patient some discomfort. If then a tube is to be used it should obviously be used to the greatest possible effect and discomfort mitigated as much as possible. It is pointless to subject the patient to nasogastric intubation if no attempt is made to ensure that the tube accomplishes its purpose. This means ensuring that the tube does not become blocked and that it lies at all times in the optimum position for evacuating fluid and gas from the stomach. The question remains how best to service these tubes to maximum advantage. The options are intermittent aspiration, spigoting in the interval, as appears to be standard practice, to leave the tube open to drain spontaneously into a receptacle, or a combination of intermittent aspiration and open drainage.

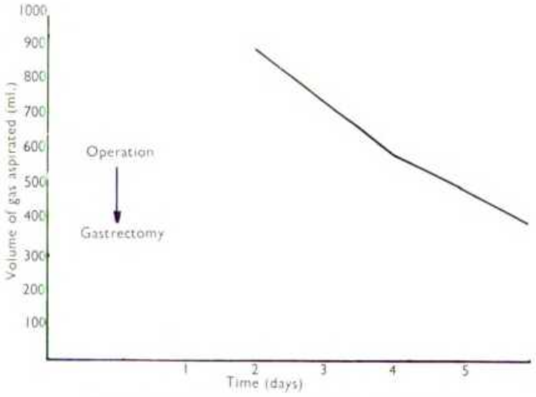

FIG. 3.—*Case* 2. Nasogastric tube gas collection.

METHODS AND THE AIM OF THE INVESTIGATION

In the patients investigated the nasogastric tube was connected by tubing led under water to a gas-collecting apparatus placed at the bedside (*Fig.* 1).

By this means gas passing from the stomach up the nasogastric tube was collected and measured during successive 24-hour periods.

A fluid trap was interposed between the patient and the gas collector in which accumulated gastric contents which siphoned over from time to time; in the patients investigated this spontaneously siphoned fluid amounted to volumes up to as much as 500 ml. in a 24-hour period.

The stomach was aspirated intermittently, disconnecting the nasogastric tube from the gas-collecting apparatus for the purpose.

The object of the investigation was to determine how much gas spontaneously vented from the stomach via the nasogastric tube if it was left on open drainage in between aspiration as an indication as to the possible advantage of open drainage which would justify recommending its routine adoption.

RESULTS

The results for 6 patients investigated are portrayed in *Figs.* 2–7 and featured in *Table I.*

It is to be noted that the peak of gas collection was reached in general on the second postoperative day and thereafter tailed off, presumably as gastric motility returned following the immediate transient postoperative loss of stomach activity.

DISCUSSION

The results of this investigation revealed that by spigoting nasogastric tubes between aspirations in order to avoid soiling the bed linen a substantial

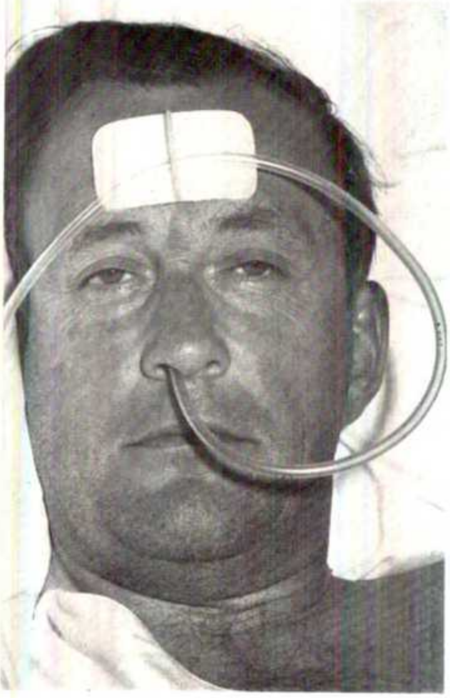
FIG. 10.—Repeated 'nil' aspiration recordings followed by a large volume of aspirate (300 ml.) after adjusting the position of the nasogastric tube.

opportunity is lost to decompress further the upper gastro-intestinal tract. Full utilization of the tubes is, therefore, not being exploited.

On the basis of this investigation it would appear justifiable to recommend that nasogastric tubes should be managed by continuous drainage into a suitable, convenient receptacle such as a disposable polythene bag (*Fig.* 8). Disposable bags suitable for open-drainage management are available from Simpla Plastics Ltd., Phoenix Estate, Caerphilly Road, Cardiff.

Experience with this type of management has repeatedly shown that substantial quantities of gas and fluid eruct and siphon over into the collecting bag, thus contributing to the comfort and well-being of the patients.



ADDENDUM

A Nasogastric Tube Retaining Device.—The standard method of retaining a nasogastric tube in position is to fix it to the patient's nose with a piece of zinc-oxide strapping. This method, which is simple and effective if rather crude, has the disadvantages that it is uncomfortable for the patient and deters easy adjustment of the tube's position as to do so necessitates pulling the strapping off the patient's face and detaching it from the tube, which manœuvre requires a good deal of manipulation and causes some discomfort (*Fig.* 9).

Notwithstanding that a nasogastric tube is positioned correctly on its insertion, it cannot be assumed that that position will remain the correct one throughout the period of its utilization as kinking of the tube may occur; also change of position of the patient, retching, and alterations of gastric tone may subsequently prevent the tube coming into contact with the stomach contents. A nil gastric aspiration result recorded repeatedly on the balance chart is the 'give-away' of the situation and indicates the necessity for adjusting the tube's position (*Fig.* 10).

An alternative means of retaining a nasogastric tube in position which meets the dual requirements of being comfortable for the patient and enabling ready adjustment of position has been designed and has proved its worth in practice. It is made of plastic, is disposable, and consists of a flange 4 × 6 cm. bearing at right-angles to it a fenestrated blade with slots of graduated size to accommodate the several gauges of nasogastric tubing.

The flange of the device is stuck to the patient's forehead with a double-sided plaster (Chiron); the correctly positioned tube is threaded through the fenestrated blade which acting with a cleat action grips it and holds it in position without occluding its lumen which remains clear for intermittent aspiration and open drainage (*Fig.* 11).

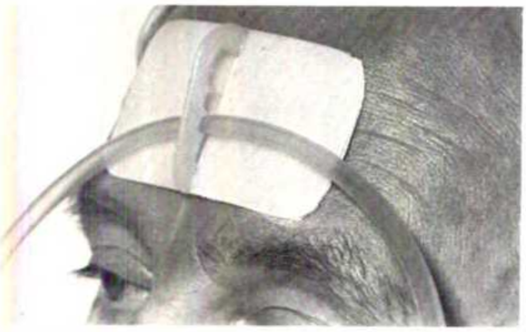


FIG. 11.—The disposable nasogastric tube-holding device in use.

Adjustment of the tube's position is readily accomplished by liberating it from the cleat until the new position is obtained and then cleating the tube again.

These devices can remain in position for several days and are well tolerated by patients who quickly become unaware of their presence. They are available from Down Bros., Mayer & Phelps Ltd., Church Path, Mitcham, Surrey.

TREATMENT OF PERITONITIS WITH PER- AND POSTOPERATIVE IRRIGATION OF THE PERITONEAL CAVITY WITH NOXYTHIOLIN SOLUTION

By R. G. PICKARD
SURGICAL REGISTRAR, ST. GEORGE'S HOSPITAL, LONDON

SUMMARY

The present paper describes a technique for irrigating the peritoneal cavity in severe peritonitis, both at the time of laparotomy and in the immediate postoperative period, with a solution of noxythiolin. A consecutive series of 9 cases with fulminating peritonitis of various causes treated by this method is presented together with the operative findings, a discussion of the postoperative progress, and the bacteriological studies of the irrigating device. A full review of the literature of peritoneal lavage in the management of peritonitis is included in the discussion.

PERITONITIS, of whatever origin, still presents an extremely common and dangerous problem in emergency surgery. In all age-groups it carries a high morbidity and mortality, but particularly in middle and advanced years.

Conventional methods of management include preoperative resuscitation, operative treatment, followed by a period of nasogastric suction, intravenous therapy to maintain adequate hydration and to correct the electrolyte imbalance until the period of paralytic ileus has resolved, the use of systemic antibiotics, and in the more severe cases showing evidence of circulatory collapse the judicious use of blood transfusion and systemic steroids.

The work of such eminent authorities as Fine, Lillehei, Filler, and Sleeman (Filler, Sleeman, Hendry, and Phlaski, 1966; Filler and Sleeman, 1967) leaves very little doubt that the chief factor leading to circulatory collapse and death in peritonitis is the absorption of Gram-negative organisms and their associated endotoxins from the peritoneal cavity, and that, furthermore, as soon as viable organisms are eliminated from the peritoneal cavity the danger of circulatory collapse diminishes rapidly.

It would seem desirable in the management of peritonitis that, in addition to the supportive measures outlined above, as much as possible is done both at the time of operation and in the immediate postoperative period to sterilize the peritoneal cavity of contaminating organisms, and thus to attack the problem at source. Failure to do this will inevitably lead to loculated collections of pus gathering in between coils of intestine and in rather more defined anatomical spaces such as the pouch of Douglas, which will obviously lead to a situation jeopardizing the recovery of the patient.

This paper consists of a relatively short series of 9 patients, all operated on personally, and presenting acute surgical emergencies with symptoms and signs of widespread peritonitis with associated signs suggestive of Gram-negative bacteriaemia, i.e. tachycardia, very poor peripheral perfusion, and low central venous pressure (with the exception of *Case* 5). All the patients were treated by conventional measures, but in addition the peritoneal cavity was thoroughly lavaged with a dilute noxythiolin (Noxyflex) solution, and furthermore a similar solution was dripped into the peritoneal cavity postoperatively for periods varying from 24 to 72 hours.

The leading paper on this subject is that of Browne and Stoller (1970), who used noxythiolin at the time of operation but did not perfuse it into the peritoneal cavity postoperatively, and who present a very impressive series of 23 patients with exclusively faecal peritonitis, with a mortality of 3 patients, 2 of whom were thought to have died from pulmonary embolus.

The present paper presents the methods of per- and postoperative lavage employed in a variety of types of peritonitis, and in the last part gives a full historical review of the place of peritoneal lavage in the management of life-threatening peritonitis.

PATIENTS AND METHODS

The patients with the exception of *Case* 5 presented with severe generalized peritonitis and all were operated on. Conventional methods of postoperative management were adhered to, i.e., nasogastric suction, intravenous fluids, blood transfusion where indicated, and monitoring the central venous pressure. As regards antibiotic therapy, all the patients received penicillin (2 MU. 6-hourly) and streptomycin (0·5 g. b.d.), except where indicated to the contrary.

At the time of operation about 5 g. of noxythiolin powder were dissolved in 500 ml. of normal saline and liberally lavaged around the peritoneal cavity until the fluid returning was completely clear; if contamination was severe another 500-ml. aliquot was prepared. It was interesting to note that the solution seemed to be very effective at detaching fibrinous plaques from the bowel wall. When the operative treatment had been concluded, a large sterile Ryle's tube was inserted via a stab wound into the peritoneal cavity, the tip of the Ryle's tube being adjusted to lie in the position where maximal sepsis would be expected to occur, i.e., in the pouch of Douglas where a low large-bowel anastomosis had been carried out for either perforated diverticulitis or carcinoma. Two corrugated drains were usually introduced by separate stab incisions to permit free egress of the drainage fluid—ileostomy bags could always be fitted around these. While the main operation wound was being closed the assistant gently poured in more diluted noxythiolin solution.

During the postoperative period the Ryle's tube was connected to a conventional drip arrangement, and noxythiolin solution, again in the concentration of 5 g. of noxythiolin to 500 ml. of normal saline, was dripped in continuously every 12 hours; the drainage fluid was collected in loosely attached ileostomy bags around the drain sites. The total period of postoperative irrigation varied from 24 to 72 hours depending quite empirically on the estimated degree of contamination. When it was decided to conclude the irrigation, the Ryle's tube was withdrawn from the abdomen in the usual way and the tip was cut off and sent for culture.

The selection of cases for this method was fairly discriminatory, all the patients included in this series being desperately ill and in real danger of perishing. Furthermore, the patients were all aged 45 years or over. As the studies of intraperitoneal noxythiolin seemed to be rather limited at the time when the present series was undertaken, although no untoward effects have been recorded so far, it was felt unjustifiable to use this agent on young people, and in particular no children with peritonitis complicating appendicitis were treated by this method.

The choice of the dosage régime was rather empirical, and it may in future be possible to use larger doses. No untoward effects were noted in this series.

CASE REPORTS

Case 1.—Mrs. G. A. aged 56 years, was admitted on 26 Feb., 1970, with signs of a generalized peritonitis. The patient had had little previous medical history except an anterior colporrhaphy operation carried out in 1964. She also had had a peri-urethral abscess.

Laparotomy (26 Feb.) revealed a generalized peritonitis which appeared to be primary, as no other pathological lesion could be found in the abdomen. The abdominal cavity was irrigated with noxythiolin. Postoperatively the noxythiolin solution (1 per cent) in normal saline was run in via the Ryle's tube in the peritoneal cavity for 24 hours.

Swabs of the peritoneal cavity at operation grew haemolytic *Streptococcus*, and the tip of the Ryle's tube when sent for culture was sterile.

The patient did extremely well postoperatively, there being no wound infection and no significant postoperative pyrexia.

Case 2.—Mr. C. C., aged 73 years, was admitted in March, 1970, with a 72-hour history of lower abdominal pain which was getting progressively worse, associated with severe anorexa and vomiting and also symptoms of tenesmus. On examination the patient appeared to be rather 'toxic' with a temperature of 37·8° C. with signs suggestive of peritonitis in the lower abdomen. In particular he was extremely tender per rectum.

Laparotomy through a lower right paramedian incision revealed a gangrenous appendix in the rectovesical pouch and a very severe pelvic peritonitis, with multiple loops of small bowel in a pool of pus. Appendicectomy was carried out and the loops of bowel were liberated from the pelvic sepsis, the pelvic cavity being washed out liberally with large quantities of noxythiolin solution. A Ryle's tube was inserted through a stab wound and the tip was left in the rectovesical pouch which was irrigated for 48 hours postoperatively. The patient had no serious postoperative pyrexia and recovered extremely quickly. Culture of the tip of the irrigating catheter was sterile.

Case 3.—Mr. R. H., aged 48 years, was seen urgently in the surgical clinic on 2 July, 1970, with intense pain in the left iliac region which had developed over the preceding 48 hours. On examination he was found to be tender in the left iliac fossa, but there was nothing to suggest either obstruction or generalized peritonitis. Straight radiographs of the abdomen in the erect film revealed a small quantity of gas under the right diaphragm, and it was concluded that the patient had had an attack of acute diverticulitis with possible localized rupture of either an abscess or a diverticulum. He was treated conservatively to begin with, but a barium-enema examination revealed an unequivocal carcinoma at the lower sigmoid area.

Laparotomy (14 July) through a left lower paramedian incision revealed a carcinoma of the lower sigmoid which had perforated locally, and numerous loops of small bowel were adherent to it. The loops of bowel were dissected free but with spillage of a great deal of pus from the larger pericolic abscess around the growth. A formal resection was carried out with end-to-end anastomosis, the peritoneal cavity being liberally irrigated with noxythiolin solution and a Ryle's tube being left down to the rectovesical pouch. The patient was irrigated for 72 hours postoperatively. He did extremely well, pyrexia was not a problem, and the wound healed cleanly.

The swab from the abscess grew a heavy colony of *Escherichia coli* organisms, but the Ryle's tube which had been left in the rectovesical area was sterile when withdrawn.

Pathology of the specimen revealed a deeply infiltrating carcinoma.

Case 4.—Mrs. G. S., aged 62 years, was admitted on 29 July, 1970, with signs and symptoms suggestive of advanced pelvic peritonitis. This had appeared very quickly in the space of about 48 hours. She did, however, give a history of some bowel irregularity for 3 months.

This patient was explored immediately because of the severity of her signs and a perforated carcinoma of the rectosigmoid area was encountered with very severe faecal peritonitis. An immediate resection of the neoplasm was carried out with end-to-end anastomosis and a Ryle's tube was left down to the area of the anastomosis after irrigating the peritoneal cavity with noxythiolin. The patient was irrigated for 48 hours postoperatively with noxythiolin solution. The tip of the Ryle's tube was sent for culture and grew coliform bacilli in rather scanty numbers.

Histology of the resected specimen showed the presence of a deeply infiltrating carcinoma.

Case 5.—Mr. T. O'D., aged 48 years, had been investigated at the surgical out-patients' department for some time with abdominal pain and some evidence of chronic gastro-intestinal blood-loss; barium studies had been equivocal.

The patient was admitted on 14 Aug., 1970, with evidence of haematemesis and melaena and was initially treated conservatively. Forty-eight hours later he had a fresh attack of haematemesis and it was noted that the vomit smelt faeculent. He was explored through a left paramedian incision, when a huge fungating carcinoma of the splenic flexure was encountered which had invaded the greater curvature of the stomach. The main tumour, which was the size of a pineapple, was mostly outside the bowel and the stomach, but was obviously the cause of a malignant gastrocolic fistula which accounted for the patient's faeculent vomiting.

The tumour was dissected free from the retroperitoneal parietes which it had invaded and the attached spleen was removed. A Billroth-I gastrectomy and a large segmental resection of the splenic flexure of the colon were also carried out to achieve clearance. During the dissection there was wholesale spillage not only of faeculent material but also of masses of polypoid malignant tissue.

Postoperatively the patient had a rather stormy course with a high swinging pyrexia (the only patient in this series to do so). The Ryle's tube was left in the left subphrenic space as this was thought to be the area of maximum contamination. The perfusion was run for 72 hours at the usual rate of 500 ml. per 12 hours, with 5 g. of noxythiolin in each bottle, and the effluent drained from two quite large flank drains (*Figs.* 1, 2).

The indwelling Ryle's tube was removed after 72 hours and the tip was amputated and sent for culture. This grew a heavy growth of coliform bacilli. The patient was put on large doses of penicillin and streptomycin for the first 8 days postoperatively but was still running a high pyrexia and was 'switched' to intravenous cleporin (500 mg. 4-hourly). On the tenth postoperative day he developed sudden pain in the right side of the chest and it was assumed that he had sustained a pulmonary embolus. He was accordingly put on anticoagulants.

The patient made slow and steady progress and was eventually discharged 3 weeks after admission, with a slight discharging sinus where the Ryle's tube had been inserted which still grew coliform bacilli. Screening of the diaphragm had not revealed a subphrenic abscess and at the time of discharge his temperature had completely settled down.

Case 6.—Mr. S., aged 66 years, was admitted in August, 1970, with physical signs of a very advanced and severe peritonitis. The history was that he had had a partial gastrectomy carried out 15 years previously for a duodenal ulcer. He had suddenly developed cramping abdominal pains in the epigastrium about 6 hours prior to admission. On admission he showed signs of poor peripheral circulation with a tachycardia of 110 beats per minute and a blood-pressure of 100/50.

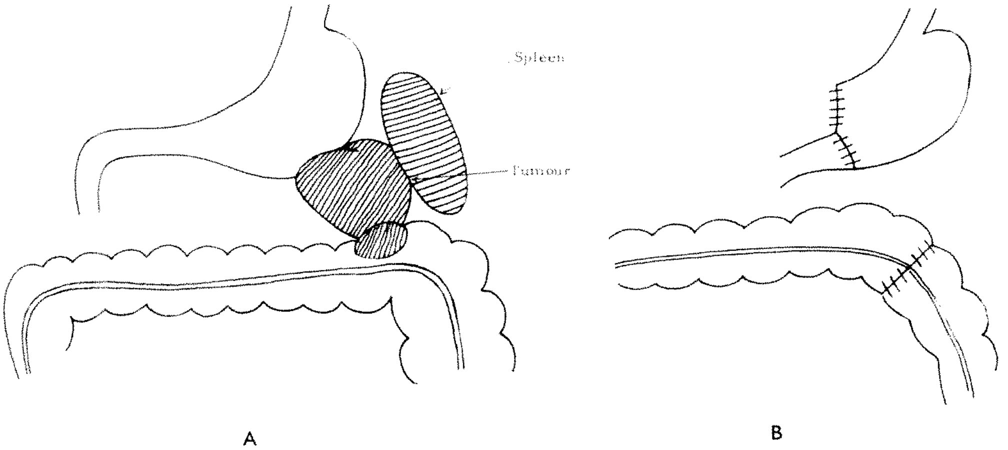

FIG. 1.—*Case* 5. A, Malignant gastrocolic fistula. B, After Billroth-I gastrectomy and left-sided large-bowel resection.

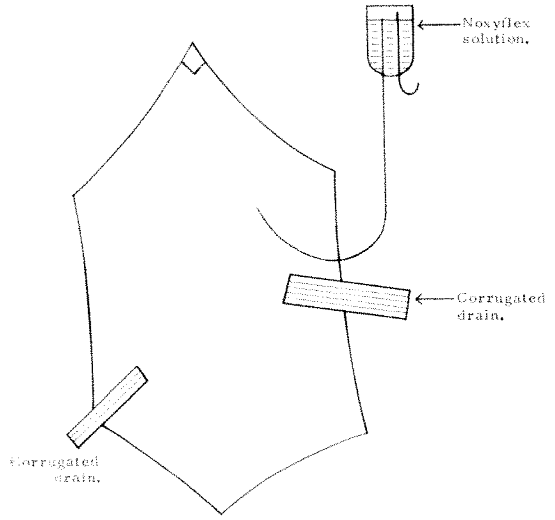

FIG. 2.—*Case* 5. Diagram of the irrigation of the peritoneal cavity using a sterile Ryle's tube inserted under the left cupola of the diaphragm. Two corrugated drains are inserted in the flanks bilaterally.

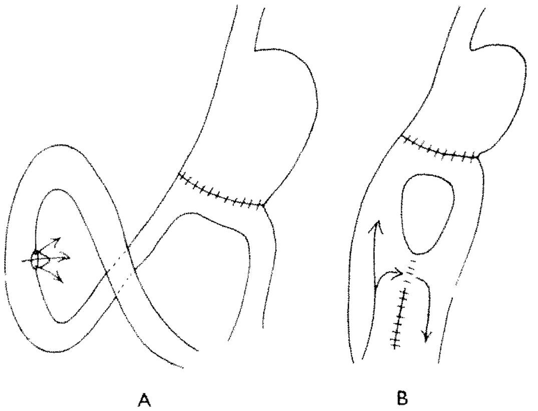

FIG. 3.—*Case* 6. A, The volvulus of the afferent loop of the gastrectomy with perforation of the bowel and consequent biliary peritonitis. B, Reduction of the volvulus with a wide entero-anastomosis between the afferent and efferent loops.

The radiographs of the abdomen were not particularly helpful and only showed a slightly 'ground-glass' appearance suggestive of free fluid in the abdomen.

After preliminary resuscitation, the patient was operated upon, and on opening the abdomen a very severe and profuse biliary peritonitis was encountered. The mechanism of this was found to be a volvulus of the afferent loop of the antecolic Polya gastrectomy around a band. The volvulus had obviously raised the intraluminal pressure in the afferent loop to such an extent that it had 'blown off' a perforation in the mesenteric border of the small bowel thus liberating the afferent loop contents into the peritoneum. The bowel comprising the volvulus was very oedematous and bruised but perfectly viable. The perforation was oversewn in two layers, the band was divided and the volvulus was reduced. In order to prevent this happening again the afferent loop of the bowel was sutured to the efferent loop of the gastrectomy and a wide entero-anastomosis was constructed. Noxythiolin was instilled at the time of operation and dripped in postoperatively for 48 hours (*Fig.* 3).

The patient did extremely well, and in the morning following the operation was reading a newspaper and showed no signs of toxicity.

The tip of the Ryle's tube when sent for culture was sterile.

Case 7.—Mrs. M. G., aged 88 years, had been treated in the out-patients' department for some considerable time for severe diverticulitis proved by repeated barium-enema examinations. Because of her generalized decrepitude it was decided to try to treat her conservatively.

Because of a recent exacerbation of her symptoms she had been admitted at the end of August, 1970, for a period of conservative management and assessment. At 8.00 a.m. on 4 Sept., whilst in hospital, she obviously developed a perforation of her diverticular bowel, with signs of gross peritonitis and poor peripheral circulation. After a period of intensive resuscitation she was operated on approximately 3 hours after the onset of her symptoms. Through a left paramedian incision it was found that she had a gross faecal peritonitis. The peritoneal cavity was washed out with noxythiolin solution and a badly perforated sigmoid colon was encountered, the perforation being through a large diverticulum pointing laterally. An immediate sigmoid colectomy was carried out with end-to-end anastomosis, and a Ryle's tube was left down to the pouch of Douglas and was brought out through a small stab incision. In addition two corrugated drains were also inserted.

The patient had a reasonably smooth postoperative progress to begin with, her ileus settling down after about 72 hours, at which time the noxythiolin infusion was stopped. The tip of the Ryle's tube was sent for culture and was sterile.

On the fourth postoperative day the patient was passing one motion per rectum and was drinking very well. However, her cardiovascular state was not very good and she developed a congestive cardiac state which gradually got worse and she died on 21 Sept. from general decrepitude and a bad heart, but there was no indication of any further abdominal trouble.

Histology of the resected specimen of sigmoid colon confirmed the original diagnosis of severe diverticulitis.

Case 8.—Mr. J. R., aged 61 years, was admitted on 8 Jan., 1971, at 12.30 p.m. with a history that at 7 a.m. he had been straining at defaecation and had suddenly developed a very severe pain in the 'pit of his stomach'. He had gone to work as a dispensing chemist's assistant but had found it quite impossible to carry on working. He denied any significant previous abdominal or bowel symptoms, but was on anticoagulants for a deep venous thrombosis in his left leg. On examination he had a completely rigid abdomen with absent bowel-sounds, a tachycardia of 120 beats per minute, and a blood-pressure of 110/70. His peripheral circulation was very poor, with a dense peripheral cyanosis.

After preliminary resuscitation and checking his prothrombin time he was operated on within an hour of admission.

At operation a fulminating faecal peritonitis was encountered. The sigmoid colon was quite severely affected with diverticulitis, and a perforation, 1·5 cm. in diameter, was encountered at the apex of the sigmoid loop. An immediate sigmoid colectomy was carried out with end-to-end anastomosis and the appendix was removed. The peritoneal cavity was irrigated with noxythiolin solution and a Ryle's tube was left down to the site of the anastomosis and brought out through a stab drain site. Noxythiolin was dripped into the peritoneal cavity for 72 hours postoperatively. The tip of the Ryle's tube was sent for culture and found to be sterile, as was a wound swab. The patient did extremely well postoperatively, never developing a temperature of above 36·7° C. By the fourth day his ileus had settled down and he was passing flatus per rectum, and he started passing a motion on the fifth day quite normally.

His wound healed perfectly and he was discharged 12 days after operation. Histology confirmed the original diagnosis of diverticulitis.

Case 9.—Mr. J. F., aged 35 years, was admitted on 2 April, 1971, from another hospital with a 2-year history of recurrent severe attacks of pancreatitis. On examination he was found to have evidence of a mass in the left hypochondrium which was felt to be an inflammatory pseudocyst of the tail of the pancreas. He was explored on 14 April when a huge collection of fluid was found in the tail of the pancreas overlapping the left kidney which was drained and found to contain a mixture of blood-clot and pancreatic juice. This was drained externally via a large Malecot catheter.

Postoperatively the patient complained of recurrent upper abdominal discomfort which suddenly became worse on the morning of 29 April at 7.00 a.m. when he presented with an obvious upper abdominal peritonitis. A provisional diagnosis of a perforated stress ulcer was made, and he was resuscitated and operated on as quickly as possible.

At the second laparotomy a large perforated duodenal ulcer was encountered with evidence of widespread peritonitis. There was also evidence of continued pancreatitis, all the tissues in the gastroduodenal area having the consistency of friable wet cheese. With extreme difficulty a tag of omentum was secured and sutured across the perforation with interrupted atraumatic thread sutures. Because of the very grave mixture of a perforated duodenal ulcer in the presence of an active pancreatitis it was decided to irrigate the peritoneal cavity with noxythiolin, both by lavage at operation and by a postoperative drip. The Ryle's tube was left in Rutherford Morrison's pouch and irrigation was carried out for 72 hours postoperatively.

It had been noted before the second laparotomy that the contents of the drainage-tube from the pancreatic pseudocyst were growing a mixture of coliforms, anaerobic streptococci, and *Pseudomonas*. The tip of the Ryle's tube was sent for culture when removed on the third day and was found to be sterile. The patient's condition improved dramatically after the second laparotomy and apart from several episodes of quite severe abdominal pain, which were thought to be due to recurrent minor bouts of pancreatitis, he made steady progress and showed no signs of continued intra-abdominal sepsis. His wound became slightly infected but this settled down quite quickly and he was eventually discharged on 2 June, 1971.

DISCUSSION

The use of per- and postoperative lavage of the peritoneal cavity in a systematic attempt to eradicate infection from the peritoneal cavity in the case of fulminating peritonitis does not appear to have attracted the attention it deserves.

Historically the first reference found in the literature was that of Joseph Price of Philadelphia (1905), who used sterile water in large amounts at the time of laparotomy. In 1910 Deaver argued that this was not indicated, and in fact was frankly dangerous as it might very well spread the infection elsewhere in the peritoneal cavity. Franz Torek (1911) in the period 1911–14 appears to have been very much in favour of peroperative irrigation, and is recorded as making long incisions in cases of peritonitis and using very large quantities of water to irrigate the peritoneal cavity. It is interesting to note that he did not permit the use of sponges or swabs in the peritoneal cavity whilst this was going on. He is reported to have reduced the mortality of diffuse peritonitis at that time from a uniform 100 per cent to approximately 40 per cent incidence.

There the matter appears to have remained dormant until the classic paper of Burnett, Brown, Rosemond, Caswell, Buchor, and Tyson (1957) from Philadelphia. They record the case of a young man seen by them in 1942 with a catastrophically severe peritonitis complicating a neglected appendicitis. At that time they washed his peritoneal cavity out with 500 ml. of normal saline containing 0·8 per cent sulfanilamide and left a metal sump drain down to the pelvis. This young man recovered very quickly and his maximum postoperative temperature was not above 37·4° C. Burnett and others were very much impressed by this case and they treated a series of 3 cases of severe peritonitis by this method, but substituting antibiotics for the sulphonamide that they had employed of necessity in 1942. In their cases the lavage was carried out at the time of operation but no attempt was made to carry out irrigation in the postoperative period. They proceeded to perform experimental studies in animals with severe experimental peritonitis and found that the best results were achieved by lavage of the peritoneal cavity with a saline solution of penicillin and streptomycin with the exhibition of these antibiotics intramuscularly for 48 hours postoperatively.

Table I.—DETAILS OF THE PRESENT SERIES

CASE NO.	AGE (years)	OPERATIVE FINDINGS	PROCEDURE	POSTOPERATIVE PYREXIA AND PROGRESS	WOUND	ANASTOMOTIC LEAK	CULTURE OF CATHETER
1	56	Peritonitis (haemolytic *Streptococcus*)	Irrigation with noxythiolin	Nil Excellent	Very clean	None	Sterile
2	73	Peritonitis (perforated appendicitis)	Appendicectomy with irrigation with noxythiolin	Nil Excellent	Very clean	None	Sterile
3	48	Perforated carcinoma of the sigmoid colon	Sigmoid colectomy and noxythiolin irrigation	Nil (significant) Excellent	Very clean	None	Sterile
4	62	Perforated carcinoma of the rectosigmoid colon	Anterior resection and noxythiolin irrigation	Nil (significant) Excellent	Clean	None	Scanty growth of coliforms
5	48	Malignant gastrocolic fistula (carcinoma of the colon; splenic flexure) (*see Figs.* 1 and 2)	Billroth-I gastrectomy; resection of splenic flexure; splenoid growth completely removed	Very severe (but no subphrenic abscess) Stormy progress but survived	Very infected	None	Heavy growth of coliforms
6	66	Volvulus of afferent loop of gastrectomy with severe biliary peritonitis (*see Fig.* 3)	Reduction of volvulus; suture of perforation; fixation of afferent to efferent loop; entero-anastomosis	None Excellent	Very clean	None	Sterile
7	88	Faecal peritonitis and perforated diverticulitis	Sigmoid colectomy	Nil, but died from heart failure	Clean	None	Sterile
8	61	Faecal peritonitis (from a perforated diverticulitis)	Sigmoid colectomy	Nil Excellent	Clean	Nil	Sterile
9	38	Pancreatitis and perforated stress duodenal ulcer	Closure of perforation with great difficulty	Nil (significant) Slow progress but made a complete recovery	Troublesome wound infection, grew coliforms	Nil	Sterile

Artz, Barnett, and Grogan (1962) point out the magnitude of the problem that severe peritonitis presents, and indicate that the mortality from peritonitis in the Mississippi University Medical School in the period 1955–60 was 34·5 per cent. Artz and others carried out an extremely extensive experimental survey in dogs with faecal peritonitis and showed that the best results were obtained with early irrigation of the peritoneal cavity in combination with antibiotic therapy. They quote the experimental work of Schatten and Abbott (1953), who used a dog model of appendiceal peritonitis and showed that under these circumstances intravenous Terramycin produced a mortality rate of 100 per cent, whereas when it was instilled intraperitoneally the mortality rate was 41·1 per cent.

Other studies of intraperitoneal antibiotics include that of Cohn and Cotlar (1962), who showed the beneficial effect of intraperitoneal kanamycin on experimental peritonitis in dogs, and went on to use this in a large series of 128 patients with peritonitis (the majority of whom were suffering from either appendicitis or perforated peptic ulcer), with an overall mortality of 8·9 per cent. They employed a dose of 1·9 g. of kanamycin suspended in 50 ml. of normal saline in their patients, but they do not lay very great stress on intraperitoneal lavage in the postoperative period.

Two rather more important papers in recent years have demonstrated the potential value of supplementing peroperative lavage with postoperative irrigation of the peritoneal cavity. First, Schumer, Lee, and Jones (1964), in a largely experimental study, demonstrated the value of intermittent postoperative irrigation with antibiotic solutions in guinea-pigs with peritonitis. Secondly, McKenna, Currie, McDonald, Mahoney, Finlayson, and Lawsham (1970) studied two matched groups of 25 patients each suffering from fulminating peritonitis over a 3-year period. The first group was treated by purely conventional measures, i.e., fluid and electrolyte replacement, antibiotics, and laparotomy to define and treat the precipitating lesion. The mortality in this group was over 50 per cent. In the second group the patients were treated in exactly the same manner but, in addition, the peritoneal cavity was irrigated at the time of the laparotomy with up to 4 litres of a balanced salt solution. Two infusion cannulas were left in the subhepatic spaces at the termination of the laparotomy, and two large sump drains were also left in each iliac fossa to drain off the fluid. In the postoperative period the peritoneal cavity was irrigated with large amounts of a balanced salt solution (up to 16 litres in the first 8 hours) which contained 25 mg. of kanamycin and 1 MU. of penicillin in each litre. By these measures the mortality in this group was reduced by 40 per cent and the morbidity by an estimated 50 per cent. Of great interest in this very thorough piece of work was the fact that peritoneography with Conray 60 was carried out in the postoperative period in 5 patients and showed that there was free perfusion to all the recesses of the peritoneal cavity.

The experimental work of Filler and others (1966) and Filler and Sleeman (1967) leaves very little doubt that one of the principal lethal factors in peritonitis is the continuance of infection in the peritoneal cavity. By using very elegant labelled-dye experiments they demonstrated that the presence of haemoglobin and its derivatives seems to block the absorptive 'pores' of the peritoneal lining. By the same token, residual loculated infection in the peritoneal cavity, particularly in association with haemoglobin derivatives, is very recalcitrant to the entry of antibiotics given by conventional parenteral means.

Browne and Stoller (1970), in a combined experimental and clinical study, have used the agent noxythiolin in the treatment of faecal peritonitis. Their experimental studies, using rats, mice, and guinea-pigs suffering from *E. coli* peritonitis, indicated the dramatic improvement in mortality gained by exhibiting this agent, and also the remarkable lack of toxicity. Clinically their study was confined to faecal peritonitis complicating perforated lesions of the large bowel, and they emphasized the very high mortality from this condition as described in the literature. Goligher and Smiddy (1957) reported a mortality of 70 per cent, whilst Dawson, Menon, and Roxburgh (1965) recorded a figure of 77 per cent. Browne and Stoller (1970) reported a series of 23 patients with faecal peritonitis treated by conventional measures but in addition irrigation was carried out with proflavine solution at operation, and the abdomen was then closed leaving behind 2·5–5 g. of noxythiolin in 100 ml. of sterile water, but without any postoperative infusion. Their results are very encouraging with a mortality of only 3 out of 23 patients, and 2 of these deaths were due to pulmonary embolism. From the table of their cases it does not appear as though a left-sided colonic resection was carried out with end-to-end anastomosis for either perforated carcinoma or diverticulitis of the descending colon or sigmoid.

Noxythiolin is not an antibiotic. Chemically it is oxymethylene methyl-thiourea, and although its beneficial effect is not fully understood it is thought possible that it decomposes with the liberation of small quantities of formaldehyde as follows:—

$$CH_3 \cdot NH \cdot CS \cdot NH \cdot CH_2OH \longrightarrow CH_3 \cdot NH \cdot CS \cdot NH_2 + HCHO.$$

As Browne and Stoller (1970) emphasize, noxythiolin seems to be an antibacterial agent effective *in vitro* against all micro-organisms, including those that are completely resistant to other antibacterial agents (Horsfield, 1967). This argues that one of the greatest advantages that noxythiolin has over any antibiotic in the peritoneal cavity is that resistant organisms will not develop. That the action of noxythiolin is not specifically antiseptic is suggested by the interesting work of Wright and McAllister (1967), who gave lethal doses of pure endotoxin to mice and found that noxythiolin had a highly significant protective effect. One other effect has recently been discovered by Jamieson (1970), who found that HeLa cells grown in tissue culture in the presence of 0·025 per cent noxythiolin suffered severe cytotoxic changes. This correlated with the finding of Garrett (1969) that intravesical instillations of noxythiolin were a helpful adjunct in the treatment of bladder neoplasms submitted to radiotherapy. If noxythiolin were found to be cytotoxic to malignant cells in the peritoneum it would be a very useful agent, particularly in the prevention of seedlings from colonic tumours. Conventional measures taken to prevent peritoneal seeding by malignant cells are rather unsatisfactory, particularly as agents such as mercury salts and the mustards are highly toxic and might well delay wound healing.

The present series of 9 cases indicates a variety of causes of peritonitis (*Table I*). Noxythiolin solution has been used in large quantities (up to 1·5 litres at the time of operation), washing out the peritoneal cavity until the returning fluid was quite clear. The concentration has been 5 g. of noxythiolin to 500 ml. of normal saline. As Jamieson (1970) points out, the effective bacteriostatic concentration lies between 0·075 and 0·125 per cent, so that the concentration employed here should be perfectly effective, and furthermore the dose of intraperitoneal noxythiolin delivered at laparotomy has been fortified by a continuous intraperitoneal infusion for up to 72 hours postoperatively. An interesting corollary of this has been to send the tip of the infusing tube for culture, and in only 2 cases was any significant infection present, which, by extrapolation, must mean that the adjoining peritoneal cavity was sterile.

The most impressive finding in the present cases has been the remarkable lack of toxicity shown by the patients in the postoperative phase. On only 1 patient (*Case* 5) was there any significant difficulty with the postoperative 'toxicity'.

Study of the laparotomy wound has also been most instructive. In only 2 patients (*Cases* 5 and 9) was there any significant evidence of wound infection. Both these wounds when cultured grew *E. coli* organisms. The other wounds in the series healed with quite conspicuous rapidity and lack of complications. Although a series of 9 cases with a wound infection rate of 22 per cent is not really a statistically significant sample it is suggestive. All 9 patients by the nature of their intra-abdominal pathology were very much at risk as regards wound infection, and these findings are very much at variance with those of Bird, Bunch, Croft, Hoffman, Humphreys, Rhind, Rosenberg, Whittaker, Wilkinson, and Hall (1971), who employed noxythiolin in a series of appendicectomy wounds and found that no benefit accrued from its use. Two criticisms can be cited against their paper: first, they do not appear to have done any bacteriological studies on the wounds under observation; and secondly, they used noxythiolin powder instilled directly into the wound. Noxythiolin powder has a relatively low molecular weight and therefore as it is water soluble must have a relatively high osmotic activity, tending to absorb water into the wound cavity and possibly to accentuate the formation of haematomas. Furthermore, if one assumes that noxythiolin breaks down with the liberation of formaldehyde this will *a fortiori* potentiate the osmotic activity of the solution locally in the wound cavity and leads to possibly damaging concentrations of formaldehyde in the wound. It is suggested that it would be rather more instructive to carry out a clinical trial of abdominal wounds using a more physiological concentration of noxythiolin in saline solution and it is hoped to do this in the near future. In this context it is interesting to record that in none of these cases was any brownish discoloration found around the wound, in contrast to the findings of Bird and others (1971).

The final point of discussion arises from doing emergency left-sided resections of the large bowel (5 in this series) with end-to-end anastomosis rather than the classic three-stage procedure in cases of perforated lesions of large bowel. Roxburgh, Dawson, and Yeo (1968) have presented a series of patients with perforated diverticulitis, and point out that the results obtained from immediate resection are very much superior to those of simple transverse colostomy and drainage of the perforated area, this latter procedure doing nothing for the basic pathology except diverting the faecal stream; furthermore, elderly people will not tolerate repeated operative interventions. The conclusion that immediate resection is the procedure of choice in the treatment of large-bowel pathology is borne out by Madden (1967), who over a 16-year period compared the results of treating perforated lesions of the large bowel by primary resection against staged procedures. The mortality-rate in patients treated by the former method was 8 per cent, and by the latter 35 per cent. In the context of this paper it is interesting to note that Madden recommended the instillation of 300 ml. of a penicillin solution (50,000 U. per mn.) at the time of operation.

In conclusion it is suggested that in the light of Browne and Stoller's (1970) paper on the use of noxythiolin at the time of operation, and the series of McKenna and others (1970) using very large quantities of irrigating fluid containing kanamycin and penicillin postoperatively, the best solution may well be to use noxythiolin at the time of operation in large quantities and to perfuse the peritoneal cavity postoperatively with the same agent via a strategically situated irrigating catheter. The advantages of noxythiolin are its lack of toxicity and the fact that, as far as is known, bacteria are not capable of producing noxythiolin-resistant mutants. Finally, the exciting work of Jamieson (1970) suggesting that noxythiolin has carcinostatic properties would make it ideal for use in intra-abdominal malignancies where the mustard compounds and mercury salts are not without real hazard.

In conclusion, it is emphasized that the dose régime used here is purely empirical, and it may well be that larger volumes and more prolonged perfusion times are feasible.

Acknowledgements.—In the preparation of this paper I am indebted to Mr. Rodney Smith, of St. George's Hospital, London, and Mr. R. L. Canney and Mr. B. A. Lilwall, of the Kent and Canterbury Hospital, under whose care the patients discussed in this paper were admitted, for their helpful advice and encouragement.

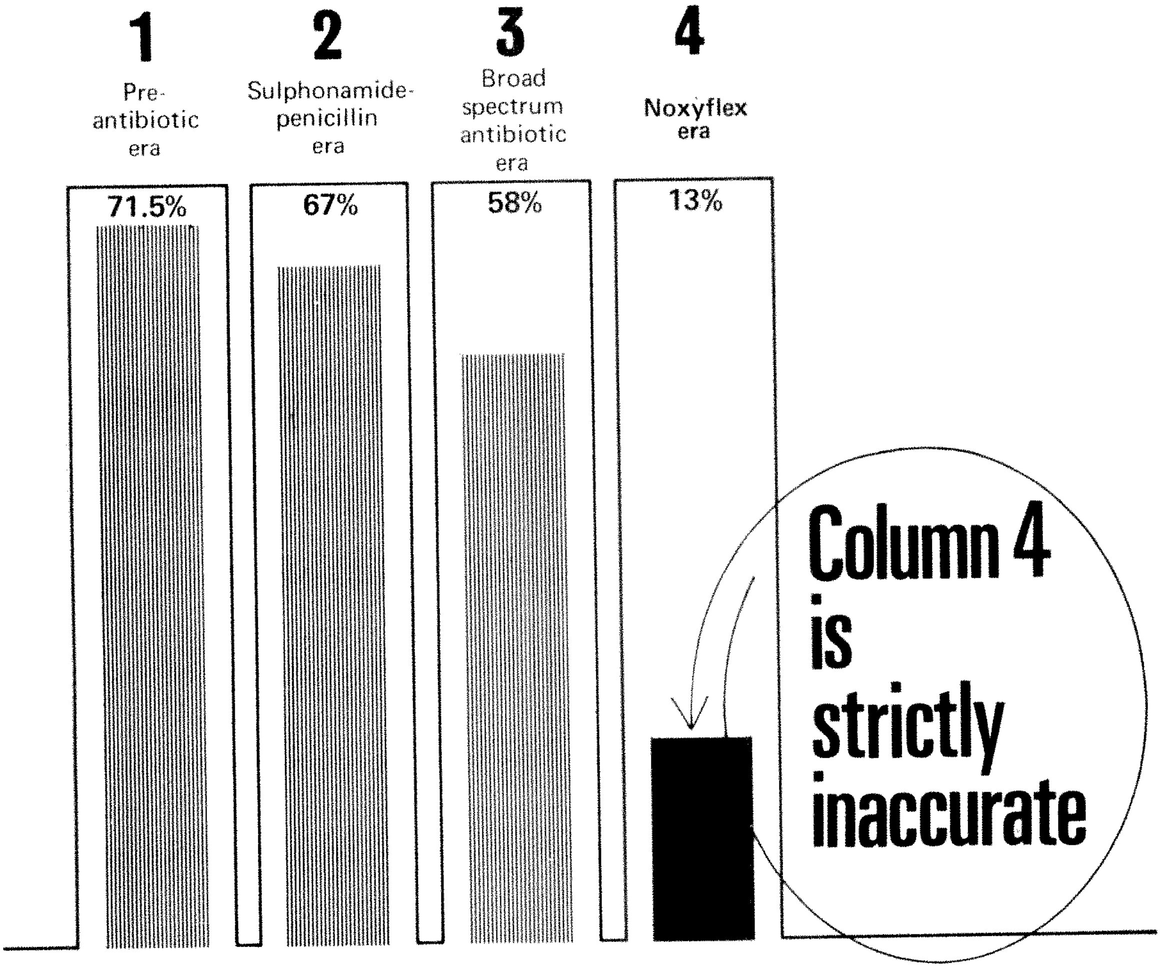
The graph below compares mortality rates due to faecal peritonitis, era by era.
It is not pedantically accurate because its sources differ. But the point is fairly made.



Column 4 is strictly inaccurate

Why inaccurate? Because column 4 refers to 23 cases of faecal peritonitis which were treated successfully with Noxyflex. But the *3 deaths which occurred were due to causes other than peritonitis - as post-mortem revealed. **The mortality rate due to peritonitis can therefore be regarded as zero.**

* The whole graph, and the causes of the deaths referred to are the subject of the new Noxyflex folder "Why three deaths?" You will receive at least one copy!

When bacterial contamination of the peritoneum is diagnosed or suspected: Noxyflex

Now ICI bring to surgical scrubs the proven advantages of Hibitane in

hibiscrub

TRADE MARK

Antibacterial Activity

From the bacteriological point of view the demand is for a surgical scrub which combines maximum antibacterial activity with pronounced residual effect.

'Hibiscrub' fulfills these requirements. It is not only rapidly effective against both gram positive and gram negative organisms but also exhibits good residual activity – a major advance in the development of surgical scrubs.

Hand Care

The effect of prolonged usage on the hands of surgical staff is a critical factor in the acceptability of any surgical scrub. Sensitivity reactions, excessive detergency etc., can lead to the abandonment of certain scrub regimes.

'Hibiscrub' is positively pleasant to use – nurses using it regularly have reported on the excellent condition of their hands.

KEEPING THE STERILE FIELD STERILE

—that is the objective of patient drapes in theatre

BARRIER* Theatre Drapes — unlike absorbent cotton drapes — are treated to resist strike-through of fluids — thus reducing the risk of bacterial transfer to the open wound.

BARRIER* Theatre Drapes also provide a number of other advantages:—

✳ Drapes are folded, cuffed and marked for convenient, aseptic handling.

✳ A full range of both composite and single item drape sets are available for the majority procedures.

✳ Presented in both sterile form and for inclusion in hospital prepared packs.

✳ Complemented by an advanced and unique drape system of absorbent/repellent adhesive towels.

✳ Completely disposable, reducing the work load in service departments and eliminating associated laundry problems.

SPONTANEOUS RUPTURE OF THE OESOPHAGUS

AVOIDANCE OF POSTOPERATIVE MORBIDITY

BY M. R. B. KEIGHLEY,* R. W. GIRDWOOD, M. I. IONESCU, AND G. H. WOOLER
DEPARTMENT OF CARDIOTHORACIC SURGERY, THE GENERAL INFIRMARY AT LEEDS, AND LEEDS UNIVERSITY

SUMMARY

Twelve cases of 'spontaneous rupture' of the oesophagus occurring over a period of 20 years (1951–71) are reviewed. The principal clinical and radiological features are described and the factors concerned in the pathogenesis of this condition are discussed. Although the mortality rate in this study was low (8 per cent) the incidence of severe postoperative complications was considerable, occurring in 10 of the 11 operative survivors. The importance of early diagnosis and adequate surgical treatment in the avoidance of this high morbidity is stressed.

SPONTANEOUS perforation of the oesophagus is no longer rarely documented in the literature and early clinical recognition is becoming increasingly common (Barrett, 1946; Mackler, 1952; Sealey, 1963). Although survival from the event without surgical treatment was extremely rare (Anderson, 1952) the results of direct suture of the torn oesophagus have indicated that this previously lethal condition can now be successfully treated (Barrett, 1947).

Despite comprehensive accounts of the clinical and radiological features (Christofordis and Nelson, 1957; Toghill, MacGuire, and Raut, 1968), spontaneous perforation still carries an alarming morbidity and mortality (Tuttle and Barrett, 1963).

This report re-evaluates the importance of early diagnosis and adequate operative repair not only to reduce the mortality of spontaneous rupture but also to avoid the considerable morbidity associated with a prolonged convalescence in those who survive.

CLINICAL MATERIAL

The records of all the patients admitted to the Thoracic Surgical Department of the General Infirmary at Leeds with spontaneous rupture of the oesophagus during the 20-year period between 1951 and 1971 were studied. The presenting clinical and radiological features were recorded and the factors concerned in the aetiology, mortality, and morbidity were analysed.

A diagnosis of spontaneous rupture of the oesophagus was made in 14 patients. Two of these occurred after lung resection for carcinoma, and although the site and appearances of the perforation in these cases were similar to those of the remaining 12 patients the question of operative damage to the oesophagus could not be excluded. For this reason these 2 cases were discarded from the present analysis and are described elsewhere. The remaining 12 subjects provide the basis of this report.

Incidence, Age, and Sex Distribution.—The annual incidence showed a slow decline from 1951 to 1971. This was largely the result of a steady fall in the admission of non-cardiac cases to the present unit and the frequent management of spontaneous rupture entirely by general surgical units. The records department of this hospital confirmed this trend, particularly over the last 5 years of this review.

The majority of these patients were men (75 per cent) and the average age was 57 years (range, 45–75 years).

Table I.—CLINICAL FEATURES OF 12 CASES OF 'SPONTANEOUS RUPTURE' OF THE OESOPHAGUS

Feature	*No. of Cases*
Predisposing factors	
Vomiting	12
Suppressed vomit	7
Alcohol	5
Large meal	5
Associated oesophageal pathology	
Hiatus hernia	2
+ Oesophagitis	1
Post-cricoid web	1
Mallory–Weiss tear	1
Symptoms	
Sudden chest pain and dyspnoea	11
Abdominal pain	7
Phrenic nerve irritation	4
Signs	
Pneumothorax or effusion	8
Abdominal signs	8
Surgical emphysema	7
Cyanosis	5
Radiographic features	
Hydropneumothorax	8
Effusion only	3
Mediastinal emphysema	3
Pneumoperitoneum	1

Presenting Features.—With only 1 exception all the patients presented with severe chest pain and dyspnoea. Physical examination revealed air or fluid in the affected hemithorax in 8 patients, and 5 patients were also cyanosed on admission. In addition to these features 7 patients complained of severe abdominal pain with clinical signs of upper abdominal peritonitis, and 4 patients had a history of phrenic nerve irritation with shoulder-tip pain. Surgical emphysema of the neck was present in 58 per cent (*Table I*).

There was only 1 case in whom a chest radiograph did not confirm the presence of air or fluid in the affected pleural cavity. Mediastinal emphysema was seen in 3 patients, and only 1 patient had radiographic evidence of air in the peritoneal cavity (*Table I, Fig.* 1).

Diagnosis.—A gastrografin swallow performed in 8 patients was without exception both diagnostic of oesophageal perforation and provided evidence of the site and extent of the leakage. The results of oesophagoscopy as a diagnostic measure were less reliable, with evidence of rupture in only 4 of the 6 patients in whom preoperative oesophagoscopy was performed.

The time lapse between perforation and diagnosis was analysed. The patients fell into four groups: 25 per cent presented within 6 hours of perforation, 25 per cent between 6 and 24 hours, a further 25 per cent between the first and second days, and the remainder (25 per cent) after 48 hours. In the latter group the diagnosis was in fact made between the fifth and twelfth days after perforation (*Fig.* 2).

---

* Present address: Surgical Registrar, Leeds (St. James's) University Hospital, Leeds LS9 7TF.

A high incidence (50 per cent) of diagnostic error occurred. Three patients were taken to the operating theatre with a diagnosis of perforated peptic ulcer; in 2 of these cases an ulcer was found at laparotomy and a gastrectomy was performed before they were referred to the thoracic department. Two cases were admitted under their physicians with a suspected myocardial infarction, and another patient was treated for 3 days for a spontaneous pneumothorax. Pulmonary embolus and pneumonia were also considered in the initial diagnosis of 2 other cases.

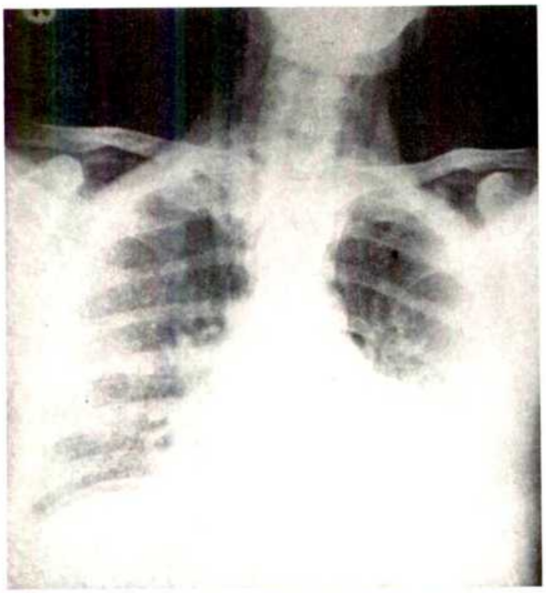

FIG. 1.—Anteroposterior chest radiograph demonstrating surgical emphysema of the neck, a pneumoperitoneum, and fluid in the affected hemithorax.

Table II.—OPERATIVE FINDINGS IN 12 CASES OF 'SPONTANEOUS RUPTURE' OF THE OESOPHAGUS

Finding	*No. of Cases*
Site of rupture	
Lower third	11
Middle third	1
Average length of tear	
Muscle, 4 cm.	(12)
Mucosal tear, 5·75 cm.	(7)
Direction of tear longitudinal	(10)
Side of rupture	
Left	11
Right	1
Extent of rupture	
Into pleura	11
Confined to mediastinum	1
Soiling of peritoneum	1

The figures in parentheses refer to the total number of cases where a record was made of the operative findings in question.

Operation Findings.—The site of rupture was recorded within the lower third of the oesophagus in all except 1 patient. In this case a longitudinal tear was identified at the level of the left main bronchus associated with a large mediastinal abscess. It was interesting to note that a long history of oesophagitis was recorded in this patient. Additional involvement of the cardia by spontaneous rupture occurred in 2 cases in whom a concomitant hiatus hernia was also demonstrated.

The operative records describe the tear as being longitudinal in direction, posterolateral in position, and predominantly on the left side (*Table II*). The length of the rupture measured an average of 4 cm. In 7 patients in whom the extent of the mucosal tear was also recorded it was found to be consistently longer, with an average length of nearly 6 cm.

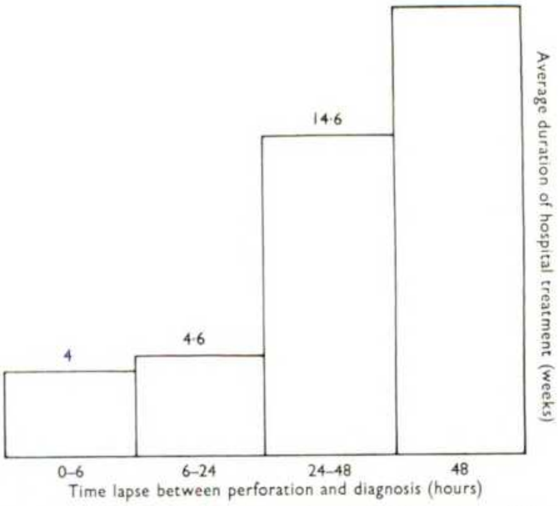

FIG. 2.—The relationship between the time of diagnosis and the morbidity.

Table III.—RESULTS OF TREATMENT IN 12 CASES OF 'SPONTANEOUS RUPTURE' OF THE OESOPHAGUS

Result			*No. of Cases*
Mortality			1
Morbidity from early complications			10
Empyema	7		
Oesophagopleural fistula	4		
Leaking suture line	3	Defined by contrast radiology	
Early stricture	3		
Subphrenic abscess	2		
Persistent sinus	1		
Renal failure (dialysis)	1		
Mediastinal abscess	1		
Morbidity from late complications			2
Longstanding stricture	1		
Chronic osteomyelitis	1		
Reoperation for complications			6
Rib resection/decortication	5		
Secondary anastomosis	3		
Jejunostomy	3		
Drainage of subphrenic space	1		

Treatment and Results.—Direct suture of the perforation was undertaken in every case despite a late diagnosis at over 5 days in 3 patients. Jejunostomy was also undertaken as a primary or secondary procedure in 5 patients. There was only 1 death in this series (an incidence of 8 per cent); this occurred following a delay in diagnosis in a patient referred to us 7 days after the onset of chest pain. He was admitted moribund with a tension pyopneumothorax. Despite immediate decompression and attempted resuture he died 24 hours after operation.

The incidence of postoperative complications as seen in *Table III* was considerable, occurring in 10 of the 11 survivors. These complications were largely the result of further leakage from the site of perforation, resulting in the formation of empyemata, oesophagopleural fistulae, a mediastinal abscess, and a persistent sinus in the wound. Evidence of leakage or stricture formation at the suture line was shown on postoperative contrast radiology in half of the cases. Subphrenic abscess formation was also demonstrated in 2 patients, suggesting leakage into the peritoneal cavity either before or after repair of the rupture.

These complications were attended by prolonged hospital stay, ranging from 2 to 22 weeks after operation, and in 3 patients the length of hospital stay exceeded 3 months. *Fig.* 2 shows a close relationship between the time the diagnosis was made after the perforation and the duration of hospitalization owing to postoperative complications.

Secondary surgical treatment for postoperative complications was undertaken in 50 per cent of the cases and in many of them more than one procedure was required (*Table III*).

Late complications occurring a year after the onset of perforation were recorded in only 2 cases. One patient developed chronic osteomyelitis in the vertebral bodies of D.V.5 and 6 following a long-standing empyema. The second case developed a stricture in the lower third of the oesophagus which persisted and required regular dilatations; this patient had had a previously normal oesophagus.

DISCUSSION

The principal clinical and radiological features in 12 cases of spontaneous rupture of the oesophagus have been outlined. These findings have emphasized the importance of early accurate diagnosis and immediate treatment in the avoidance of a high incidence of postoperative complications.

Most cases of spontaneous rupture occurred following forceful vomiting and particularly after attempts had been made to suppress this desire by contraction of the cricopharyngeus, thus converting the flaccid oesophagus into a high-pressure chamber (Moynihan, 1954). Post-emetic dehiscence, which includes all the cases described in the present study, has been renamed 'primary pressure rupture' and the term 'spontaneous rupture' is reserved for those occurring at rest or during sleep (Heroy, 1952; Clark and Tankel, 1964). 'Secondary pressure rupture' might be an apt description of those cases occurring after epilepsy (Klein and Grossman, 1943), asthma (Raffle, 1958), and parturition (Kennard, 1950). Abbott, Mansour, Logan, Hatcher, and Symbas (1970) have recently emphasized the importance of neurological disorders in the aetiology of this condition.

The lower third of the oesophagus is certainly the commonest site of perforation both in our own experience and in other reports (Nealon, Templeton, Cuddy, and Gibbon, 1961). Experimental pressure studies have consistently found this to be the weakest point of the oesophagus (Mackenzie, 1884; Bodi, Fanger, and Forsythe, 1954). This is considered to be a result of the distribution of smooth muscle, in which the longitudinal fibres taper out at the squamo-columnar junction and where the number and size of oblique fibres are also reduced (von Mollendorf, 1927).

Spontaneous rupture is primarily a muscular defect, the mucosa offering considerable resistance to pressure before perforation occurs (Mackenzie, 1884). Our own findings have shown, however, that when perforation has occurred the mucosa splits in such a way as to exceed the extent of the tear occurring in the muscular layer.

It is interesting that the left side should be involved more frequently than the right. This has been attributed to the support afforded by adjacent structures such as the aorta and liver (*Lancet*, 1963). Spontaneous perforation is not confined to the lower third of the oesophagus, however, and there are an increasing number of reports in which perforation has been recorded in the middle third and the cervical region (Russell, 1953; Ross, 1961; Hamilton, 1967).

The association of combined oesophageal pathology and spontaneous rupture deserves further discussion, particularly in those patients with concomitant hiatus hernia (3 in our series). It has been shown elsewhere that the pressure within the stomach during normal vomiting is considerably greater than that in the oesophagus (Atkinson, Bottrill, Edwards, Mitchell, Peet, and Williams, 1961). When vomiting is suppressed, however, contraction of the cricopharyngeus causes an enormous increase in the intraluminal oesophageal pressure. It is argued, therefore, that an incompetent hiatus is a predisposing factor in spontaneous rupture, particularly during normal vomiting, by allowing a high pressure to occur within the oesophagus even without involvement of the cricopharyngeal sphincter. It is interesting to note that evidence of suppressed vomiting was lacking in every patient with a hiatus hernia in this review, but was present in all but 2 of the remaining patients.

The patient in whom a post-cricoid web was found on preoperative oesophagoscopy also had no history of an attempt to avoid vomiting. It is conceivable that upper oesophageal obstruction may predispose to a high intraluminal pressure below the site of obstruction during normal vomiting, thereby resulting in oesophageal dehiscence.

The syndrome of haematemesis following repeated vomiting (Mallory and Weiss, 1929) which was recorded in 1 of our patients has been thought to be associated with spontaneous rupture (Small and Ellis, 1958). Recent evidence, however, suggests that the Mallory–Weiss syndrome is primarily a mucosal tear in the cardia following gastric distension and elevation of the oesophagogastric junction into the chest through a lax hiatus (Hodges, 1965). The pathogenesis of spontaneous rupture is quite different and is the result of a tear occurring in the muscular fibres of the oesophagus and must be regarded as an entirely different entity (Holmes, 1966).

The clinical and radiological diagnosis of spontaneous rupture has been described elsewhere (Barrett, 1946; Samson, 1951; Mackler, 1952; Marston and Valk, 1959; Sealey, 1963) and the principal findings in this study have already been stressed. Although this event is now a well-established cause of sudden abdominal pain or acute respiratory distress the early diagnosis of spontaneous rupture remains a relatively rare event. Errors of diagnosis were commonly the result of failing to obtain a chest radiograph in patients presenting with acute abdominal signs and being unaware of the value of a Gastrografin swallow in the early diagnosis. The importance of radiology by defining air within the mediastinum on a penetrated film and the use of contrast radiology in the diagnosis have been adequately stressed (Christoforidis and Nelson, 1957; Naclerio, 1957; Kerr, 1962; Toghill and others, 1968).

Prior to the first successful repair (Barrett, 1947) spontaneous rupture was almost uniformly fatal (Barrett, 1946). Although early primary repair has become the standard surgical practice the mortality-rate following this procedure continues to be considerable (Sealey, 1963; Abbott and others, 1970). The results of the present review are encouraging and should be attributed to prompt intercostal drainage, adequate débridement of the mediastinum, and an early feeding jejunostomy in all the patients presenting after 48 hours. On the other hand, the morbidity in terms of postoperative complications was alarming, occurring in 10 of the 11 survivors.

Complications largely occurred from leakage at the site of the sutured oesophagus. It is conceivable that inadequate repair may be responsible for the high morbidity following primary suture, particularly if careful examination of the extent of the mucosal tear is not undertaken at operation. Adequate repair of the perforation may thereby prevent secondary leakage from this site. Two of our patients developed a subphrenic abscess following spontaneous rupture. One must assume that this event could have been avoided if a Gastrografin swallow had been used to define the extent of the leakage.

It is well known that more damage occurs to the mediastinum and peri-oesophageal tissues following spontaneous rupture as compared with instrumental perforation. This is probably the result of autolysis from gastric contents entering the mediastinum under high pressure. The mortality and morbidity following spontaneous rupture have been attributed to this phenomenon (Tuttle and Barrett, 1963). For this reason recent authors have advocated alternative methods of operative treatment, particularly in those patients presenting 24 hours after perforation. These have included onlay gastric patch repair (Thal and Hatafuku, 1964) and T-tube drainage (Abbott and others, 1970). We feel that the emphasis should be placed not on new methods but on early diagnosis and immediate and adequate primary suture.

It appears that the greatest hazard of spontaneous rupture lies not only in a high mortality but in the incidence of severe and debilitating postoperative complications. This is associated with a considerable morbidity in terms of the length of hospital stay. It is concluded that the only means of reducing this alarming morbidity lies in the increasing awareness of this condition and the use of contrast radiology to define the site and extent of the perforation. The importance of adequate and early direct suture of the full extent of the mucosal tear in preventing further leakage cannot be overstressed.

CONCLUSIONS

1. Spontaneous rupture of the oesophagus carries a high morbidity in those who survive surgical treatment.
2. The incidence of postoperative complications would be considerably reduced if early diagnosis was established. The use of immediate contrast radiology in all patients with sudden chest pain and abdominal signs after forceful vomiting is advised, so that the site and extent of oesophageal rupture may be defined.
3. Adequate repair of the perforation by examining the extent of the mucosal dehiscence may prevent secondary leakage from the site.

SHORT NOTES OF RARE OR OBSCURE CASES

A CASE OF PRIMARY LIVER TUMOUR ASSOCIATED WITH PORPHYRIA

By R. T. WADDINGTON
NORTHERN GENERAL HOSPITAL, SHEFFIELD

SUMMARY

A case is described of primary liver carcinoma in a patient with a 10-year history of porphyria. Death resulted from occlusion of the pulmonary artery by tumour embolus.

PORPHYRIA has been described secondary to liver tumours (Hamminga, 1951; Tio, Leisjne, Jarrett, and Rimington, 1957), but in the case presented here the porphyria preceded the recognition of a primary liver carcinoma by 10 years. No similar example has been found in a survey of the literature.

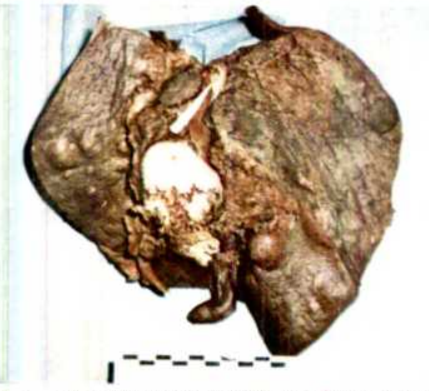

FIG. 1.—Liver; tumour has invaded the inferior vena cava.

CASE REPORT

The patient, a 52-year-old glasswork engineer, was seen in the Rupert Hallam Department of Dermatology, Hallamshire Hospital, Sheffield, in July, 1960, with a blistering eruption of the hands and face. This was initially thought to be a light-sensitivity reaction aggravated by heat from the furnaces at his place of work and was accordingly treated with oral chloroquine sulphate and topical steroids. Closer questioning 1 week later revealed that he had been drinking up to 8 pints of beer daily since his youth in the Merchant Navy and that for 3 years he had suffered intermittent attacks of 'haematuria'. He had no other urinary complaints and specifically denied any alimentary or neurological symptoms. Apart from the skin eruption and dark urine the physical examination was normal and in particular there was no hepatomegaly. The urine, which was dark brown in colour and fluorescent under Wood's light, repeatedly contained an excess of porphyrins but no blood. The serum bilirubin, thymol turbidity and floculation tests, and serum alkaline phosphatase were all normal. The bromsulphthalein test had to be abandoned when the patient collapsed on injecting the dye. A diagnosis of porphyria was made and the oral chloroquine, which is known to aggravate existing porphyria, was stopped. No specific therapy was offered but the patient was advised to reduce his alcohol intake. Unfortunately he repeatedly failed to attend and was lost to review.

In July, 1970, the patient was admitted to the Northern General Hospital, Sheffield, with a 3-day history of severe pain in the right loin. He had lost 19 kg. in weight in the preceding 7 months and complained of general malaise and anorexia for 3 weeks. A marked weakening of the voice was noted and it was difficult to converse with him. On examination the patient was noticed to be jaundiced and had scattered spider naevi over the face and trunk. The abdomen was grossly enlarged and a nodular liver was palpable, reaching to four fingers below the costal margin. No other abdominal masses were felt and there was no ascites. The blood electrolytes were normal although the blood-urea was 84 mg. per 100 ml. Serum amylase was normal. The liver-function tests were as follows: bilirubin, direct positive, 4·6 mg. per 100 ml.; alkaline phosphatase, 20·1 K.A. units; zinc turbidity, 9 U.; total proteins, 6·79; electrophoresis, small increase in alpha II globulins and gamma-globulins; serum glutamic oxaloacetic transaminase, 74 I.U. per litre; serum glutamic pyruvic transaminase, 31 I.U. per litre. Urinary porphyrins on a single test were not raised.

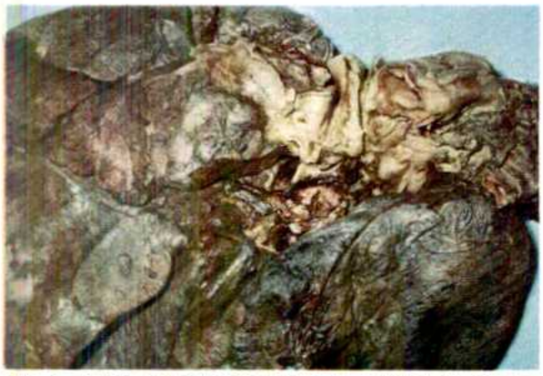

FIG. 2.—Lung; the pulmonary artery is occluded by tumour embolus.

A diagnosis of carcinomatosis with multiple liver secondaries was made. The patient's condition rapidly deteriorated with signs of bronchopneumonia and he died 3 days later.

The salient post-mortem findings were as follows: The peritoneal cavity contained some blood-stained fluid. The liver was massively enlarged and infiltrated with tumour (*Fig.* 1). This appeared to be secondary tumour but no primary was identified. The tumour had spread into the inferior vena cava. A mass of necrotic glands was present in the porta hepatis. The spleen was of normal size and the gall-bladder contained two pigment mulberry stones but no tumour. The lungs were grossly oedematous and congested and blood-stained fluid was present in the trachea and main stem bronchi. The pulmonary artery was occluded by tumour embolus (*Fig.* 2).

The liver histology showed extensive infiltration by discrete nodules of primary hepatic carcinoma which were walled off in many areas by fibrous tissue and showing characteristic polymorphic and malignant cells with attempts at columnar and rosette formation (*Fig.* 3). There was no evidence of liver cirrhosis.

DISCUSSION

The porphyrias can best be divided into two main types: hepatic and erythropoietic, depending on the main site of formation of the abnormal porphyrins and their precursor (Goldberg, 1968) (*Table I*).

Table I.—TYPES OF PORPHYRIA

- Hepatic porphyria
  - Acute intermittent
  - Variegate (mixed)
  - Cutaneous hepatic
    - Hereditary
    - Acquired
  - Hereditary coproporphyria
- Erythropoietic porphyria
  - Erythropoietic protoporphyria
  - Congenital

Hepatic porphyria may present in one of two ways. The acute intermittent type is transmitted as a Mendelian dominant character, manifesting itself by unexplained abdominal pains, paresis, or psychiatric states. The cutaneous type presents as a photosensitivity disease, often with evidence of hepatic insufficiency. The diagnosis is made by finding abnormal porphyrins in the urine or faeces.

Alcohol and drugs, such as chloroquine, barbiturates, sulphonamides, and oestrogens, are known to provoke acute attacks, as may the withdrawal of protein and carbohydrates from the diet. In Turkey cases of porphyria due to fungicide intoxication have been described (Cam, 1959).

Hamminga (1951) reported a case of porphyria with liver metastases from an intestinal tumour, and Tio and others (1957) described the case of a woman who developed photosensitivity associated with marked porphyrin excretion in old age. She had a benign liver tumour, the removal of which cured her clinical symptoms. Church (1971) had a case of porphyria in which a liver tumour was shown on liver scan.

In the present case it cannot be proved that the primary liver carcinoma was responsible for the porphyria as the opportunity was not taken to study the biochemical nature of the tumour tissue. Nevertheless, the association of hepatic porphyria and liver tumour now seems real, and it is suggested that serial liver scans be performed in all patients with hepatic porphyria in order to detect such tumours at an early stage.

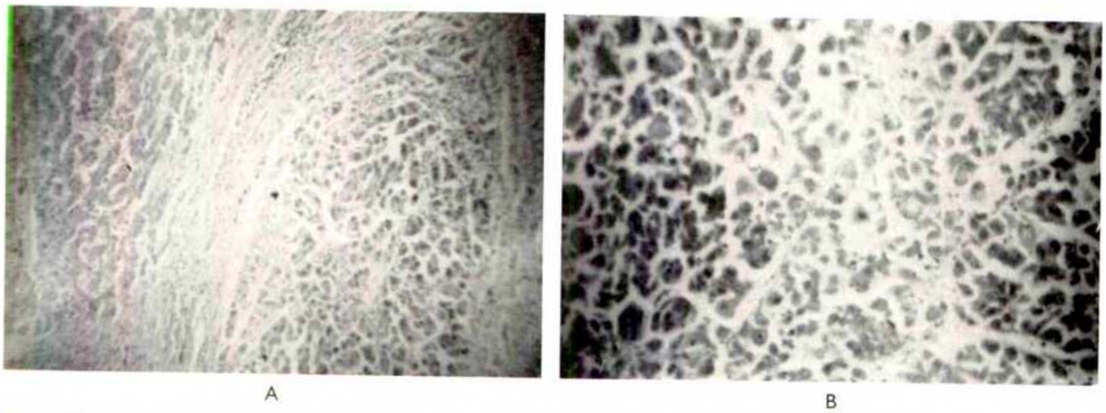

FIG. 3.—Photomicrographs of the liver: A, low-power view; B, high-power view, showing characteristic polymorphic malignant cells with attempts at columnar and rosette formation.

Tumour embolus large enough to block the pulmonary artery is uncommon, but it is now recognized that right atrial myxoma and choriocarcinoma cells may present with recurrent pulmonary emboli, eventually producing pulmonary hypertension (Oakley, 1970).

When the pulmonary artery is totally occluded by tumour the usual primary sources are sarcoma, or renal or hepatic carcinoma which have directly invaded the inferior vena cava. In these instances death results from acute cor pulmonale.

Acknowledgements.—I wish to thank Mr. F. J. P. O'Gorman, Honorary Director of the University Surgical Unit, Northern General Hospital, and Dr. I. B. Sneddon, Rupert Hallam Department of Dermatology, Hallamshire Hospital, for help in the preparation of this paper.

I also thank Dr. P. Day, Senior Registrar in Pathology, Northern General Hospital, for the post-mortem and histology reports, and Mrs. J. White who photographed the specimens.

PEDUNCULATED TERATOMA OF RECTUM INFESTED WITH BILHARZIASIS

By Y. EL-KATIB

LECTURER IN SURGERY, FACULTY OF MEDICINE, CAIRO UNIVERSITY

SUMMARY

A teratoma presenting as a pedunculated rectal polyp is reported. The teratoma was infested with *Bilharzia* ova.

TERATOMAS of the rectum are rare. Most of the reported cases have been solid or cystic dermoids. In the case reported here representatives of all three germinal layers were present and thus it warrants the name 'teratoma'. The teratoma was infested with *Bilharzia* ova, and this is believed to be the first report of such an association.

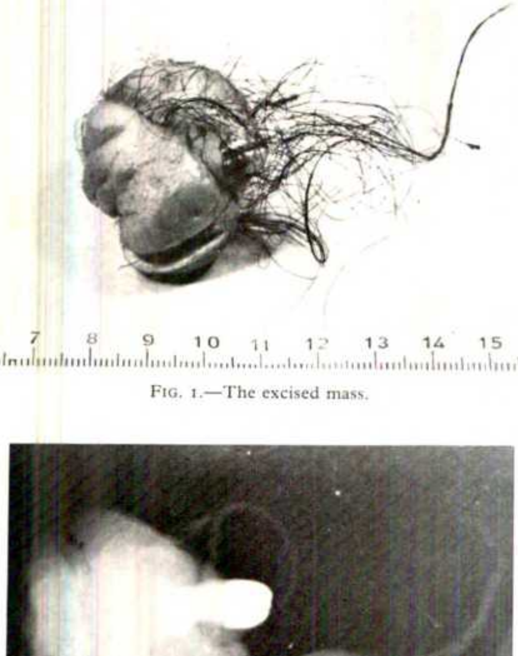

FIG. 1.—The excised mass.

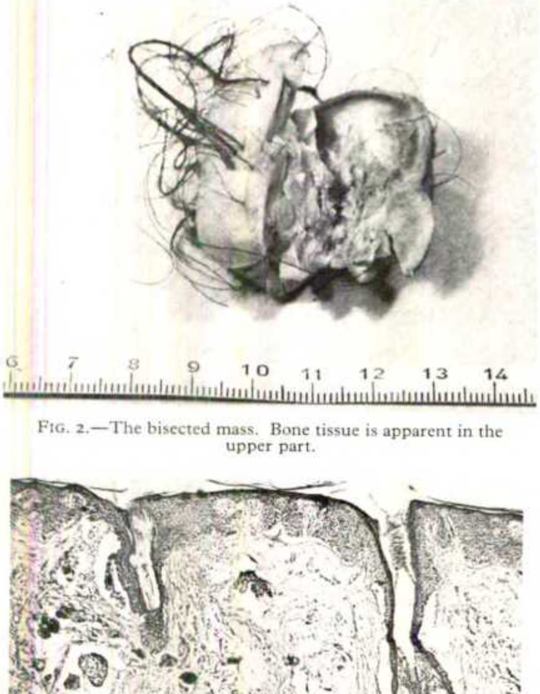

FIG. 2.—The bisected mass. Bone tissue is apparent in the upper part.

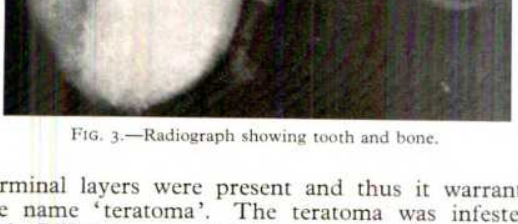

FIG. 3.—Radiograph showing tooth and bone.

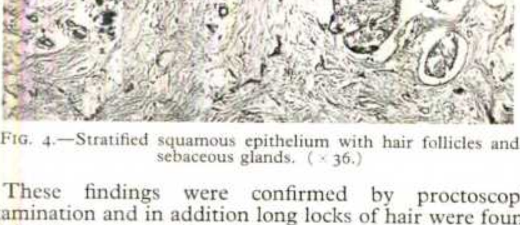

FIG. 4.—Stratified squamous epithelium with hair follicles and sebaceous glands. (× 36.)

CASE REPORT

An 8-year-old girl presented complaining of bleeding per rectum of 2 days' duration. No mass protruded per rectum during defaecation. The girl had been treated 2 years before for intestinal bilharziasis. The patient looked healthy and had no recent history of trauma.

On rectal examination a tooth was palpated. The immediate impression was that this might have been swallowed. The tooth was found to be stuck to a smooth mass lying free in the lumen of the lower rectum, being attached to the anterior wall in the middle line by a slender stalk.

These findings were confirmed by proctoscopic examination and in addition long locks of hair were found arising from the surface of the mass.

Under general anaesthesia and through a proctoscope the pedicle was transfixed and the mass excised.

The mass measured 4 × 3 cm. (*Fig.* 1) with a tooth definitely stuck to its substance and with a mass of hair growing over the whole surface. There was a small superficial ulcer on the surface which may have accounted for the bleeding that the patient had had on admission. Otherwise, the surface was smooth and the consistency was firm.

On bisection of the mass yellowish tissue was found, interspersed in places by hard whitish tissue (*Fig.* 2), which was later proved to be bone. The mass was completely solid with no cystic spaces.

Radiographic examination showed a tooth arising from an area of bone, simulating a tooth arising from part of a mandible (*Fig.* 3).

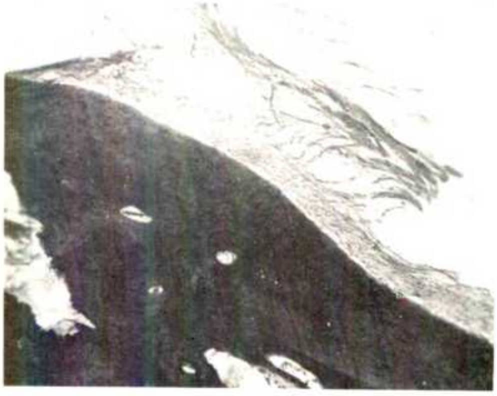

FIG. 5.—Bone and smooth muscle. (× 45.)

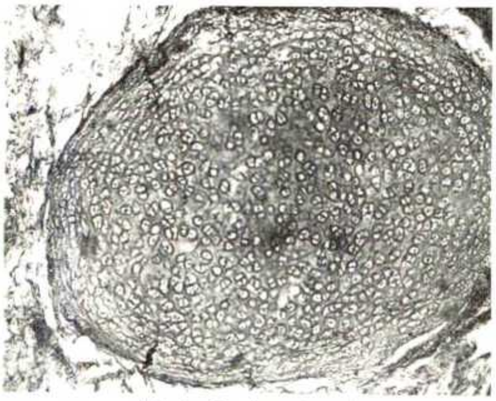

FIG. 6.—Cartilage. (× 45.)

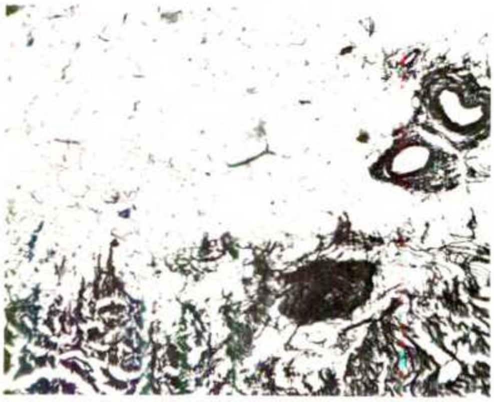

FIG. 7.—Adipose tissue, smooth muscle, and blood-vessels. (× 45.)

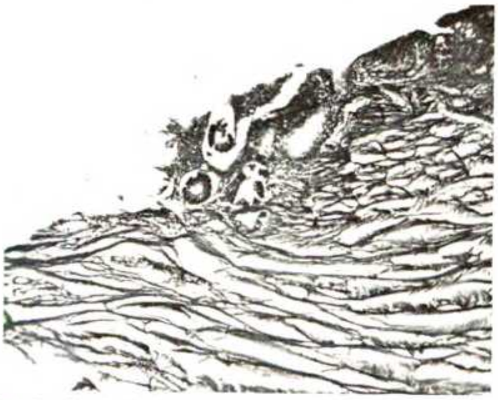

FIG. 8.—Glands lined by columnar epithelium with basal nuclei. (× 45.)

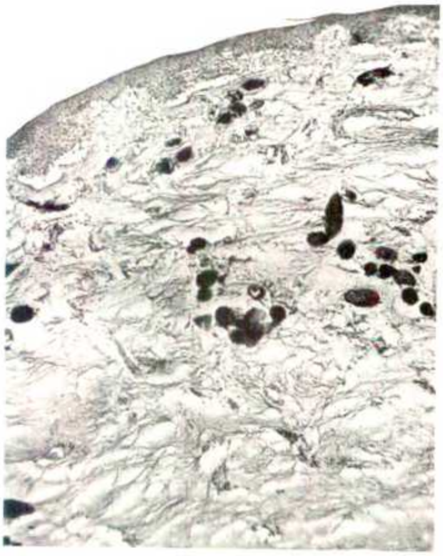

FIG. 9.—*Bilharzia* ova under the cutaneous covering. (× 50.)

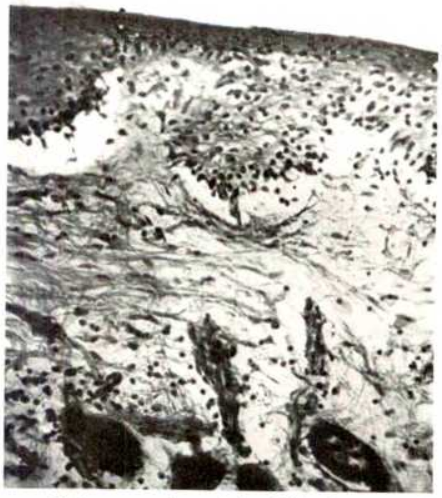

FIG. 10.—High-power view of the *Bilharzia* ova under the cutaneous covering. (× 174.)

HISTOLOGY.—Sections showed a conglomeration of tissues. The surface was covered with stratified squamous epithelium with hair follicles and sebaceous glands (*Fig.* 4). The substance of the mass included bone (*Fig.* 5), a circular area of cartilage (*Fig.* 6), adipose tissue, and smooth muscle (*Fig.* 7). There were also a few glands lined by columnar mucus-secreting epithelium with basal nuclei, simulating intestinal or biliary-duct epithelium (*Fig.* 8).

The most interesting feature on microscopy was the presence of *Bilharzia* ova amongst the tissues (*Figs.* 9, 10). The ova were mostly concentrated under the skin covering.

DISCUSSION

Teratomas have been reported in different positions in the body. These sites include the sacrococcyx, the mediastinum, the ovaries, the testis, the liver (Kiryabwire and Mugerwa, 1967), the stomach (Paul, Cooray, and Wickremasinghe, 1962), and the Fallopian tube (Gray and Hitchock, 1969).

Willis (1953) defines a teratoma as 'a true tumour or neoplasm composed of multiple tissues of kinds foreign to the part in which it occurs'.

A convenient classification of teratoid tumours is that made by Hedblom (1937), who separated these tumours into epidermoids, dermoids, and teratomas. The epidermoids are cysts containing only derivatives of ectoderm. The dermoids contain tissues of mesodermal as well as of ectodermal origin. The teratomas are solid tumours which contain derivatives of ectoderm and mesoderm as well as entoderm. The case of the pedunculated rectal dermoid reported by Nigam (1947) contained representatives of ectoderm and mesoderm, viz., skin, hair, bone, and fibromuscular tissue, but not entodermal structures and so was rightly called 'dermoid'. In the case reported here the ectoderm was represented by skin, hair, sebaceous glands, and a tooth. The mesoderm was represented by bone, cartilage, fat, and smooth muscle. The entoderm included mucous glands lined by columnar epithelium, and thus the tumour is a true teratoma.

The most popular theory about the mode of origin of teratomas was elaborated by Willis (1951), who suggested that teratomas arise from foci of totipotential cells which escape the influence of the primary organizer during embryonic development. He suggested that the disturbance occurs in the area of the primitive streak and the head process, because a large number of teratomas occur in the median and paramedian regions of the body; hence the occurrence of the present teratoma strictly in the middle line of the anterior rectal wall.

Teratomas are definitely more common in females. Gross, Clatworthy, and Meeker (1951) reported 40 cases, 32 of which were in females, and it was suggested that the female ovary differentiates later than the male testis, making females more susceptible to developmental abnormalities and accounting for the higher incidence of teratomas in females.

The presence of *Bilharzia* ova in the present teratoma can be explained if we remember that the patient had had bilharziasis earlier in her life, and that the veins into which the *Bilharzia* worms would migrate to deposit their ova in the rectal wall are the same veins which drain the teratoma.

JOINT RUPTURE IN REITER'S DISEASE

BY RICHARD W. GARNER AND ALASTAIR G. MOWAT*

RHEUMATOLOGY UNIT, NUFFIELD DEPARTMENTS OF MEDICINE AND ORTHOPAEDIC SURGERY, UNIVERSITY OF OXFORD,
NUFFIELD ORTHOPAEDIC CENTRE, OXFORD

SUMMARY

A case of knee-joint rupture in Reiter's disease, in which a posterior communicating cyst was excised, is reported. The mechanisms of joint rupture and the differentiation of the clinical signs from those of deep venous thrombosis in the calf are discussed. The relevant literature has been reviewed.

SPONTANEOUS joint rupture is an occasional complication of joint disease and occurs most frequently in association with inflammatory joint disease, particularly rheumatoid arthritis (Dixon and Grant, 1964; Good, 1964; Jayson, Swannell, Kirk, and Dixon, 1969). Rupture occurs most commonly at the knee-joint. An acute polyarthritis with effusions, commonly involving the knee-joints, occurs in Reiter's disease, but rupture of a joint has only been reported once (Weese and McCarty, 1969). We report a second case of knee-joint rupture in Reiter's disease in which excision of a communicating posterior cyst was carried out.

CASE REPORT

An 18-year-old unmarried man with no previous history of joint disease was admitted to hospital in

---

November, 1968, with a 2-week history of general malaise, accompanied by pain and swelling of the knees, the right ankle, and the second and third metacarpophalangeal joints of the left hand. He also had pain in the lower back. At the onset of his illness he had developed dysuria without a urethral discharge, and later an erythematous ulcerated lesion appeared on the roof of his mouth. He had not had conjunctivitis or skin lesions. He admitted to a casual sexual contact 4 weeks prior to admission. There was no family history of joint disease.

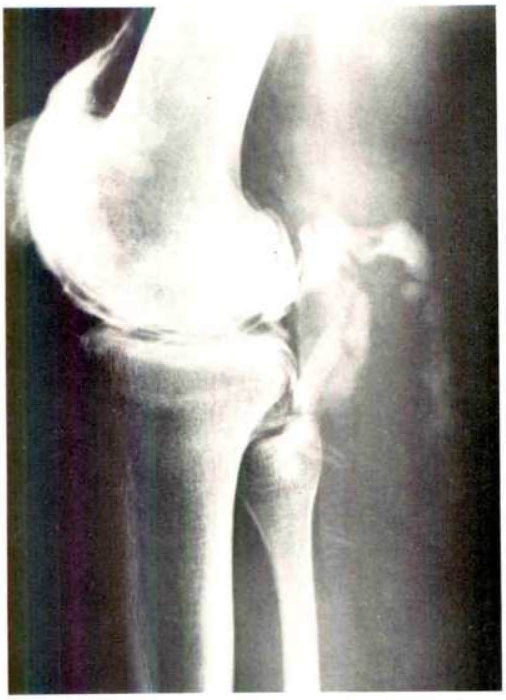

FIG. 1.—Arthrogram of the right knee showing the posterior cyst and the extravasation of dye from the upper part of the cyst.

On examination there was swelling, tenderness, and limited movement of both knees, the right ankle, and the second and third metacarpophalangeal joints of the left hand. There was no tenderness of the sacro-iliac joints.

Investigations revealed the following: haemoglobin concentration, 13·8 g. per 100 ml.; E.S.R. (Westergren), 95 mm. in 1 hour; total leucocyte count, 10,900 per c.mm. with a normal differential count; serum uric acid, 2·8 mg. per 100 ml. Serological tests for gonorrhoea, syphilis, brucellosis, and the rheumatoid factor were negative. Cultures of mid-stream urine, blood, and joint fluid were sterile. Direct examination of the synovial fluid showed the presence of many polymorphs but no 'Reiter's cells' (Pekin, Malinin, and Zvaifler, 1967). Direct examination of the urine showed the presence of many pus cells. Radiographs of the involved joints were unremarkable.

The patient was treated with soluble aspirin (4 g. per day), bed-rest, and immobilization of the legs and left hand in plaster-of-Paris splints. The knees were aspirated and injected with hydrocortisone acetate (50 mg.). He gradually improved and was discharged symptom-free 6 weeks later, at which time his haemoglobin concentration was 13·5 g. per 100 ml. and his E.S.R. 67 mm. in 1 hour. He was able to discontinue the salicylate therapy and was symptom-free for over a year until June, 1970, when he began to be troubled by pain and swelling of the third and the fourth right metatarsophalangeal joints and small effusions were noted in his knees. His haemoglobin concentration was 16·2 g. per 100 ml. and his E.S.R. 22 mm. in 1 hour. Despite an intra-articular injection of hydrocortisone acetate (50 mg.) the right knee continued to be swollen but without pain, stiffness, or limitation of movement.

In early September, 1970, the patient noticed a fullness at the back of his right knee which prevented full extension. Three days later while at work he stumbled, forcibly straightening the right knee. He immediately developed severe pain in the calf which became progressively tender, swollen, and red, and he noticed a simultaneous reduction in the size of the knee-joint effusion. He had no other symptoms and was admitted to hospital a day later.

On examination the right knee was swollen and tender and the range of movement was 10–115°. There was a tender cyst, 4 cm. in diameter, in the popliteal fossa. The circumference of the calf was increased by 4 cm. and was warm and tender. Homan's sign was positive but there was no engorgement of the superficial veins. Peripheral pulses were normal. There was a little tenderness of several of the metatarsophalangeal and the left sacro-iliac joints. Rupture of the right knee-joint was confirmed by arthrography (*Fig.* 1).

At this time the haemoglobin concentration was 14·1 g. per 100 ml., the E.S.R. was 65 mm. in 1 hour, and the total leucocyte count was 8400 per c.mm. with a normal differential count. The tests for gonorrhoea and rheumatoid factor were negative on both serum and synovial fluid. Culture of the synovial fluid was sterile. Examination of the synovial fluid again showed many polymorphs but no 'Reiter's cells'. Radiographs showed the presence of early erosive changes in several metatarsophalangeal and both sacro-iliac joints.

The patient was treated with soluble aspirin (4 g. per day), bed-rest, and splintage of the right leg. The right knee was aspirated and injected with hydrocortisone acetate (50 mg.). The acute symptoms settled rapidly but because of the continued presence of an enlarged posterior cyst which prevented full extension of the joint, excision was undertaken on the seventh hospital day. The cyst was found to lie between the heads of the gastrocnemius muscle with a communication to the posterior knee-joint. The communication was closed without the use of a fascial flap. It was confirmed, as suggested by the arthrogram, that rupture had taken place from the cyst. Pathological examination of the cyst showed it to be lined by synovial tissue. The appearances of this tissue and of a portion of synovial tissue removed from the posterior compartment of the joint were consistent with a diagnosis of Reiter's disease (Kulka, 1962).

The patient made an uneventful recovery. At the present time he has no symptoms or signs in the right knee and the range of movement is 0–130° with no extension lag. His foot symptoms have been improved by the provision of suitable in-soles for his shoes. His haemoglobin concentration is 14·9 g. per 100 ml. and his E.S.R. 17 mm. in 1 hour.

DISCUSSION

The diagnosis of Reiter's disease in the present case is based upon the history, the pattern of the arthritis, and the urinary-tract findings. The patient also had typical lesions on the roof of the mouth. Weinberger and Bauer (1955) thought that the diagnosis of Reiter's disease should be restricted to cases in which the triad of arthritis, conjunctivitis, and urethritis is present. However, ocular symptoms may be minimal or absent (Hancock and Mason, 1965). A small number of patients appear to have unremitting disease and the annual risk of subsequent attacks of Reiter's disease, which remains constant over many years, is about 15 per cent (Csonka, 1960). It is amongst this group of patients with continuing or recurrent disease that sacro-iliac joint involvement is most common. Sacro-iliitis may occur in up to 40 per cent of cases and the subsequent differentiation of Reiter's disease from ankylosing spondylitis may be difficult (Good, 1962; Hancock and Mason, 1965; Sairanen, Paronen and Mahonen, 1969).

Most reports of joint rupture have been in patients with rheumatoid arthritis but it has been recorded in association with osteo-arthrosis (Tait, Bach, and Dixon, 1965). The knee-joint is most commonly involved but rupture has been reported in the wrist (Jayson and others, 1969) and in the elbow (Goode, 1968). Rupture of the knee-joint is generally associated with the presence of a cyst in the popliteal space, and indeed, as in the present case, the rupture usually takes place from this cyst. These cysts are typically enlargements of the normal gastrocnemio-semimembranous bursae (Baker's cysts; Baker, 1877), but they may occur in other situations as in the case reported here (Perri, Rodnan, and Mankin, 1968). Jayson and Dixon (1970c) have demonstrated that there is a valvular connexion between the joint space and the posterior cyst at the knee and that this only allows the movement of fluid from the joint to the cyst. Very high joint pressures may be generated in patients with inflammatory joint disease with effusion and this will be transmitted to the cyst (Jayson and Dixon, 1970b). Indeed, because of the valvular mechanism the pressure in the cyst may be higher than that in the knee. The possibility of rupture is increased in inflammatory joint disease since there is an increase in joint elastance (Jayson and Dixon, 1970a). Knee-joint rupture is usually accompanied by the sudden onset of pain in the calf and many patients notice that there has been a reduction in the size of the joint effusion. The physical findings in the calf resemble those of a deep venous thrombosis (Good, 1964; Hench, Reid, and Reames, 1965). However, if the possibility of joint rupture is considered a correct diagnosis will usually be made, since there is often evidence of joint disease and a posterior cyst and there is rarely engorgement of the superficial veins as occurs with deep venous thrombosis. Arthrography is the most useful investigation (Tait and others, 1965; Perri and others, 1968) and demonstrates the posterior cyst and the extravasation of fluid beneath the deep fascia and its dispersion amongst the muscle bundles. Some fluid may pass into the superficial fascia (Tait and others, 1965), as in the present case. With this type of arthrography 15–20 ml. of a water-soluble radio-opaque dye are injected into the anterior knee-joint, a firm supporting bandage is applied, and the patient is briefly exercised (1–2 minutes) before radiographs are taken.

Although there has been only 1 previous report of joint rupture, which also occurred in the knee-joint, in Reiter's disease (Weese and McCarty, 1969), thrombophlebitis of the leg veins has been reported as a complication (Csonka, 1966; Engleman and Weber, 1968). These reports did not exclude the possibility that the symptoms and signs were due to joint rupture.

Immediate management consists of rest and aspiration of the knee-joint. Local support of the calf and the intra-articular injection of corticosteroids may be helpful. Although the symptoms can be controlled by such means, in the presence of continuing inflammatory joint disease a recurrence would seem likely. Experience in rheumatoid arthritis suggests that excision of the posterior cyst with closure of the defect in the posterior capsule of the joint, together with anterior synovectomy of the knee-joint in some cases, offers a more definitive form of management (Geens, Clayton, Leidholt, Smyth, and Bartholomew, 1969). In the case reported here the joint symptoms settled but the persistence of an enlarged posterior cyst which prevented full extension of the knee-joint led us to undertake surgical excision of the cyst. Grahame, Ramsey, and Scott (1970) have reported the beneficial effect on both the joint synovitis and the posterior cyst of the intra-articular injection of radioactive colloidal gold. This, or the injection of other isotopes, may offer an alternative to surgical treatment.

CENTRAL RUPTURE OF THE LIVER WITH MASSIVE LIVER-CELL NECROSIS

A CASE REPORT AND REVIEW OF THE LITERATURE

By S. R. SONI* and V. PERSAUD
UNIVERSITY COLLEGE HOSPITAL OF THE WEST INDIES, JAMAICA

SUMMARY

A case of massive central rupture of the liver in which the patient became jaundiced is described. Autopsy revealed, in addition to the intrahepatic haematoma, large areas of infarction in the liver, some of which had become infected and had given rise to septic embolization to various organs. There was deranged liver function which is ascribed to the structural changes found in the liver. The occurrence of hepatocellular jaundice with this type of liver injury has not, to our knowledge, been previously recorded. It is suggested that immediate investigation and treatment are essential if the patient is to survive.

CENTRAL rupture of the liver following blunt trauma to the abdomen is an unusual injury. The case reported here is distinguished further by the development of severe liver dysfunction, a complication that we have been unable to find recorded in the literature.

CASE REPORT

A 69-year-old woman, who had previously been in good health, walked into the Casualty Department of University College Hospital, Kingston, Jamaica, on 19 Jan., 1969, half an hour after the car which she had been driving had overturned following a 'blow-out' of a front tyre. She had not lost consciousness and she remembered the steering wheel striking her chest.

Examination revealed no abnormality except for slight bruising and tenderness over the right costal margin. Over the next 3 hours her blood-pressure changed from 140/90 to 110/60 mm. Hg and the pulse-rate increased from 80 to 96 per minute. She vomited once. The tenderness in the right hypochondrium increased and bowel-sounds, which had been normal, disappeared. However, there were no signs of free fluid in the peritoneal cavity and abdominal paracentesis was negative. A chest radiograph was normal and the haemoglobin was 8·7 per 100 ml. A diagnosis of ruptured liver was made and a laparotomy was performed 5 hours after the accident.

Through an upper midline incision the peritoneal cavity was found to contain a little blood-stained fluid. The liver was slightly enlarged, had rounded edges, and was notably tense, but its surface was smooth and not bruised and its capsule was perfectly intact. There was some bruising of the stomach and a small tear in the mesentery of the terminal ileum was oversewn. The other abdominal organs were normal. The abdomen was closed without drainage, there being troublesome oozing from the wound edges at this time. The patient had received 500 ml. of normal saline, 500 ml. of Dextraven, and 1 litre of blood intravenously.

The following day the patient continued to ooze from her wound. Investigations showed that the haemoglobin was 9·3 g. per 100 ml.; white blood count, 17,800 per c.mm.; platelet count, 135,000 per c.mm.; whole-blood clotting time, 5 minutes; prothrombin time, 16 seconds; partial thromboplastin time, 58 seconds; and plasma-fibrinogen, 600 mg. per 100 ml.

On the second postoperative day gastric aspiration was discontinued and it was noticed that the patient was jaundiced. The jaundice increased rapidly and on the third day the following investigations were performed (the results were only obtained a few days later): serum bilirubin, 12·0 mg. per 100 ml. (direct 6·6 mg. per 100 ml.); serum glutamic oxaloacetic transaminase, 648 U. per 100 ml.; alkaline phosphatase, 22 K.A. units; thymol flocculation, negative; serum electrolytes: Na, 138 mEq./l.; K, 4·1 mEq./l.; Cl, 101 mEq./l.; and HCO$_3$, 17 mEq./l.; blood-urea, 58 mg. per 100 ml.; Hb, 8·9 g. per 100 ml.; white blood count, 11,900 per c.mm. The urine output was 600–800 ml. per 24 hours and the urine contained bilirubin and urobilinogen.

On the fifth postoperative day the patient's temperature rose to 38·3° C. and the pulse-rate increased to 100/120 per minute. She was digitalized and a chest radiograph showed some opacification at the base of the right lung. The serum bilirubin was now 10·0 mg. per 100 ml. (direct 6·5 mg. per 100 ml.); serum glutamic oxaloacetic transaminase, 422 U. per 100 ml.; serum glutamic pyruvate transaminase, 572 U. per 100 ml.; alkaline phosphatase, 20 K.A. units; and blood-urea, 92 mg. per 100 ml. That evening her condition became worse and she complained of feeling cold and sweaty. Her temperature was 38·9° C., the pulse-rate was 160 per minute, and the blood-pressure was 120/70 mm. Hg. An electrocardiogram showed a sinus tachycardia and a central venous line a pressure of 1–2 cm. of saline. She was transfused with saline but her condition continued to deteriorate. She became confused, and whilst a nasogastric tube was being passed, she aspirated vomit and died.

At autopsy the immediate cause of death was aspiration of vomit. The liver weighed 1600 g., was tense, and showed a large, subcapsular haematoma on the diaphragmatic surface of the right lobe (*Fig.* 1). The capsule was intact. The cut surface revealed a massive central rupture extending throughout the right lobe with small tears in the left lobe, the destroyed parenchyma being replaced by fresh blood-clot (*Fig.* 2). There were, in addition, large, irregular, yellowish areas of infarction throughout both lobes (*Fig.* 3). The extrahepatic biliary system and blood-vessels were normal.

Microscopically, liver cells adjacent to the haematoma were necrotic with some areas showing incipient organization with fibroblastic cells. The centres of many of the infarcted areas had undergone suppuration and cystic change and Gram-negative organisms were demonstrated in some of these lesions. Cells more remote from the haemorrhage and necrosis showed mild fatty change only. Similar septic infarctions with, in some cases, abscess formation with clumps of bacteria were found in the myocardium of the left ventricle and intraventricular septum and in the subpleural regions of both lungs. There was acute fibrinous pleurisy over the right lung and some of the lung sections showed small blood-vessels filled with Gram-negative organisms. The adrenal cortex showed focal areas of haemorrhagic necrosis. The kidneys were slightly swollen and pale and the cut surface of the left kidney revealed a wedge-shaped cortical septic infarction. Microscopically there was also evidence of early tubular necrosis.

---

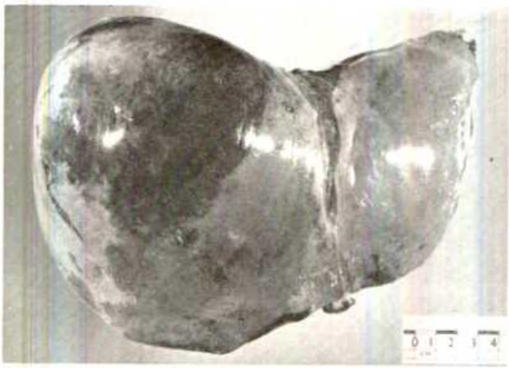

FIG. 1.—Upper surface of the right lobe of the liver showing the subcapsular haematoma. (The capsular tear seen in the extreme left of the picture is an artefact produced during manipulation at autopsy.)

DISCUSSION

With the rising number of motor-vehicle accidents blunt trauma to the abdomen is increasing, and Fitzgerald, Crawford, and DeBakey (1960) state that in their experience the liver is the most commonly involved organ in such injuries. Although many large series of liver injuries have been published (Sparkmann and Fogelman, 1954; Madding, 1955; Hellstrom, 1961; Crosthwait, Allen, Murga, Beall, and DeBakey, 1962; Hanna, Bell, and Cochran, 1965; McClelland and Shires, 1965) central rupture of the organ is very rare as in most cases the liver capsule is torn. Robertson and Graham (1933) collected 5 patients, including 2 of their own, and a further case was added later by Robertson (1937). Since then a few cases have been reported and these have had various clinical and pathological presentations—delayed rupture of a slowly expanding intrahepatic haematoma (Richardson, Gumbert, and Gale, 1967), extensive necrosis of the right lobe of the liver (Foster and Chandler, 1967), acute renal failure following a central haematoma compressing the inferior vena cava (Vasko and Scott, 1966), and a case which was diagnosed a year after injury (Shapiro, McBride and Luna, 1967).

Jaundice may occur after central rupture of the liver (Sandblom, 1948) and was considered to be due to haemorrhage into the biliary system (haemobilia) with subsequent obstruction to bile outflow. In a review of 52 published reports of haemobilia by Steichen and Sheiner (1966), they note that 13 of the patients had a central liver rupture. Since haemobilia was not present in our patient it seems reasonable to assume that the jaundice resulted from resorption of bile from the haematoma cavity and/or from the massive liver-cell necrosis. The necrosis was perhaps caused directly by the trauma, or by pressure on the liver cells or the blood-vessels supplying them by the expanding haematoma.

The rise in transaminase levels probably reflected the degree of liver damage (Wroblewski and LaDue, 1956), and although Martin (1947) stated that trauma involving up to 50 per cent of the liver in dogs did not impair the conventional liver-function tests, Hellstrom (1966) found a significant increase in serum-transaminase activity in these animals which was roughly proportional to the extent of the liver injury.

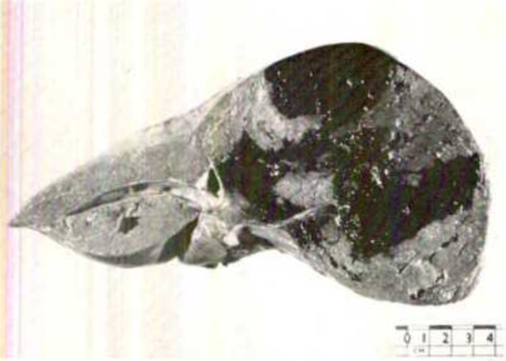

FIG. 2.—Cut surface of the liver showing massive central haemorrhage into the right lobe with subcapsular extension. Small tears (arrow) are seen in the left lobe.

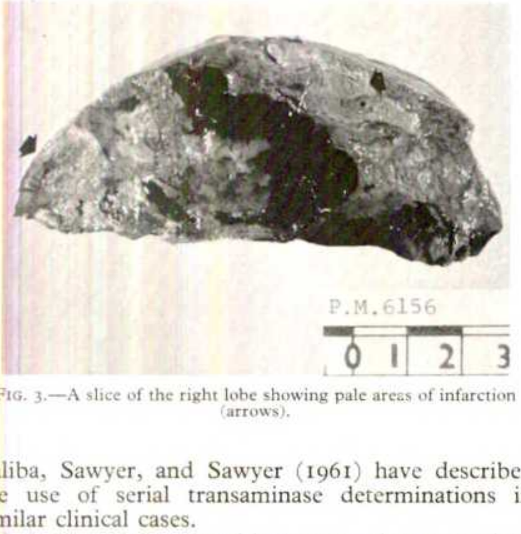

FIG. 3.—A slice of the right lobe showing pale areas of infarction (arrows).

Saliba, Sawyer, and Sawyer (1961) have described the use of serial transaminase determinations in similar clinical cases.

Infection of the central haematoma is a recognized complication (Sandblom, 1948) and it is believed that the infecting organisms are derived from the bloodstream. In our patient it was the infarcted areas and not the haematoma that had become septic. There was no obvious primary source of infection but the organisms may have been derived from the bowel. It would appear that the septic emboli to the heart, lungs, and left kidney came from these infected areas in the liver. Other forms of emboli that have been described following liver trauma such as fat emboli (Grant and Reeve, 1951) and liver tissue itself (Steiner, 1957; Johnston, 1959) were not demonstrated in this patient.

Suspicion that this type of injury has occurred should be alerted by the combination of the appropriate clinical history and the findings at operation of a tense liver with rounded edges. The present case illustrates how short the postoperative period may be and thus early investigation and further treatment are essential. The central haematoma is a space-occupying lesion and can be demonstrated by a variety of means; selective hepatic arteriography seems to have been the most successful (Boijsen, Judkins, and Simay, 1966; Hermann and Hoerr, 1967), with operative cholangiography (Spencer, Menguy, and Eiseman, 1963; Whelan and Gillespie, 1965) and hepatic scintiscanning (Graff, 1963; Burdine and Hill, 1967) being useful in some cases.

When faced with this sort of problem at operation the initial line of attack should probably be to evacuate the haematoma and, after thorough débridement of the cavity, to attempt to suture the liver as would be done for the more common 'straightforward' liver tears.

Curative operation in the present case would have been difficult because of the extent of the liver injury, but as massive liver resections are now an accepted form of treatment for extensive liver trauma (Byrd and McAfee, 1961; Poulos, 1963; Judd and Moore, 1966; Foster and Chandler, 1967) right lobectomy may have offered the only chance of saving this patient.

MALAKOPLAKIA OF THE COLON

BY W. BIRKENSTOCK AND J. H. LOUW

DEPARTMENT OF SURGERY, UNIVERSITY OF CAPE TOWN, SOUTH AFRICA

SUMMARY

A case of malakoplakia of the colon in a young man who presented with symptoms and signs suggestive of ulcerative colitis is reported. It is suggested that a careful search for Michaelis-Guttmann bodies in all chronic inflammatory lesions may reveal a much higher incidence of malakoplakia.

MALAKOPLAKIA (soft plaque) is an extremely rare non-neoplastic lesion of uncertain origin. For many years it was believed to be limited to the urinary bladder where it produces scattered, smooth, rounded, yellowish swellings surrounded by a zone of hyperaemia in the trigone and base of the bladder. Later, however, similar lesions affecting other parts of the urinary system and also the genital tract have been reported, and more recently there have been reports of malakoplakia affecting the gastro-intestinal tract. In the present paper a case of colonic malakoplakia which presented a difficult diagnostic problem is reported.

CASE REPORT

The patient, a 29-year-old farmer, presented to his medical practitioner in July, 1969, complaining of pain in the left upper quadrant of his abdomen associated with troublesome flatulence. These symptoms persisted and by September, 1969, the pain had become much more severe and radiated to his back. At that time he had also noticed that his stools were soft, offensive, and sometimes mixed with blood, but they did not float and were dark in colour. He had lost his appetite and had had repeated attacks of nausea and vomiting. Later the stools had become more watery, contained blood and mucus, and his general condition had deteriorated considerably. Sigmoidoscopy revealed oedematous friable mucosa and a biopsy of the mucosa showed ulceration suggestive of ulcerative colitis; no parasites were found. An indefinite mass was also detected in the left upper quadrant of the abdomen and barium-enema studies suggested ulcerative colitis. The patient was treated with oral cortisone, prednisolone enemata, and sulphasalazine. His general condition improved and the diarrhoea became less troublesome. The mass in the left upper quadrant persisted. A second barium enema revealed the presence of a fistula between the descending colon and a loop of small bowel. A diagnosis of Crohn's disease was entertained but the treatment was not changed. The mass seemed to diminish in size and by October, 1969, he was much improved and was sent home.

Six weeks later the patient returned in a very poor condition with evidence of anaemia and toxaemia and with a swinging temperature up to 38·4° C. The diarrhoea was no longer troublesome but the abdominal mass was larger and very tender. Two weeks later, on 19 Dec., 1969, laparotomy was performed elsewhere and a large, irregular, fixed mass was found in the region of the splenic flexure involving both the large and small bowels. The rest of the bowel was normal except for some thickening of the caecum. A loop of small bowel, which included the enterocolic fistula, was detached from the mass and about 6 cm. were resected. The opening in the large bowel was sutured and the area was drained. Transverse colostomy was performed. Biopsies taken at the time of the operation were sent to the Department of Pathology of the University of Cape Town, where a diagnosis of malakoplakia was made.

On 25 Feb., 1970, the patient was admitted to Groote Schuur Hospital. He was obviously toxic with a swinging pyrexia of up to 39° C., a white cell count of 13,300, and a haemoglobin level of 7·5 g. per cent. The mass in the left upper quadrant was easily palpable and about 12 × 8 cm. in size. The patient was treated with several antibiotics including ampicillin and cephalothin, while sulphasalazine was continued. His general condition appeared to improve, but he developed an abscess over the left greater trochanter which had to be drained. The temperature continued to swing and the mass persisted. A further barium enema revealed an obstructing lesion of the descending colon with leakage into the paracolic region.

On 14 April, 1970, laparotomy was performed. A large mass was found in the left loin involving the greater portion of the descending colon, which was resected together with the upper part of the sigmoid colon and the left half of the transverse colon up to the colostomy.

The report of the pathologists was as follows:—

'Specimen consists of a colon measuring 35 cm. in length. Roughly half-way along its length is a hard mass which is closely adherent to the bowel wall; it measures 6·0 cm. in diameter. Its outer surface is congested and roughened, whilst the cut surface is grey with irregularly branching, linear, yellow areas, which project above the cut surface.

'The opened bowel shows some narrowing at the site of the mass with mild dilatation of the proximal segment (9·0 cm. in circumference) compared to the distal segment, which measures 6·0 cm. in circumference.

'The mucosal surface is grossly abnormal with a loss of haustrations except for small segments near the lines of excision.

'The mucosa in most of the specimen is yellowish-tan in colour and thickened. This thickening is accentuated in focal areas giving rise to nodules and pseudo-polypi, which project from the surface.

'Sections into the wall of the intestine show the thickened, yellowish mucosa to be well delineated from the normal-appearing muscularis. Section through the mass shows it to be intimately related to the bowel wall. The subserosal tissues cannot be discerned from this mass but the muscularis has retained its normal appearance except for an area where it is traversed by a diverticulum. Section along the part of one of the diverticula shows it to extend into the "tumour" mass for a distance of 2·5 cm. (*Fig.* 1.)

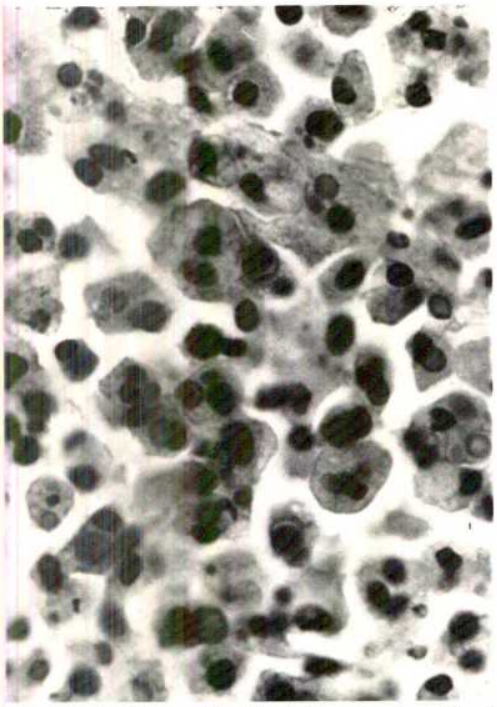

FIG. 1.—Section showing cells with calcified spherules (Michaelis-Guttmann bodies), some of which are laminated.

'The histological features are uniform throughout the bowel wall, the differences being merely quantitative in type. In the smaller, yellow nodules, sheets of macrophages are present in the submucosa, with sparing of the mucosa, muscularis mucosa, muscularis, and serosa. In the polypoidal lesion aggregates of these cells are once again seen, except that extension into the mucosa with consequent ulceration are present. The muscularis and serosa are uninvolved except where diverticuli have penetrated the muscularis; here the macrophages have extended into the serosa and presumably resulted in the formation of a large mass.

'The mass is composed of sheets of histiocytes with very little intervening stroma or other inflammatory cells. In areas, foreign body-type giant cells are present. At the periphery of the mass, the cells have become elongated and spindle shaped. All of these varieties of cells contain intracytoplasmic PAS-positive granules and many contain calcified spherules (Michaelis–Guttmann bodies), some of which are laminated. No bacteria could be demonstrated.'

The patient's postoperative course was satisfactory but on the ninth postoperative day he became distended and vomited and examination revealed signs of peritonitis. His abdomen was therefore re-explored and 3 m. of twisted and strangulated small bowel had to be resected. The subsequent course was rather stormy, but he gradually improved and was discharged from hospital on the twenty-seventh postoperative day.

On 29 Aug., 1970, the patient was readmitted for assessment. He was in excellent general health and had gained 22·5 kg. in weight. An excretory urogram showed some narrowing of the left ureter but good function of the left kidney. On 4 Sept. continuity of the colon was restored, and at surgery no pathology could be found, apart from an area of thickened peritoneum in the left paracolic gutter. Biopsy revealed areas of fibrosis and haemosiderin deposits, but no evidence of malakoplakia. He recovered rapidly and was discharged on the thirteenth postoperative day having normal bowel function. When last seen in December, 1970, he was in excellent health and sigmoidoscopy failed to reveal any evidence of ulceration or mucosal abnormality.

DISCUSSION

In 1902 Michaelis and Guttmann gave an account of a lesion of the bladder which had the characteristic features of malakoplakia. It was, however, left to Von Hanseman to suggest the descriptive term in 1903. He noted that the predominant cells in the plaques were histiocytes with many of these cells containing large inclusions, which have been called Michaelis-Guttmann bodies, but could not find a specific aetiological factor. Thereafter, there were sporadic reports of lesions invoving the bladder and less commonly the upper urinary tract (Melicow, 1957). In 1958, Haukohl and Chinchinian reported involvement of the testis, and further cases have been described by Blackwell and Finlay-Jones (1959) and Brown and Smith (1967). In 1965 Goldman reported a case with the typical lesion in the prostate.

A case of malakoplakia of the colon was reported by Turner and Lattes in 1963 and another by the same authors in 1965. Involvement of the colon has also been reported by González-Angulo, Corral, and García-Torres (1965) and Finlay-Jones, Blackwell, and Papademetriou (1968). In 1967 Yunis, Estevez, Pinzon, and Moran described a case of malakoplakia involving the bladder, colon, and stomach, and in 1970 Blackshear reported the lesion in an appendix.

From most of the reports it would appear that the condition tends to be self-limiting and there have been reports of spontaneous regression (Cristol and Broders, 1946; Boonstra and Bates, 1950). Deaths from complications have been reported by Scott and Scott (1958), Turner and Lattes (1963), and Goldman (1965). Females have been affected more often than males in a ratio of 4·5 to 1.

Although malakoplakia has been recognized for more than 70 years and the pathology has been well described, the aetiology is still in doubt. Early investigations suggested that the lesions were variants of tuberculosis, sarcoid, or a non-specific granuloma. This hypothesis gained some support from later reports of favourable clinical responses to long-term administration of drugs effective against mycobacteriae.

Turner and Lattes (1965) concluded on the basis of histochemical studies that the characteristic Michaelis-Guttmann bodies in 'malakoplakia cells' are of glycolipid composition 'compatible with capsular polysaccharide, lipopolysaccharide, or endotoxin of micro-organisms'. *Escherichia coli* has often been cultured from the lesions and therefore proposed as an aetiological agent. Yunis and others (1967) suggested that these bodies consisted of a neutral glycoprotein with a central core of acid mucopolysaccharide, possibly of bacterial capsular origin. Around this core are deposits of glycolipids, calcium, and iron. They also observed transitions from small cytoplasmic granules within 'malakoplakia cells' to typical Michaelis-Guttmann bodies.

Electron microscopic studies by McKiel, Eisenstein, and McDonald (1962) revealed that the Michaelis-Guttmann bodies are often laminated, sometimes with a peripheral dark zone and a central pale area. At the periphery, long, thin, needle-like crystals, measuring 200–600 Å in length, have been observed. The authors suggested that this crystalline form may be due to appatite and that malakoplakia is an inflammatory state with histiocytic phagocytosis of fatty acids and/or polysaccharides with subsequent calcification uninfluenced by either fungi or virus.

Finlay-Jones and others (1968) reported their electron microscopic observations and suggested that the Michaelis-Guttmann bodies develop from large lipid-containing cytoplasmic phagosomes which undergo calcification.

No doubt meticulous search for Michaelis-Guttmann bodies in all chronic inflammatory lesions, especially those associated with *E. coli* infections, will reveal a much greater incidence of malakoplakia than has been appreciated up to the present time.

Acknowledgements.—We gratefully acknowledge permission to publish this case from the Medical Superintendent of Groote Schuur Hospital, Dr. Burger, and we would also thank Dr. Comfort of East London, who did the first operation and referred the case to us.

REVIEWS AND NOTICES OF BOOKS

The Detective-Physician. The Life and Work of Sir William Willcox, K.C.I.E., C.B., C.M.G., M.D., F.R.C.P. By PHILLIP H. A. WILLCOX, M.A., M.D., F.R.C.P. Pp. 332+xiv. 1970. London: William Heinemann Medical Books Limited. £3·50.

THIS is an excellent account of the life of a very distinguished physician who was most probably the last physician to practise both in medicine and as an analyst to the Home Office.

It is often difficult for a son to write the life history of his father, but Dr. Philip Willcox has performed his task in an interesting and lucid manner. There can be no doubt that Sir William's clinical records, kept as they were in a meticulous manner, were a great help and formed a sound basis for his biography.

The medical profession and the lay public alike are always interested in the mystery of murder especially if this entails extensive investigation.

Sir William Willcox enjoyed a very busy and varied life and this book which describes his activities is divided into five parts.

Part 1 concerns his early years and education and his training at St. Mary's Hospital with Sir Alexander Fleming and Sir Bernard Spilsbury. In 1910, while he was Consulting Physician and Senior Analyst to the Home Office, Willcox was concerned in the Hilldrop Crescent mystery in which Crippen was convicted and hanged. He resented being referred to as 'the man who hanged Crippen'.

Part 2 covers the period between 1912 and 1915. Willcox was very busy during this time as a scientific witness; he was also employed in wartime research dealing with gases which might be used in modern warfare. It was during this period that he had to deal with the 'Brides in the Bath' case.

Part 3 is devoted to Willcox's career as Consulting Physician to the Army. He served in the Dardanelles, Baghdad, Northern Persia, and India, and returned home in 1919.

Part 4 covers the years from 1919 to 1935, and reveals Willcox's great interest in teaching clinical medicine at St. Mary's Hospital and also his researches into new drugs, poisons, and rheumatic diseases.

Part 5, dealing with the final phase of his active life, details his many activities, including being Master of the Society of Apothecaries in 1935–6. He was cofounder of the Empire Rheumatism Campaign. Willcox died of a stroke in 1941 while still in active practice.

Medical historians will welcome this book, for in it Willcox is revealed as a medical seer and as a consistent searcher after justice both in his professional life and in the Courts of Law.

Blood Volume and Extracellular Fluid Volume. Second edition. By SOLOMON N. ALBERT, B.A., M.D., D.A., F.F.A. R.C.S., F.A.C.A., Maryland. 9×6 in. Pp. 295+xxxvii. Illustrated. 1971. Springfield, Illinois: Charles C. Thomas. $16.75.

THE second edition of this practical and useful monograph has been extensively revised and new illustrations and clinical cases have been added.

The surgeon of today has to undertake extensive operations for cancer, and on badly damaged patients, the results of road accidents. It is therefore important that there should be a practical evaluation of blood-loss so that proper replacement can be given.

This book gives all the answers; the author, a practical anaesthetist and a dedicated physiologist, reviews the basic principles of technique for measuring blood-volume and extracellular fluid volume. There can be no doubt that this book will interest the modern surgeon, the anaesthetist, and the physiologist.

There is an extensive bibliography at the end of this book, as well as some useful figures showing the normal blood-volume values in millilitres in both men and women.

Regionale Anästhesie mit dem Langzeitanästhetikum Bupivacain. By HANS NOLTE and JUSTUS MEYER, Munden. 9×6 in. Pp. 121+vii. Illustrated. 1971. Stuttgart: Georg Thieme Verlag. DM.22·80.

A SYMPOSIUM was organized in Bad Oeynhausen, Western Germany, dedicated exclusively to the recently developed local anaesthetic bupivacain (Marcain or Carbostesin).

The first conclusion of this symposium was that local anaesthesia still maintains its place regardless of the tendency to perform all kinds of minor operations under general anaesthesia.

Bupivacain surpasses most of the current local anaesthetics by its long-lasting effect; for instance, conduction anaesthesia lasting for approximately 5 hours is impressive.

Obstetricians reported their results of paracervical, peridural, and caudal anaesthesia during deliveries, but warned against bradycardia and acidosis of the newborn.

Although almost any kind of abdominal operation can be performed under peridural anaesthesia with bupivacain, its special use in general surgery is in postoperative pain suppression, administering intercostal or peridural blockade, if necessary for 1–3 days, by means of a peridural catheter. Dr. J. Crul, who is a Dutch professor in anaesthesiology, showed how in peripheral arterial diseases peridural anaesthesia with bupivacain suppresses pain and enables one to perform angiographies and operations on the diseased vessels by the same anaesthetic manipulation.

Head Injuries. Proceedings of an International Symposium held in Edinburgh and Madrid 2nd to 10th April, 1970. 10×7 in. Pp. 342+xvi. Illustrated. 1971. Edinburgh: Churchill Livingstone. £6.

THIS large volume contains the papers read at an International Symposium held in Edinburgh and Madrid in April, 1970.

The volume is divided into eleven sections. Sections 1–6 contain the papers read at Edinburgh, while Sections 7–11 were delivered in Madrid.

Section 1 is concerned with the prevention of head injury both in children and adults.

Section 2 deals with care at the roadside and the prevention of second accidents.

Section 3 is devoted to the organization of head-injury services.

In Section 4 craniofacial injuries come under review.

Section 5 is concerned with the long-term complications and the care of head injuries.

Section 6 deals with rehabilitation and resettlement, and Section 7 is devoted to the organization of head-injury care in the hospital.

Section 8 deals with the emergency care of head and multiple injuries, while Section 9 is concerned with the pathophysiological basis for the management of head injuries.

Section 10 deals with the diagnosis and treatment of head injuries, and lastly, Section 11 concentrates on the results of neurosurgical care of head injuries.

This is a very comprehensive symposium on head injuries and every facet of the ever-increasing problem comes under review.

An excellent reference volume on a very important subject.

Recent Advances in Cancer and Radiotherapeutics. Edited by KEITH E. HALNAN, M.A., M.D., M.R.C.P., F.F.R., Director, Glasgow Institute of Radiotherapeutics. 9¾ × 6 in. Pp. 412. Illustrated. 1972. Edinburgh: Churchill Livingstone. £6.

CANCER is a common disease and anything new in its treatment is of real interest to the medical profession, particularly surgeons.

This book, with its thirteen contributors, covers the whole field of cancer therapy in a very practical way. All the contributors are experts in their own particular field. The editor has brought together active workers in related fields to survey selected topics in a critical way.

Robert McWhirter gives an analysis of the treatment of breast cancer, and this is of importance when doctors are asking if radical mastectomy is really necessary in the treatment of this condition.

I. D. H. Todd reviews the present position of cancer chemotherapy, while M. L. N. Willoughby gives an excellent account of the management of childhood leukaemia.

Peter Clifford reviews the present position in regard to Burkitt's lymphoma; he writes with conviction, for he has treated many cases at the Kenyatta Hospital in Nairobi.

The later chapters in this book cover progress in chemotherapy, surgery, immunology, radiobiology, and radiotherapeutics.

This is a book which will appeal to all clinicians, but especially to surgeons and radiotherapists. Surgical registrars and tutors will find this book invaluable.

Diagnostische und therapeutische Fortschritte in der Krebschirurgie. By F. LINDER, Heidelberg, G. OTT, Bonn, and H. RUDOLPH, Heidelberg. 9 × 6 in. Pp. 260 + xvi. 1971. Berlin: Springer Verlag. DM.68.

ON the occasion of the eightieth birthday of Professor K. H. Bauer, one of the greatest living surgeons, his pupils and staff gave a series of lectures dealing with the present situation in cancrology.

Although the world is waiting for spectacular discoveries some advances in diagnosis and therapy are evident. Recent developments in angiography and endoscopy are definite achievements in the diagnostic field. Incontestable progress has been made in the therapy of Wilms's tumours, where the combined attack by operation, radiation, and chemotherapy (actinomycin D) has proved to be a success.

Radioactive gold implantation in the hypophysis is popular with the specialists of Professor Bauer's medical institution in Heidelberg University, though in other centres this method finds fewer followers.

This book gives an up-to-date account of recent developments in cancrology.

Surgery of Rheumatoid Arthritis. Edited by RICHARD L. CRUESS, M.D., Montreal, and NELSON S. MITCHELL, M.D., C.M., Montreal. 10 × 7 in. Pp. 211 + x. Illustrated. 1971. Oxford: Blackwell Scientific Publications. £9·75.

THIS interesting volume is the outcome of a course of lectures entitled 'The Surgical Management of Rheumatoid Arthritis', which was given under the sponsorship of the Postgraduate Board of the Royal Victoria Hospital and McGill University in Montreal in May, 1970.

The thirty-two contributors cover the whole surgical field of rheumatoid arthritis in a most comprehensive way. The emphasis is on prevention of deformities.

Many operations are currently available, and sufficient numbers of patients have been followed to permit an analysis of the results of surgery which can offer the basis for a sound surgical approach.

The many and varied surgical techniques are well described and illustrated. A dynamic brace for finger-joint reconstruction in arthritis is discussed.

This book will make a strong appeal, not only to orthopaedic surgeons, but also to plastic surgeons and rheumatologists.

Manual of Preoperative and Postoperative Care. Second edition. Edited by JOHN M. KINNEY, M.D., New York, RICHARD H. EGDAHL, M.D., Mass., and GEORGE D. ZUIDEMA, M.D., Baltimore. 9 × 6 in. Pp. 644 + xiv. Illustrated. 1971. London: W. B. Saunders Co. Ltd. £4·70.

THE second edition of this up-to-date and very practical volume is the work of over thirty contributors, who come from various surgical centres in the United States and Canada.

Every aspect of pre- and postoperative care has been carefully covered. References to standard books and important articles are to be found at the end of the various chapters. This volume is divided into two main parts.

Part 1 is concerned with general principles, such as wound healing, fluid and electrolyte therapy, blood transfusion, cardiac failure, shock, and transplantation.

Part 2 deals with the surgical care of organs and systems. This second part should prove to be of real value to surgeons as all the articles are written by practising surgeons with mature clinical experience.

The chapters dealing with multiple injuries and the care of the burned patient are outstanding.

A useful book for the modern surgeon at a very moderate price.

Contemporary Burn Management. Edited by HIRAM C. POLK, jun., M.D., Louisville, and H. HARLAN STONE, M.D., Atlanta. 9¼ × 6 in. Pp. 444 + xx. Illustrated. 1971. Edinburgh: Churchill Livingstone. £9·50.

THIS is a useful and informative book devoted to an important subject, considering that patients with burns occupy more than 10,000 hospital beds each year in America and some 7000 die as the result of the burn injury.

This book is divided into six parts. Treatment of shock associated with burns is discussed in Part 1, including crystalloid resuscitation, the Brooke formula, and fluid therapy with Dextran. Professor A. W. Wilkinson contributes an important chapter on limited-volume therapy with colloid.

Part 2 is concerned with respiratory injury, and tracheal intubation is discussed.

Part 3 deals with early wound care and the various methods of treating burns are discussed in some detail.

Immunological problems are considered in Part 4, and streptococcal, staphylococcal, Gram-negative bacteria, and fungal infections are analysed in Part 5. In Part 6 an excellent summary is given, in which techniques of wound closure, grafting, and splinting come under review.

This is a very useful reference volume giving an up-to-date account of the treatment of burns in both America and Great Britain.

It will prove of real value to both surgeons and surgical residents as a practical guide to treating patients with thermal injury. An excellent production.

Chest Injuries. By Roshan Lall Gupta, M.S., F.R.C.S. (Edin.), F.R.C.S. (Eng.), F.A.C.S., F.R.S.M. (London), Meerut, India. 8½ × 5½ in. Pp. 215 + v, with 34 illustrations. 1972. Meerut: Saritee Pvakashun. No price given.

In India as in other parts of the world chest injuries are common in both children and adults. Professor Gupta with his large clinical experience of chest injuries in both England and India has written a very practical book on these conditions. He is to be congratulated on the way in which this monograph has been printed in India on good-quality paper with well-produced illustrations.

This book should prove of real use to students and practitioners in India who want to know more about chest injuries.

Stapedectomy. By Harold F. Schuknecht, M.D., Boston. 11 × 8½ in. Pp. 119 + vii. Illustrated. 1971. Edinburgh: Churchill Livingstone. £10·50.

Today stapedectomy is a common operation and it is essential that medical men should know what the operation can achieve. Dr. Schuknecht has performed this operation on over 6000 patients and he presents his methods and results in this monograph. The clinical features of otosclerosis are examined, and the criteria for the selection of patients who will benefit from stapedectomy are discussed. The intricate operation of stapedectomy is described and illustrated in considerable detail. Special attention is given to the selection of the prosthesis used in this operation. Complications which may occur following this operation are also described.

The histopathological studies carried out by the author are interesting and convincing, and the illustrations are excellent.

This book is a valuable addition to surgical literature.

Septic Shock in Man. Edited by S. G. Hersky, M.D., Bronx, Louis R. M. Del Guercio, M.D., Bronx, and Rita McConn, Ph.D., Bronx. 9¼ × 6¼ in. Pp. 313 + xxi. Illustrated. 1971. Edinburgh: Churchill Livingstone. £4·75.

Shock is a very common condition and septic shock is associated with a very high mortality rate.

This book with its many contributors from America and Canada covers every facet of this important problem.

It is divided into eight parts. Part 1 is concerned with the background patterns in septic shock. Part 2 deals with the respiratory aspects, including pulmonary mechanics and respiratory measurement in acutely ill patients. Part 3 is devoted to oxygen transport and utilization, including oxygen uptake in septic shock. In Part 4 the metabolic aspects come under review, while in Parts 5 and 6 the cardiocirculatory aspects are examined in detail, including the use of corticosteroids in the treatment of septic shock. Part 7 deals with special problems including those of fluids in burns. Part 8 contains a very careful summary of the whole problem.

By compiling the collective experience of a diverse group of medical investigators in shock units the editors have attempted to stimulate further inquiry into this very lethal condition.

This book will have a wide appeal to all medical men, but especially to surgeons, anaesthetists, and physiologists.

The Thyroid. A Fundamental and Clinical Text. Third edition. Edited by Sidney C. Werner, M.D., D.Sc. (Med.), New York, and Sidney H. Ingbar, M.D., Boston. 10 × 7 in. Pp. 914 + xxvii, with 276 illustrations. 1971. London: Harper & Row. £14.

The third edition of this enormous work has a new co-editor and an almost completely new group of contributors. It is pleasing to note that some British contributors have been included in this edition.

The general format of the work has been preserved, but the text has been expanded.

The work is comprehensive and every facet of thyroid anatomy, physiology, pharmacology, and pathology has been well covered.

Full discussion is given to the various thyroid states, and Selwyn Taylor's article on the aetiology and pathogenesis of non-toxic sporadic goitre is excellent.

The illustrations, especially the photomicrographs, are quite a feature of the book.

There can be little doubt that this volume will become the standard work of reference on the thyroid gland and its diseases.

A Practice of Anaesthesia. Third edition. Edited by W. D. Wylie, M.A., M.B. (Cantab.), F.R.C.P., F.F.A. R.C.S., Hon. F.F.A., R.C.S.J., London, and H. C. Churchill-Davidson, M.A., M.D. (Cantab.), F.F.A. R.C.S. London. 9 × 6 in. Pp. 1549 + xviii. Illustrated. 1972. London: Lloyd-Luke (Medical Books) Ltd. £12.

The third edition of this comprehensive work on anaesthesia has been completely revised and brought up to date. It is the effort of the anaesthetists of St. Thomas's Hospital, as all the eight associate editors and the eight contributors are from that hospital.

Anaesthesia is a large branch of medicine today and it includes physics, chemistry, pharmacology, physiology, and electronics in its make-up. In this new edition some important chapters have been introduced, such as anaesthesia for dental surgery, special care units, and modern pharmacological principles as applied to this specialty.

Although this is a multi-author work the style of the book has remained unchanged and the text is still lucid and factual.

This is by far the best work on anaesthesia in the English language; it is completely up to date and as a work of reference it could not be bettered.

Chirurgische Differential-Diagnostik. Edited by Karl Vossschulte, Klinikstr., and Ludwig Zukschwerdt, Hamburg. 10½ × 7 in. Pp. 859 + xii. Illustrated. 1972. Stuttgart: George Thieme Verlag. DM.188.

This is a new textbook on the differential diagnosis in surgical conditions. Twenty-eight contributors have helped to cover the vast field from cutaneous lesions to the acute abdomen. While many subjects are discussed in detail, neonatal obstructions are dismissed in less than half a page. The book contains many lists and tables and a large number of excellently produced illustrations. On the other hand, it is strictly limited to diagnosis and does not discuss pathology or mention treatment.

It is difficult to decide for what type of reader this book has been written. It contains too much information for the medical student but, on the other hand, the practising surgeon would wish to know something about the pathology and treatment when referring to a textbook about the differential diagnosis.

In its final section this book has a long list of the normal values of many pathological investigations and this final chapter was certainly the most helpful to the reviewer.

The Anatomical Basis of Medical Practice. By R. Frederick Becker, Ph.D., James W. Wilson, Ph.D., M.D., and John A. Gehweiler, M.D. 11 × 8¼ in. Pp. 907 + xv. Illustrated. 1971. Edinburgh: Churchill Livingstone. £11.

The title of this large work might be altered to 'Living Anatomy', for the authors have certainly proved that anatomy is indeed alive. The modern medical student requires a book such as this, in which embryology, surface markings, and radiology play such an enormous part.

The authors have wisely stressed the anatomical relationships which are important in clinical medicine and surgery.

The embryology as presented depicts the many and varied congenital defects which may occur not only in the thorax and abdomen but also in the neck and brain.

The radiological anatomy is illustrated with excellent skiagrams showing the course and distribution of arteries by means of angiograms. The surface markings are depicted on living models and they are excellent.

The illustrations are quite a feature of this large volume and the line drawings have the distinct advantage in that they are mostly original.

One only wishes that such a book as this was available when one was a student in the dissecting room.

This book is alive and will be popular with students, nurses, and practitioners everywhere.

Anatomy, Regional and Applied. Fifth edition. By R. J. Last, M.B., B.S. (Adel.), F.R.C.S., Los Angeles. 9½ × 6½ in. Pp. 925 + xvi. Illustrated. 1972. Edinburgh: Churchill Livingstone. £8.

This book was born of popular demand in 1954 and since that date five new editions, besides several reprintings, have appeared. These figures show the approval of students throughout the world.

In the recent edition the new (P.N.A.) nomenclature is used throughout the text. There are 32 new illustrations, which are all original and excellent. This book retains its place as the best production on regional and applied anatomy that has so far been published.

Praxis der Schockbehandlung. Edited by Theodor Ott Lindenschmidt, Hamburg, Erich Rugheimer, Erlangen, and Hans Willenegger, Liestal. 9 × 6 in. Pp. 211 + ix. Illustrated. 1971. Stuttgart: Georg Thieme Verlag. DM.26·80.

This volume consists of the papers of a meeting held in 1970 involving surgeons, anaesthetists, and those responsible for blood-transfusion services. The book contains seventeen papers on various aspects of shock, dealing with aetiology, assessment, and treatment. The administrative problems of a blood-transfusion service have not been neglected and the majority of the papers presented are practical rather than theoretical. The discussion is presented in full. This volume should be of interest especially to those concerned with blood-transfusion services and most papers contain extensive lists of references. It is unfortunate that the papers do not have summaries, but there is a good index.

An Atlas of Diseases of the Eye. Second edition. By E. S. Perkins, M.D., Ph.D., F.R.C.S., Institute of Ophthalmology, University of London, and Peter Hansell, M.R.C.P., Hon. F.R.P.S., F.B.P.A., Westminster Medical School, London. 10 × 7¾ in. . Pp. 86 + xi. Illustrated. 1971. Edinburgh: Churchill Livingstone. £6.

The second edition of this atlas has been considerably expanded to include sections on glaucoma and anomalies of ocular movement. Several new drawings have been added and the atlas is the best so far produced with coloured drawings. The various pictures depicting the fundus of the eye are superb.

The student and practitioner will find this atlas an admirable book for ready reference.

Surgical Departments in Hospitals. The Surgeon's View. Edited by D. M. Douglas, M.B.E., M.B., Ch.M., M.S. (Minn.), F.R.C.S., F.R.C.S. (Edin.), Dundee. 8½ × 5½ in. Pp. 134 + ix. Illustrated. 1972. London: The Butterworth Group. £2·50.

This is a useful book, for it contains the views of Scottish surgeons from Aberdeen, Glasgow, Edinburgh, Falkirk, and Dundee. The problems of hospital construction with regard to out-patient departments and the lay-out of operating-theatre units and intensive care units are discussed in some detail. The important question of resuscitation facilities receives due consideration.

Some of the most interesting features of this book are the discussions on teaching and research facilities in various hospital centres.

This book will prove a useful reference volume when any new hospital projects are put forward by the Ministry; it should ensure that surgeons in the future will have some knowledge of hospital organization in Scotland.

Symposium on the Hand, Vol. 3. Edited by Lester M. Cramer, D.M.D., M.D., F.A.C.S., Philadelphia, and Robert A. Chase, M.D., F.A.C.S., Palo Alto. 11 × 8½ in. Pp. 287 + ix. Illustrated. 1971. London: Henry Kimpton. £16·10.

This volume contains the proceedings of the Symposium of the Educational Foundation of the American Society of Plastic and Reconstructive Surgeons held at Stanford University in March, 1970. The papers contain the clinical and operative experiences of twenty-six leading hand surgeons of the world.

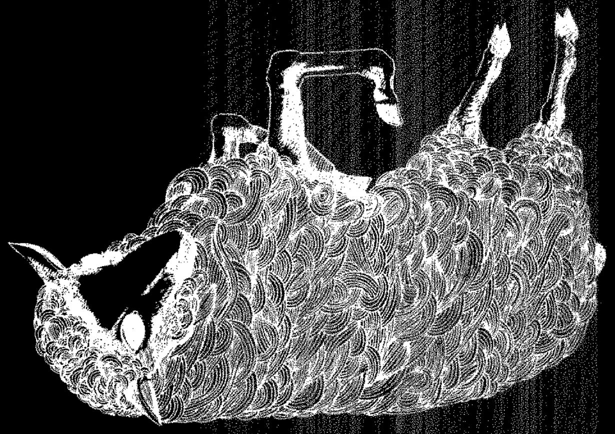
Many and varied facets of the injured hand are described in this volume, but the outstanding article is by Paul Brand on the rehabilitation of the hand in leprosy.

Another interesting paper is by L. Gómez Correa of Mexico City on hand replantation; it reveals that under suitable circumstances such a procedure is possible.

As one would expect, the treatment and reconstruction of the burned hand and fingers receive due notice. Such subjects as the painful hand, treatment of Dupuytren's contracture, assessment of peripheral nerve injuries, and the Boutonnière deformity are all considered and discussed at length.

Hand clinics are becoming common place today in our teaching hospitals and there can be no doubt that they have played an important part in lessening the bad deformities of the hand which were common a few decades ago.

This book will be a *must* to all hand and plastic surgeons.



Are the dried and twisted intestines of a dead animal really the best material for sutures in 1972?

A DEXON suture is absorbable, inert, strong and supple.
And will meet every demand you could make.
This isn't surprising, as DEXON is the first and only material created in the laboratory for use as a suture.

Man-made, absorbable homopolymer of polyglycolic acid. Supplied non-needled, or on DAVIS + GECK †ATRAUMATIC needles.

Another surgeon is about to use one of the world's finest surgical blades....
...this happens thousands of times everyday!

It happens because the blades are by Swann-Morton, the people who meet the highest requirements in surgical knives.
We need say very little about our superiority. The world's surgeons have proved it for us!

Fight cancer with a will

When testators ask your advice, please remind them of the urgent work of the Imperial Cancer Research Fund. In the Fund's up-to-date laboratories trained minds are using every weapon of modern science to fight all forms of cancer, including leukaemia.

Now one of the world's great research centres, the I.C.R.F. relies entirely on public support. The cancer problem *must* be solved. Please help now.

Patron:
H.M. THE QUEEN
President:
The Honourable Angus Ogilvy

Form of Bequest

I hereby bequeath the sum of . . . . .pounds free of duty to the Imperial Cancer Research Fund, Lincoln's Inn Fields, London, WC2A 3PX for the purpose of scientific research, and I direct that the receipt of the Honorary Treasurer or Secretary shall be a good discharge for such legacy.

Please write for further information to: The Secretary, I.C.R.F. (Dept 164),

John Wright ***FORTHCOMING TITLES***

Emergency Surgery

Ninth edition. Edited by T. J. McNAIR, M.D., F.R.C.S. (EDIN.), F.R.C.S. (ENG.), Consultant Surgeon, Royal Infirmary of Edinburgh.
Extensively revised and with about 200 new illustrations, the theme of this book still remains: when to operate, when not to operate, and how to operate under emergency conditions.
998 *pages* 1155 *illustrations* **£12·50**

Fundamental Physics of Radiology

Second edition. W. J. MEREDITH, O.B.E., D.SC., F.INST.P., Director of Physics, Christie Hospital and Holt Radium Institute; and J. B. MASSIE, B.SC., F.INST.P., Physicist, Christie Hospital and Holt Radium Institute.
In the second edition a new chapter on the treatment prescription and an appendix on modulation transfer functions have been added.
674 *pages* 460 *illustrations* **£6·25**

The Arterial Anatomy of the Kidney

F. T. GRAVES, M.S., F.R.C.S., Urological and Senior Surgeon, Staffordshire General Infirmary, Stafford.
This book is a complete work of reference on the vascular and arterial systems of the kidney, based on investigations covering many years. With the ultimate aim of improving renal surgery, a complete chapter on surgical technique has been included.
116 *pages* 75 *illustrations* **£3·25**

Surgical Techniques

HERBERT HAXTON, B.SC., M.D., CH.M. (ST. ANDREWS), F.R.C.S., Senior Surgeon, Crumpsall Hospital; Manchester Northern Hospital; Royal Manchester Children's Hospital.
This book has been written in two parts covering surgical techniques in general and techniques in specific operations. During thirty years of surgical experience the author has modified his own surgical practice in many ways, and believes that other surgeons might benefit from a description of his methods, in particular the departures from the usual.
212 *pages* 158 *illustrations* **£2·50**

Stomahesive

to provide comfort and protection in

ileostomy
ileal conduit
colostomy
fistulae

Stomahesive
has been specifically designed to firmly adhere and mould to skin surfaces even when wet and excoriated.

Stomahesive
facilitates healing of excoriation and preserves the integrity of peristomal and perifistular skin.

Stomahesive
provides a comfortable leak-free seal between appliance and skin.

Stomahesive
is prepared as a 4in. x 4in. square from gelatin, pectin, sodium carboxymethylcellulose and polyisobutylene. The exposed surface is protected by an impermeable polythene film. Stomahesive must fit closely to the stoma. A cutting guide is provided.

Why Dexon*? Why not?

1. Easy to handle – similar to silk or linen thread
2. Packed dry – convenient to use
3. High tensile strength – excellent wound support
4. Smaller gauges needed for comparable strength compared with gut
5. Braided construction – secure knots – more security
6. Predictable absorption even in contaminated areas
7. Minimal tissue reaction and inflammatory response
8. Improved patient comfort
9. Permits undisturbed wound healing
10. Less painful wounds
11. Shorter hospitalization
12. Improved cosmetic results especially with subcuticular stitches
13. Is there when it is needed, but has gone when it is not
14. Multi-uses means greater economy
15. May be removed as usual when used for skin sutures but may be left to absorb if preferred – e.g. paediatric surgery, under orthopaedic plaster casts, episiotomy repairs, circumcisions, etc.
16. Simplified stock holding, laying up for operations, nurse training
17. It is supplied on the best suture needles made

1. The braided construction may mean an initial difficulty in tying knots
2. A slight increase in tissue-drag may be experienced. Can be improved by wetting
3. Absorption of blood and other body fluids may make Dexon more difficult to see
4. Suture for suture it appears to be more expensive than other materials – cost in use is probably less
5. It is different and you may need to especially ask for it

Dexon* **the suture that supersedes catgut**

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 57. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners Ltd., St. Martin's House,* 159 *Clapham High Street, London, S.W.*4.

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

Airstrip moves and breathes just like skin.

It is not a disaster if Airstrip gets wet, the skin beneath stays dry!

Airstrip now has extra strength hypoallergenic adhesive so it won't come unstuck.

The wound heals quickly. It's protected by Melolin, the unique non-stick pad.

Airstrip is the only BPC approved Microporous Plastic Dressing.*

FOGARTY CATHETERS FOR ACUTE VASCULAR OCCLUSION

FOR: Venous Thrombectomy

Occlusion/Emergency Tamponade

Arterial Embolectomy

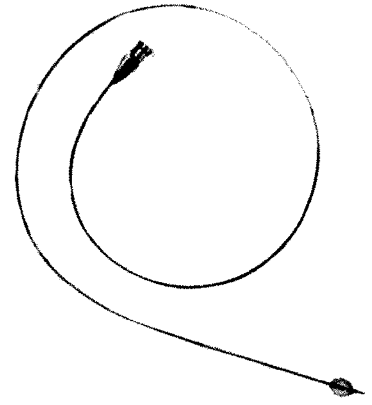
Dilation/Creation of Atrial Septal Defects in Infants

Double Lumen Balloon Catheter/Creation of Atrial Septal Defects in Infants

Biliary Balloon Probe/Exploration and Removal of Debris and Stones

Irrigation

Rugged Universal Hub Fits All Luer-Lok Type Syringes



BALLOON CATHETER CONCEPT

Each catheter has a specially constructed balloon at the distal tip (except Irrigation Catheter). In thrombectomy and embolectomy, when the catheter is introduced into a vein or artery, the instrument follows the path of least resistance and the tip threads itself past the thrombus or plaque. The balloon is then inflated with sterile fluid and the catheter withdrawn, bringing the clot with it. As an emergency tamponade, for dilation, or as a biliary probe, the balloon is similarly inflated.

GENERAL DESIGN FEATURES

1. Tips on the various types are specially designed for the particular procedure; all are soft and atraumatic.
2. Controlled symmetrical balloon geometry.
3. Secure balloon attachment by epoxied suture.
4. Length marked catheter bodies.

ALL FOGARTY CATHETERS ARE SUPPLIED STERILE

For rapid, safer post operative wound healing
Redivac closed suction apparatus
TO PREPARE
KEEP UPRIGHT
Zimmer

First intention wound healing after operation is prolonged by the accumulation of tissue fluids and blood at the site. This accumulation often encourages infection.

The problems associated with these traditional procedures are solved by Redivac Closed Suction Apparatus, which removes blood and tissue fluids and avoids the formation of haematoma.

The Redivac evacuator bottle supplies a negative pressure of 600 mm Hg. The drainage tube is laid in the wound and is passed through intact skin, some distance from the incision. It is then connected to the evacuator bottle and suction commenced.

The Redivac Closed Suction System is simple, inexpensive and comfortable for the patient. It is applicable in all deep surgical procedures. The Redivac Closed Suction System facilitates nursing and results in shorter hospitalisation of patients.

Now, to simplify treatment of pseudomonas chest infections:

Pyopen infusion

In the published papers, Pyopen's success rate in chest infections is 65% even though the majority of the patients described had severe underlying pathology.

The best results have been achieved with a dosage of 20-30G. I.V. daily. Pyopen infusion makes this dosage simpler to administer by providing Pyopen in ready-to-use infusion bottles with diluent and transfer needles for the easier preparation of infusion solutions.

Pyopen is, of course, a penicillin, and has proved valuable in patients with known renal impairment: in such cases, however, dosage should be reduced.

Adult dosage: 20-30G. I.V. daily.
In patients with renal impairment dosage should be reduced.
Contra-indications: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins. In rare cases spontaneous skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by

OP-SITE BARRIER

TRADEMARK

The most effective adhesive drape

Unlike other sterile adhesive drapes, Op-site can breathe.

Which puts it at something of a premium. Because it allows a continual exchange of gases: oxygen to the skin, water vapour away from it.

There's no maceration of tissue and no perspiration build up to loosen the adhesive. Just total conformability and strict adhesion throughout.

Because of this, Op-site may be sutured through and left to protect the skin till the stitches are removed.

Post-op protection makes sense. Use Op-site.

CRYOSURGERY

for ear nose and throat work

Cryosurgical techniques have now a proven place in E.N.T. surgery. Operating on the highly successful Joule Thompson principle (that of high pressure gas flowing through a small orifice into a chamber, rapidly cooling on expansion) the advantages of the technique are irrefutable:—

☐ Reduced discomfort during and after operation.

☐ Diminished tissue reaction.

☐ Decreased morbidity.

☐ Elimination or lessening of bleeding.

no fear
no infection
no pain

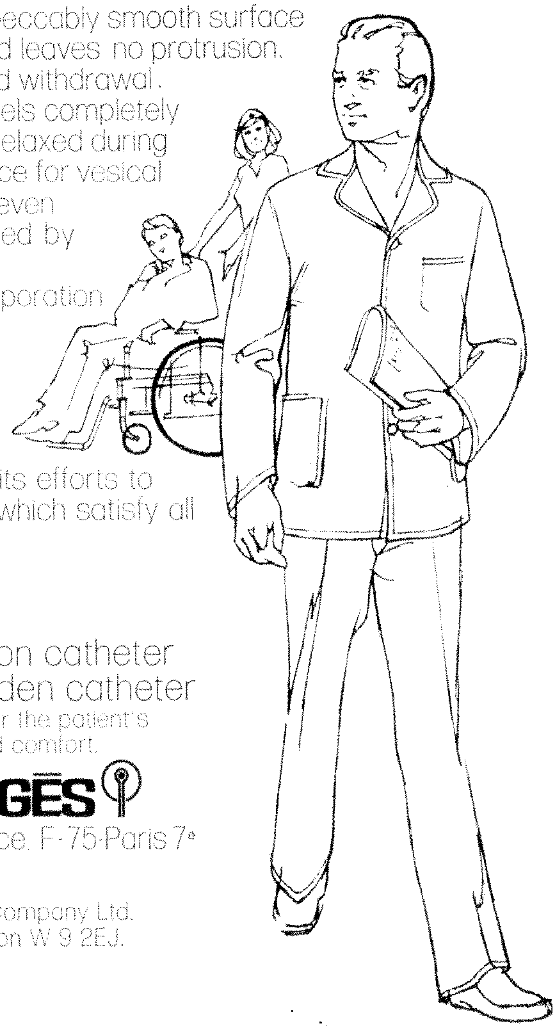
with a Porges golden balloon catheter

No pain: it has an impeccably smooth surface and the balloon when deflated leaves no protrusion. This allows easy insertion and withdrawal.

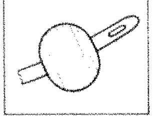
No fear: the patient feels completely reassured. He will be utterly relaxed during catheterization. A large surface for vesical support is obtained through even inflation of the balloon, ensured by reinforcing ribs.

No infection: the incorporation of active bacteriostatic compounds into the latex prevents any urinary tract infection.

Our research department has devoted all its efforts to the production of catheters which satisfy all clinical requirements:



The Porges balloon catheter



the golden catheter
created for the patient's
safety and comfort.

ORIGINAL PAPERS

DIETARY FAT, DYSPEPSIA, DIARRHOEA, AND DIABETES*

By PETER CHILDS

CONSULTANT SURGEON, PLYMOUTH GENERAL HOSPITAL, PLYMOUTH, DEVON

SUMMARY

This paper postulates that fat intolerance is a widespread metabolic disorder characterized by impairment of glucose tolerance caused by excess dietary fat intake, and cured in most cases by the fat-free diet as defined in this paper.

Fat intolerance may present as flatulent dyspepsia, surgical disease or disorder in the biliary tract, peptic ulceration, diarrhoea associated with spasm or diverticular disease of the colon or colitis, or as maturity-onset diabetes mellitus; one, two, or more of these syndromes may occur at the same or different times in the same patient. The dietary fat intake and the effect of the fat-free diet in each of these syndromes have been investigated, and the findings and their implications are discussed.

Treatment of disease and disorder in the biliary tract by sphincterotomy of the sphincter of Oddi in a series of 57 cases and of duodenal ulcer by pyloroplasty alone in 50 cases is reported. The results of treatment of duodenal ulcer by pyloroplasty alone in a series of 38 cases are compared with those after vagotomy and pyloroplasty in a similar series of 38 cases. Cure of peptic ulceration by pyloroplasty alone is reported, and vagotomy is considered to be unnecessary. The normal pylorus is defined, and the naked-eye appearances of the pylorus observed during 87 cholecystectomies are reported. The significance of these observations and of radiological abnormalities seen in routine barium-meal examinations of cases of disease or disorder in the biliary tract is discussed. Evidence is presented that the function of and pathological changes in the sphincter of Oddi and the pylorus are affected by the dietary fat intake and determine the absence or presence of abnormality in the biliary tract or of peptic ulceration respectively.

The clinical syndromes of fat-intolerant diarrhoea and its association with spasm of the colon, colitis, and diverticulitis, and of abdominal pain due to fat intolerance seen in a series of 17 children, are described as clinical entities.

The effect of the fat-free diet on glucose tolerance has been investigated in a series of 65 patients, and the significance of the increased tolerance observed has been assessed statistically. Four hundred and thirty-three glucose-tolerance tests have been performed to assess the change in glucose tolerance in 134 patients who had been on the fat-free diet for periods of 3 months to 2 years as treatment for dyspepsia due to disease or disorder of the biliary tract, peptic ulceration, diarrhoea associated with spasm of the colon, diverticulitis or colitis, obesity, and migraine. Among these patients were 23 who also suffered from diabetes mellitus. Cure of maturity-onset diabetes mellitus by the fat-free diet is reported, and evidence is produced to show that it is an acquired abnormality of the metabolism caused by excess dietary fat intake.

THE opportunity to study the natural history of dyspepsia and related conditions in the same patients over the past 20 years has produced evidence that dietary fat intake, dyspepsia, diarrhoea, and diabetes are closely interrelated. This paper presents the evidence and hypotheses which follow from this fact.

1. THE FAT-FREE DIET

The fat-free diet (F.F.D.) has been an essential part of the treatment (*Table I*). It was developed entirely from the experiences of patients, the foods and drinks forbidden being those which had caused symptoms or precipitated 'attacks' affecting the digestive system or the bowel. The diet has been called fat-free so that patients understood the purpose and avoided taking fat in any form that they could identify. It is not free of all fat; there is fat in lean meat, poultry, fish, bread, vegetables, and other foods. Patients must adhere strictly to the instructions; the total fat intake has to be decreased drastically, and vegetable fat cannot be added instead of animal fat.

---

* This paper embodies the substance of a lecture delivered to the Plymouth Medical Society in Plymouth, Devon, on 10 Dec., 1971.

Table I.—THE FAT-FREE DIET

You must NOT eat or drink any of the following, *or anything containing them*:

Butter
Cheese
Cream
Ordinary or Channel Island MILK

Margarine
YOLK of EGG
Salad cream or mayonnaise

Kipper, mackerel, or any fatty or 'oily' fish

Lard
Pork
Bacon
Ham
Sausage

Mutton
Liver
Suet

Pastry
Cake
Biscuits:
- sweet
- half-sweet
- Cornish wafer

Chocolate
Toffee

NEVER FRY   DO NOT use   Vegetable oil or fat
'edible' fat
olive oil

Look at list of 'contents' of every tin or packet: if they include fat, vegetable oil, or 'edible' fat—DO NOT USE

You CAN eat or drink the following:

FAT-FREE (or skimmed) MILK. *Beware*: NOT Low fat or MILK-FAT-FREE MILK

Alcohol
Cereals
Porridge

Bread, white or brown, fresh or toasted

Sugar
Boiled sweets

Jam
Honey
Marmalade

'Milk' puddings } made with fat-free milk
Junket }

WHITE of EGG

Custard made with egg-free powder and fat-free milk   Meringue

Biscuits: cracker or water

Potatoes: 'Boiled' 'Jacket', or mashed with fat-free milk: NOT   Roast, fried or chipped, or mashed or treated with butter

Lean beef
Lean lamb
Lean tongue

Lean breast and leg of poultry

White fish—boiled, grilled (no fat), or cooked in wine

Marmite
Bovril
Oxo

Fat-free soups
FRUIT: fresh or stewed

Mint sauce
Tomato ketchup
Fat-free pickles

YOU NEED NEVER BE HUNGRY:
YOU CAN EAT *FAT-FREE FOOD* whenever you feel the need

I have observed a large number of patients on this diet for many years; it has not deprived them of essential fatty acids. Davidson and Passmore (1969) pointed out that nature intended that human beings should obtain their requirements of vitamin D by irradiation of their skin. Fat-free milk provides calcium. Vitamin A is present in heart, kidney, halibut, and carotene in many fruits and vegetables. I have found no evidence that the F.F.D. is deficient, but any diet can be deficient if an inadequate quantity or variety is taken, and when necessary, for example, if a patient is aged and house-bound, appropriate supplements can be given. At all times, however, the need to keep the total fat intake at a minimum must be remembered.

I have estimated the change in the daily intake of fat and carbohydrate of patients who have adhered to the F.F.D.; the figures are approximate and are minimal values. The average daily decrease in dietary fat intake in 133 patients was at least 950 calories; the greater part of this was derived from cows' milk (53 per cent) and the pig (33 per cent (*Table II*). The daily intake of carbohydrate in 9 patients before and the change in carbohydrat intake after they started to take the F.F.D. ar shown in *Figs.* 1 and 2.

Table II.—AVERAGE DAILY DECREASE IN DIETARY FAT INTAKE IN 133 PATIENTS ON THE F.F.D.

FAT-CONTAINING FOODSTUFF NOT ALLOWED IN F.F.D.	DECREASE IN DIETARY FAT INTAKE (MINIMAL) (cal. per day)	PERCENTAGE TOTAL DECREASE IN DAILY DIETARY FAT (approx.	
Butter	265	28	53 per cent from cows' milk
Cheese	60	6	
Cream	45	5	
Milk (except fat-free milk)	135	14	
Margarine	85	9	
Eggs (yolk)	45	5	
Pork	60	6	33 per cent from the pig
Ham	25	3	
Sausages	40	4	
Bacon	90	9	
Lard	100	11	
Total	950	100	

II. DYSPEPSIA

A. Flatulent Dyspepsia.—Flatulent dyspepsia the commonest syndrome of indigestion, is characterized by a 'blown' or 'full feeling' in the epigastrium, discomfort not amounting to pain associated with belching, and 'acidity' or 'heartburn' These symptoms may be accompanied by attacks o nausea and vomiting of 'froth', mucus, and recently eaten food. Flatulent dyspepsia is due to fat intolerance; the symptoms are caused by eating too much fat and are cured by the F.F.D. Antacids are not necessary when a patient adheres to the F.F.D.

Flatulent dyspepsia may be the only complaint, or it may present as a 'back-cloth' to attacks of pain with or without jaundice, due to disease or disorder in the biliary tract; or in association with peptic ulceration, or radiological evidence of hiatus hernia or disease or disorder of the large bowel; or accompanying other conditions in which the dietary fat intake may or may not be recognized or significant.

B. The Biliary Tract.—

1. *The Evidence.*—The symptoms of flatulent dyspepsia are significant and are often identified as associated with dietary fat intake in 70 per cent of patients who suffer from disease or disorder of the biliary tract. Pain with or without jaundice and physical signs direct attention to the biliary tract.

In 1960 I reviewed 1699 'dyspeptic' patients seen and treated in the preceding 10 years. A clinical diagnosis of disease or disorder of the biliary tract was made in 721, and was confirmed by a cholecystogram or at operation in 379. However, the cholecystogram was normal in 342 cases in which the history and physical signs were identical with those in proved cases, i.e., typical 'biliary tract' pain, jaundice in some cases, and a palpable tender gall-bladder or guarding of muscles and tenderness in the right subcostal region. One hundred and seventy-eight of 532 'dyspeptic' patients seen during 1969–71 were proved to have gall-stones, while a cholecystogram showed no abnormality in 170 with identical symptoms and signs.

Patients suffering from disease or disorder of the biliary tract can, therefore, be grouped as follows:—

a. Those with proved gall-stones or a non-functioning gall-bladder.

b. Those in whom a cholecystogram, often repeatedly, is negative.

c. Those who have already undergone cholecystectomy.

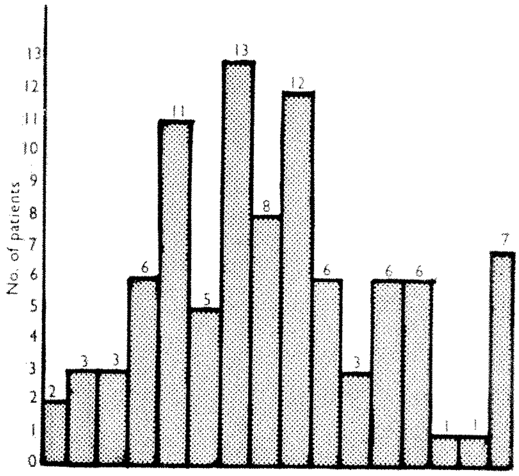

FIG. 1.—Daily carbohydrate intake in 93 patients before starting the F.F.D.

Table III.—RELATION OF DIETARY FAT INTAKE TO SYMPTOMS IN PATIENTS WITH PROVED GALL-STONES

Fat Intake and Symptoms		*No. of Cases*
On strictly F.F.D.		17
Symptom-free	11	
Suffered attacks of pain	6	
Not strictly on F.F.D.		22
Symptoms related to fat intake (2 had become pregnant)	22	
No longer dieting because they were symptom-free		11
Requiring urgent admission	4	
Symptom-free to present date	7	
Total No. of patients questioned		50

The results of inquiries in respect of dietary fat intake in each of these groups are given below.

a. Dietary fat intake in patients known to have gall-stones or a non-functioning gall-bladder.—Fifty patients who had been on the waiting list for cholecystectomy for more than 1 year who were known to have stones in or non-function of the gall-bladder had been instructed to adhere to the F.F.D. Only 6 patients who had adhered to the F.F.D. suffered from any symptoms; in 3 of these a distended mucocele of the gall-bladder was the cause of some discomfort. The F.F.D. cured all the symptoms in the remaining cases; there was only recurrence of symptoms when fat was taken (*Table III*). With few exceptions the F.F.D. cured symptoms in the patients who were suffering from gall-stones in or non-function of the gall-bladder. The exceptions have been: (i) when distension of a mucocele caused symptoms; (ii) a group of cases, to be considered in detail later, in which there was stenosis or hypertrophy of the sphincter of Oddi.

The series of patients on the waiting list did not include those for whom urgent or emergency admission was necessary. Those suffering from acute infection in the gall-bladder or common bile-duct or from persistent jaundice were not cured of symptoms by the F.F.D.; only 45 of 379 (12 per cent) cases with proved gall-stones required urgent or emergency operation.

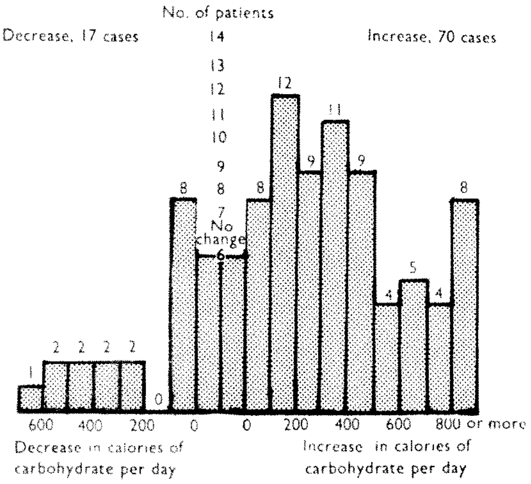

FIG. 2.—Change in carbohydrate intake on the F.F.D. in 93 patients.

b. Dietary fat intake in patients whose cholecystogram was negative.—The F.F.D. cured all the symptoms in the majority of these cases. It was impossible to carry out a statistically significant follow-up, but many patients have been followed for many years and the results have been as follows:—

i. Many patients who adhered to the F.F.D. or even to a low-fat intake remained symptom-free and did not require further investigation or treatment.

ii. Some patients who were symptom-free on the F.F.D. assumed that they were 'cured' and reverted to their former feeding habits. A small number remained symptom-free, but the majority of those who resumed their previous dietary fat intake have been seen and investigated again. In some, gall-stones had formed or the gall-bladder had become non-functioning, and these patients have undergone cholecystectomy or are on the waiting list. In others the cholecystogram was still negative and the patients have again become symptom-free on the F.F.D.

iii. Fourteen out of 170 patients whose cholecystogram was negative despite typical symptoms and signs of disease or disorder in the biliary tract did not respond to the F.F.D. There was stenosis or hypertrophy of the sphincter of Oddi in these cases; they are considered in more detail later.

iv. A small number of patients have eventually developed and undergone operation for a duodenal ulcer. This significant finding is considered later.

c. Dietary fat intake after cholecystectomy.—Follow-up of 43 patients who had undergone cholecystectomy more than 8 years earlier revealed that only 4 did not restrict their dietary fat intake.

Cholecystectomy had not cured fat intolerance. Some patients suffered the same symptoms of disease or disorder of the biliary tract after the gall-bladder and its contained stones had been removed as before the operation, but restriction of dietary fat intake relieved symptoms in 36 cases. In 3 cases sphincterotomy of the sphincter of Oddi was necessary; in only 1 of these was a stone present in the common bile-duct (*Table IV*).

Table IV.—RESULTS OF CHOLECYSTECTOMY AFTER MORE THAN 8 YEARS

Results	*No. of Cases*		
No further surgery required			40
Symptom-free. No fat restriction		4	
Symptom-free if fat intake restricted		19	
Same symptoms as before operation if fat taken	5		
Symptoms bad enough to require F.F.D.		13	
Additional symptom—diarrhoea	4		
Symptoms as before, with jaundice but cured (5 year—F.U., 8 year—F.U.)		2	
Now diabetic		2	
Further operation required			3
Stone impacted in ampulla of Vater		1	
Sphincterotomy of sphincter of Oddi		2	
Total cholecystectomies performed 1959–62			43

d. Sphincterotomy of the sphincter of Oddi (*see* Appendix 1).—Sphincterotomy of the sphincter of Oddi was performed in 57 patients. In 23 there were the usual indications for exploring the common bile-duct: jaundice at the time of operation in 15, a stone palpable in the common bile-duct in 1, during cholecystectomy after acute pancreatitis in 1, and the common bile-duct found to be dilated at time of cholecystectomy in 6. The duct was explored in 3 patients because the gall-bladder did not empty for 3–5 days after a cholecystogram. In 30 patients who all suffered from symptoms of disease or disorder of the biliary tract, pain had not been cured by the F.F.D.; the cholecystogram was positive in 6 and negative in 14, while cholecystectomy had been performed previously in 10.

Obstruction at the lower end of the common bile-duct owing to stenosis or to hypertrophy of the sphincter of Oddi was present in all the cases on which sphincterotomy was performed. In no patient could a urethral sound (Clutton's) larger than 6/10 be passed through the sphincter; in the majority even this size would not pass until sphincterotomy had been commenced. In 14 of the patients in whom the F.F.D. had not cured pain no stone, infection, or other abnormality than obstruction at the sphincter was found in the common bile-duct; in 6 of these cases section of the gall-bladder showed hypertrophy of the muscle layer and hyperplasia of the Rokitansky-Aschoff sinuses to be the only abnormalities. Stone was present in the common bile-duct in 13 of the 57 patients and was associated with jaundice in 6. Infection was present in the common bile-duct in 18 cases and was associated with stone in 7, with jaundice in 10, and with both stone and jaundice in 4.

Follow-up of 38 cases more than 1 year after sphincterotomy showed that pain was cured and patients were symptom-free if they restricted their dietary fat intake or, in some cases, adhered to the F.F.D. Only 2 patients were taking fat freely; 1 of these was symptom-free, while the other suffered occasional symptoms. In 2 cases there had been minor episodes of ascending cholangitis with fever and jaundice. In 1 of these who was explored again the sphincter had not stenosed; a 16/20 urethral sound (Clutton's) passed easily but culture of the common bile-duct bile grew *Escherichia coli*.

2. *Discussion*.—

a. 'Biliary tract' pain.—Acute attacks of pain related to disease or disorder in the biliary tract are precipitated by a specific and excessive ingestion of fat, usually after a period of prolonged high dietary fat intake. The latter may itself cause pain of more gradual onset, but such a pain may be associated with a 'hormonal' episode such as menstruation or 'taking the Pill', or the first attack of 'biliary colic' may occur in relation to pregnancy, most commonly at 6 months or soon after delivery. 'Hormonal' episodes of pain occur when the dietary fat intake has been high for some time. The F.F.D. removes the stimulus which causes 'biliary tract' pain. As shown above, patients suffering from 'biliary tract' pain have been cured by the F.F.D. unless irreversible changes have occurred in the sphincter of Oddi. If flatulent dyspepsia has been present in these patients this too has been cured by the F.F.D.

Colic due to a gall-stone is relatively uncommon. Mobile stones in the gall-bladder cannot cause pain; most gall-bladders which contain stones communicate freely with the common bile-duct and there is no evidence that stones repeatedly become impacted and released. A gall-stone can impact in the cystic duct and the gall-bladder will initially undergo spasmodic contractions; once these have ceased the gall-bladder becomes 'non-functioning' and pain is then due to distension or consequent acute infection of the gall-bladder. A stone in the common bile-duct may cause pain when impacted at the lower end of the duct, but most stones move freely up and down the duct. Stones even when present in the gall-bladder or common bile-duct cannot cause pain in the majority of cases, nor is stimulation of pain by dietary fat and relief by the F.F.D. compatible with the theory that stones are the usual cause of biliary tract pain.

The occurrence of typical 'biliary colic' in so many cases in which the cholecystogram is negative has been stressed earlier. Cronin and Middleton (1963) similarly concluded that gall-stones or cholecystitis could not explain the symptoms in such patients. The F.F.D. cures the symptoms in most of these cases but if it does not sphincterotomy of the sphincter of Oddi does so. The same 'biliary tract' pain which occurs in the absence of the gall-bladder as was present before cholecystectomy is cured by the F.F.D. in most cases and by sphincterotomy of the sphincter of Oddi when the F.F.D. fails. Cattell, Colcock, and Pollack (1962) recognized that obstruction of the common bile-duct occurred at the sphincter of Oddi, either as the only demonstrable change in the entire biliary tract or complicating other conditions in the common bile-duct or gall-bladder. They found that sphincterotomy was necessary to cure symptoms in selected cases. They accepted that in long-standing cases chronic spasm could lead to fibrotic stenosis of the sphincter, but concluded that fibrosis was a more common cause of obstruction than spasm. They used intravenous cholangiography to diagnose obstruction. I have found that failure to cure symptoms by the F.F.D. is a certain indication of the need for sphincterotomy.

Ivy, Voegtlin, and Greengard (1933) showed that, provided the gall-bladder was concurrently excited to contract, 'gall-bladder pain' was experienced in a normal human subject when there was spastic obstruction of the intramural portion of the common bile-duct. Ivy (1947) found no evidence of sphincters in the biliary tract other than the sphincter of Oddi; the latter when in spasm could prevent evacuation of the gall-bladder. Bergh and Layne (1938) caused 'biliary colic' by distension of the bile-duct, and Bergh (1948) found that an irritable sphincter could result in hypertrophy of the sphincter muscle.

It is primarily the function of the sphincter of Oddi which determines whether normal or abnormal conditions exist in the biliary tract; the dietary fat intake plays a major part in determining whether the sphincter functions normally or not. In the early stages of disease or disorder of the biliary tract isolated episodes of spasm of the sphincter of Oddi 'triggered' by an excess of dietary fat intake result in an 'attack' of 'biliary tract' pain. Spasm is reversible and the F.F.D. prevents all symptoms. When hypertrophy or fibrosis of the sphincter has occurred owing to repeated episodes of acute spasm or to chronic 'subclinical spasm' caused by a prolonged high dietary fat intake, pain is not relieved by the F.F.D. and sphincterotomy is necessary. This hypothesis that spasm, hypertrophy, or fibrosis of the sphincter of Oddi causes obstruction at the lower end of the common bile-duct accounts for the incidence of infection and stone formation in the common bile-duct. It explains inadequate, incomplete, and sometimes little or no emptying of the gall-bladder, 'layering' of bile, stone formation, and infection in the gall-bladder. It is consistent with the clinical finding during an acute attack of 'biliary colic' of a tender, palpable, distended gall-bladder which is no longer palpable once the acute pain has ceased. Such cases, often incorrectly labelled 'acute cholecystitis', show no pyrexia or rise in the total or differential white blood count. If a cholecystogram is performed after the attack a normally functioning gall-bladder is shown; if stones are present in such a gall-bladder and cholecystectomy is performed the gall-bladder wall is found to be normal on section or may show hypertrophy of muscle and hyperplasia of Rokitansky-Aschoff sinuses as the only abnormalities. The latter, noted earlier in the series of sphincterotomies, must be the consequence of prolonged sphincter spasm, hypertrophy, or fibrosis which makes emptying of the gall-bladder more difficult.

The gall-bladder cannot empty during the acute phase of sphincter spasm. The dietary fat stimulus which caused the spasm may also increase the flow of liver bile, thereby increasing distension of the obstructed bile-duct and gall-bladder. If the flow of bile is great enough contraction of the gall-bladder, though it cannot empty the gall-bladder, may increase pressure in the common bile-duct sufficiently partially to overcome the spastic sphincter so that bile escapes into the duodenum, producing the copious bile vomit which sometimes occurs at the height of the pain.

The constant severe central epigastric pain which radiates outwards to the right and sometimes to the left subcostal regions through to the back and interscapular region must be caused by distension of the whole biliary duct system. Colicky pain spreading from the right hypochondrium must be due to contractions of the gall-bladder attempting to empty into an already distended and obstructed common bile-duct. It is impossible to say how much pain is due to the spastic sphincter itself.

b. Jaundice.—Approximately one-third of all the patients who suffered from gall-stones became jaundiced at some time (*Table V*). Jaundice occurred when the common bile-duct was filled with stones and debris or in association with cholangitis with or without stones in the common bile-duct, but it was seen most often after an 'attack' of 'biliary colic'. In some cases stone was present in a normal or non-functioning gall-bladder but there was no stone or infection in the common bile-duct itself. In other cases a cholecystogram performed after the jaundice had cleared was normal. In a small number of cases in which jaundice had persisted for longer than usual exploration of the common bile-duct revealed no abnormality apart from some hypertrophy of the sphincter of Oddi. In 1 case not even this abnormality was present.

Table V.—INCIDENCE OF JAUNDICE IN PATIENTS WITH PROVED GALL-STONES, 1950–9

Incidence of Jaundice	*No. of Cases*		
A. The whole series:			
Total No. with proved gall-stones			379
Not jaundiced, and no relevant history of jaundice		266	
Actually jaundiced when seen		36	
With history of associated 'biliary colic'	22		
Painless jaundice	13		
Associated with rigors	1		
Relevant history of jaundice, not jaundiced when seen		77	
Total No. jaundiced, or with relevant history of jaundice			113
B. Patients who had actually undergone operation:			
Total No. who had undergone operation			228
Jaundice present in, or relevant history of jaundice			74
C.B.D. explored in		30	
Stones found in C.B.D.	16		
No stones in C.B.D.	14		
Stones removed from C.B.D. at later operation		6	
C.B.D. explored at first operation	1		
C.B.D. not explored at first operation	5		
Total No. of cases in which stone found in C.B.D.			22
Jaundice present, or relevant history of jaundice in absence of stone in C.B.D.			52

The clinical presentation of the jaundice in these cases was always the same. A fat-containing meal had been eaten, and some hours later the patient experienced a severe attack of central epigastric pain which often radiated to the interscapular area and in some cases to the right and left subcostal regions. It was a constant pain, becoming more severe at times. In some patients there was also aching or severe pain under the right costal margin, and colicky pain radiated from the gall-bladder area. While the pain was severe some patients vomited a copious, watery, yellow or green, bitter fluid. The pain ceased as suddenly as it commenced and the patient apparently recovered completely. Twenty-four to 48 hours after the pain had ceased symptomless jaundice developed. There was darkening of urine only in some patients, the conjunctivae became icteric in others, while the jaundice sometimes involved the whole body. It was transient, persisting only for a day or two, or became widespread and remained for a week or longer, but it faded without any treatment other than the F.F.D.

This transient jaundice, so often called 'obstructive' and raising fears of a stone in the common bile-duct, could not be caused by extrahepatic obstruction. It occurred when there were no stones in the common bile-duct (*Table V, B*), and it was seen when there were no stones in the gall-bladder and the cholecystogram performed after the jaundice had cleared was normal. It was symptomless and painless, commencing only when the patient had recovered from the acute 'attack' and the pain; it developed after any spasm or potential obstruction had subsided completely, and at the height of the most severe pain there was often evidence in the form of copious 'bile' vomit that bile was escaping from the common bile-duct. No pyrexia or rise in the total or differential W.B.C. or other evidence of infection accompanied the jaundice. This jaundice like the pain was 'triggered' by a high dietary fat intake, and when the jaundice was recurrent some patients identified a particular food which precipitated it. Laboratory tests indicate that the jaundice is obstructive in type but that bile is present in the stools. It may be that back-pressure from the distended bile-ducts transmitted to the liver is responsible, but this can act only for the duration of pain and part of the cause of the distension must be continued formation of bile. It is possible that the fat which stimulates the pain may also cause the jaundice. As it is certain that the jaundice will clear operation is not performed while it is present and liver biopsy cannot be obtained.

The disturbed metabolism due to excess dietary fat intake (*see below*) may be the cause of jaundice.

C. Peptic Ulceration.—

1. *The Evidence.*—

a. Pyloroplasty alone as the surgical treatment of duodenal and gastric ulcer (*see* Appendix 2).—Capper (1967) showed that gastric ulcers healed after pyloroplasty because 'a wide, incompetent pylorus does not permit a narrow, forceful regurgitation' of duodenal contents into the stomach. I have since 1967 used pyloroplasty alone in the surgical treatment of peptic ulceration and related conditions because I concluded that if the duodenal contents could 'squirt' one way gastric contents could 'squirt' in the opposite direction.

Pyloroplasty alone was followed by healing of both duodenal and gastric ulcers (*Table VI*). Failure only occurred when the pyloroplasty did not remain widely open, and the ulcers healed after a second pyloroplasty; in only 1 case has a third pyloroplasty been necessary and this has proved successful. The causes of failure have been identified. In 1 case two layers of sutures had been inserted; the second layer inverted the first layer too much and the patient's stomach only emptied when she was lying on her right side. In 2 cases scar tissue formed as a duodenal ulcer healed and constricted the pyloroplasty. In the other cases which required a second operation serum-proofed silk sutures had caused excessive tissue reaction and constricted the lumen by massive fibrosis and adhesions.

Table VI.—RESULTS OF PYLOROPLASTY ALONE AS THE SURGICAL TREATMENT OF DUODENAL AND GASTRIC ULCER

REASON FOR OPERATION	NO. OF CASES	REQUIRED SECOND OPERATION	FOLLOWED UP FOR MORE THAN 1 YEAR	'CURED'	RECURRENT SYMPTOMS		ALSO REQUIRED OPERATION ON BILIARY TRACT
					Ulcer	Other	
Duodenal ulcer	50	7	38	34	1	3	7
Gastric ulcer	18	2	15	15	0	0	0
Prepyloric muscle hypertrophy	14	1	13	11	1	1	7
Total	82	10	66	60	2	4	14

Table VII.—RESULTS OF VAGOTOMY AND PYLOROPLASTY COMPARED WITH THOSE OF PYLOROPLASTY ALONE AS THE SURGICAL TREATMENT OF DUODENAL ULCER

TYPE OF OPERATION	NO. OF CASES FOLLOWED UP FOR MORE THAN 1 YEAR	NO. OF CASES 'CURED'	RECURRENT SYMPTOMS		EPISODIC DIARRHOEA
			Certainly due to Ulcer	Possibly due to Other Causes	
Vagotomy and pyloroplasty (operations performed 1964–7)	38	29	6	3	6
Pyloroplasty alone (operations performed 1968–70)	38	34 (4 cases required second operation)	1	3	0

Symptoms of recurrent ulceration have always developed within 3 months of the pyloroplasty in the cases which failed. I have used a single layer of Dexon to close the pyloroplasty in 30 cases during the past 18 months, and there has been no symptom of failure in any of these cases.

b. Comparison between vagotomy and pyloroplasty, and pyloroplasty alone as the surgical treatment of duodenal ulcer. The results of treatment of duodenal ulcer by pyloroplasty only in 38 cases followed for more than 1 year, and by vagotomy and pyloroplasty in 38 cases followed for more than 4 years have been compared (*Table VII*).

Over all, 34 of 38 patients on whom pyloroplasty only was performed and 29 of 38 patients who underwent vagotomy and pyloroplasty are certainly cured of ulcer. Four of the 'pyloroplasty only' series did require a second operation because of technical failure of their first operation. It is likely that the cause of failure in the 'vagotomy and pyloroplasty' series was due, as in the 'pyloroplasty only' series, to technical failure of the pyloroplasty. Within the past year I have operated on 2 failed cases of the 'vagotomy and pyloroplasty' series; in both, the first pyloroplasty which had been sutured with serum-proofed silk had become stenosed, and I have performed a new pyloroplasty using Dexon and a single layer of sutures. There is a significant difference between the two series in the incidence of episodic diarrhoea, which occurs only in those patients who have suffered a vagotomy. The evidence from my preliminary results is that vagotomy is not necessary to cure an ulcer and is detrimental to the patient.

Table VIII.—COMPARISON OF CASES TREATED BY VAGOTOMY AND PYLOROPLASTY AND THOSE TREATED BY PYLOROPLASTY ALONE FOR DUODENAL ULCER

TYPE OF OPERATION	TOTAL NO. OF CASES	SEX		HISTORY OF MELAENA AT HAEMATEMESIS	HISTORY OF PERFORATION	HISTORY OF FAT INTOLERANCE		ALSO REQUIRED OPERATION ON BILIARY TRACT			
		Male	Female			Before Operation	After Operation	Earlier	At Same Time	Later	Total

* Cholecystectomy, 2 cases; cholecystostomy, 2 cases; sphincterotomy, 1 case.

† Cholecystectomy and sphincterotomy, 3 cases; cholecystostomy, 2 cases; sphincterotomy, 2 cases.

Table IX.—RESULTS OF VAGOTOMY AND PYLOROPLASTY FOR DUODENAL ULCER AFTER 4 OR MORE YEARS WITH REFERENCE TO FAT INTOLERANCE

Results	*No. of Cases*	
'Cured'		29
Symptom-free. No dietary restriction of any kind	9	
Symptom-free if avoids 'fats and fries'—less or	8	
more	5	
Symptom-free on low-fat diet	2	
Recurrent symptoms required treatment and cured by F.F.D.	3	
Required operation on the biliary tract	2	
'Not cured'		9
Undoubtedly recurrent ulceration	6	
Equivocal symptoms	3	
Total (operations performed 1964–7)		38

c. Fat intolerance in duodenal ulcer patients.—The patients in both series of duodenal ulcer cases who suffered from symptoms 'possibly due to other causes' were all fat intolerant (*Table VII*); they presented symptoms of flatulent dyspepsia, with pain of 'biliary tract' type in some cases. The clinical features in the two series are compared in *Table VIII*. It had been found to be wise or even essential to restrict the dietary fat intake after pyloroplasty for duodenal ulcer. Follow-up of patients who had undergone vagotomy and pyloroplasty for duodenal ulcer showed that a similar restriction had been found necessary (*Table IX*). The incidence of fat intolerance and disease or disorder of the biliary tract in patients suffering from duodenal ulcer is significant.

d. Observations on the normal pylorus and changes which occur in it.—From 1969 to 1971 I observed during 87 cholecystectomies the state of the oesophageal hiatus, prepyloric muscle, and pyloric aperture or ring. The normal pyloric aperture relaxed to a lumen of 2 cm. diameter; proximally the antrum and distally the duodenal cap relaxed to 3–4 cm. diameter; only at the level of the pyloric ring, at the pyloric aperture itself, was there any decrease in diameter of the lumen from the antrum to the duodenum; in the relaxed state there was no 'pyloric canal'. Palpation of the stomach wall in the prepyloric region in these cases revealed little or no increase in the thickness of the muscle layer compared with the pars media of the stomach (*Fig. 3*).

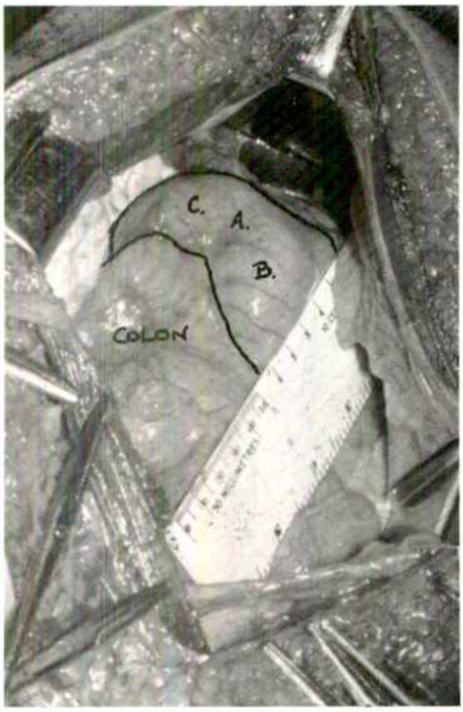

FIG. 3.—Normal pylorus in relaxed state. A, Slight constriction at relaxed pyloric ring, with 2-cm. diameter pyloric aperture. B, Immediate prepyloric region relaxed to 4 cm. and more, with no thickening of muscle in its wall. C, Relaxed duodenal cap.

There was no apparent enlargement of the oesophageal hiatus in 27 of the 87 cases, but only in 9 of these cases was there also relaxation of the pyloric ring to 2 cm. with no evidence of thickening of the prepyloric muscle. In 28 cases the pyloric ring relaxed to 2 cm. with no evidence of hypertrophy of the prepyloric muscle, but in 59 cases there was restriction of relaxation of the pyloric ring, and the greater the restriction the more marked was palpable thickening of the prepyloric muscle. All stages were found, from the normal pylorus, through increasing extent of restricted relaxation of the pyloric aperture and hypertrophy of the prepyloric muscle, to 2 cases with a duodenal ulcer crater present, gross narrowing of the pyloric ring, and marked prepyloric muscle hypertrophy with formation of a 'pyloric canal' just proximal to the ring (*Tables X, XI*).

Table X.—OBSERVATIONS OF PREPYLORIC MUSCLE HYPERTROPHY MADE DURING 87 CHOLECYSTECTOMIES (MID-1969 TO MID-1971)

DEGREE OF PREPYLORIC MUSCLE HYPERTROPHY	NO. OF CASES	PYLORIC APERTURE RELAXED TO:—			
		2 cm. Diameter	1–2 cm. Diameter	1 cm. Diameter	< 1 cm. Diameter

Total	10	2	0	3	5	0	2	3	5

* Some thickening of the pyloric ring.

e. Pylorospasm seen in 'fat-intolerant' patients.—Two 'fat-intolerant' patients operated upon in the past year had suffered from flatulent dyspepsia with epigastric pain, belching, acidity, and nausea and vomiting of bile during attacks. The cholecystograms were normal in both cases. A barium-meal examination was normal in the woman but in the man showed deformity of chronic or recurring duodenal ulceration. The patients were symptom-free while they adhered to the F.F.D. At laparotomy the gall-bladder, common bile-duct, and pancreas were normal in both cases. The pylorus appeared to be normal most of the time; the pyloric aperture relaxed to 2 cm. diameter, with no thickening of the prepyloric muscle, and there was no evidence of past or present peptic ulceration. However, in both patients spasms lasting for a minute or more at a time occurred intermittently, converting the pyloric antrum, prepyloric region, pyloric ring, and the duodenal cap into a rocky-hard mass which whitened with contraction. When the spasm ceased the whole area again relaxed widely and appeared to be normal. No operative procedure was performed. The patients were discharged on the F.F.D. more than 1 year ago and have remained symptom-free while on the F.F.D., but since the woman has been using non-milk-fat milk she has had indigestion and pain.

f. Barium-meal examination in biliary tract Disease.—During the survey of dyspeptic patients seen and treated during the years 1950–9 I noted the frequency of evidence in routine barium-meal examinations in patients suffering from disease or disorder of the biliary tract of abnormality at the oesophageal hiatus and the pylorus. Hiatus hernia was demonstrated in more than 11 per cent of 379 patients proved to have gall-stones, while abnormality was demonstrated at the pylorus in 17 per cent of 379 cases with proved gall-stones, and in 15 per cent of 342 cases diagnosed clinically to have gall-stones but in whom the cholecystogram was negative (*Table XII*).

Table XII.—BARIUM-MEAL EXAMINATION IN BILIARY TRACT DISEASE

TYPE OF BILIARY TRACT DISEASES	NO. OF CASES	PREOPERATIVE BARIUM MEAL		DEFORMITY OF DUODENAL CAP	PYLOROSPASM	DUODENAL ULCER
		No.	Percentage Abnormal			
Non-malignant surgical disease of biliary tract	379	202	17	23	12	1
Clinical diagnosis of surgical disease of biliary tract: cholecystogram negative	342	342	15	29	16	4
Total	721	544	17	52	38	5

2. *Discussion*.—The normal pylorus does not control emptying of the stomach but prevents reflux during duodenal cap systole (Martin and Burden, 1928; Johnson, 1961). Keet (1962) showed that in a relaxed state in normal persons the pyloric aperture was 1·5–2·0 cm. in diameter, while the canalis egestorius was 4–8 cm. diameter when completely relaxed. My own observations are in agreement with

those of Keet that the normal relaxed pylorus is one in which there is no increase in thickness of the circular muscle layer in the prepyloric region as it nears the pyloric ring and that the ring itself relaxes to give an aperture of 2 cm. diameter. Any increase in thickness of the circular muscle layer in the prepyloric region as compared with the pars media and any restriction of relaxation of the pyloric ring itself must be pathological.

When dyspeptic patients have been followed over many years successive barium-meal examinations have shown a progression of changes from irritability of the duodenal cap or intermittent pylorospasm in the early years, through a stage of more persistent spasm, sometimes with initial delay in the commencement of emptying of the stomach, to a stage of deformity of the duodenal cap, perhaps with prepyloric deformity but with no ulcer crater, finally to the demonstration of an ulcer crater. Many of these patients have suffered from flatulent dyspepsia and complained that 'fats' aggravated or precipitated their symptoms. I have been convinced in many cases that the symptoms were related to the biliary tract despite repeated negative cholecystograms. Eventually, however, duodenal ulceration has been proved, and at operation a definite feature has always been marked hypertrophy of the prepyloric muscle.

I have no statistically significant series of patients suffering from peptic ulceration who have been treated by the fat-free diet, but the results in cases so treated have been consistent with the thesis that excess dietary fat is an important aetiological factor in peptic ulceration. In early cases pylorospasm is still reversible and symptoms have been completely controlled by the F.F.D., as in the 2 cases cited in (*e*) above. In established cases in which prepyloric muscle hypertrophy, fibrosis, and even active ulceration have been present the appetite has been regained and dyspeptic symptoms other than pain have been relieved by the F.F.D. during the waiting period before operation.

An association between dietary fat intake and disease or disorder of the biliary tract is generally accepted. I have found an undoubted association between biliary tract abnormality and peptic ulceration. Twelve of 76 patients who underwent operation for duodenal ulcer also required operation on the biliary tract (*Table VIII*) and 6 of 57 patients who required sphincterotomy of the sphincter of Oddi also suffered from duodenal ulcer, while gross prepyloric muscle hypertrophy required operation in 5 others. The incidence of fat intolerance in cases of duodenal ulceration (*Table VIII*), the frequency of changes at the pylorus, limitation of relaxation of the pyloric ring, and hypertrophy of prepyloric circular muscle found in patients who have proved gallstones (*Tables X, XI*), and the incidence of radiological evidence of abnormality at the pylorus in cases of disease or disorder in the biliary tract (*Table XII*) make it difficult to believe that there is not a close link between biliary tract and pyloric disorders, and I suggest that the dietary fat intake is the link between the two parts of the digestive system.

Just as it causes spasm of the sphincter of Oddi I believe that an excess of dietary fat intake can stimulate pylorospasm. Crohn and Reiss (1920) showed that milk was a strong acid-producing stimulant and was only slowly emptied through the pylorus, and that the combination of milk and egg was a very powerful stimulant to gastric secretion causing hyperacidity and hypersecretion with prolongation of the emptying time. Waldron (1971), when combining cholecystograms and barium-meal examinations, found that the fat stimulus given to stimulate gall-bladder contraction delayed stomach emptying appreciably. The fat stimulus used was Prosparol, 50 per cent being ground nut oil—a vegetable fat. Spasm narrows the pyloric lumen but the pylorus becomes normal again when the spasm ceases. If pylorospasm is frequent or persistent prepyloric muscle hypertrophy may result and the lumen becomes permanently narrowed by the rigid, thickened muscle layer. The rate of stomach emptying, as measured by barium-meal examination, is rarely altered in these cases. If the lumen is narrowed but the rate of emptying remains the same the flow of gastric (or duodenal) contents through it must be faster and more forceful, in fact a 'jet'. Capper (1967) demonstrated that a reflux 'jet' of alkaline duodenal contents caused atrophic gastritis and gastric ulceration; a 'jet' of acid gastric contents, impinging always on one or two localized areas of duodenal mucosa before mixing with and being neutralized by duodenal contents, must cause localized duodenal ulceration. If the pylorus is incompetent as well as narrowed a jet can 'squirt' in both directions and cause coexisting duodenal and gastric ulcers. Pylorospasm may persist long enough for a duodenal ulcer to develop; if the pylorus then relaxes completely the ulcer can heal and the pylorus appears normal with only a healed scar remaining, but if fibrosis develops as the ulcer heals it may constrict the lumen and cause recurrence of ulceration. The extent of narrowing of the lumen owing to fibrosis of a healed ulcer or to moderate hypertrophy of the prepyloric muscle consequent upon repeated or persistent spasm may not be enough by itself to cause 'jet' formation but it might do so if further spasm was superadded. This hypothesis explains why pyloroplasty alone cures both duodenal and gastric ulcers and fails to do so when the lumen of the pyloroplasty does not remain widely patent.

Martin and Burden (1928) arraigned 'pyloric achalasia' as the cause of chronic dyspepsia, of ulcer symptoms in the absence of peptic ulcer, and of the development and chronicity of the peptic ulcer. They recognized that failure of cure by pyloroplasty was due to incomplete abolition of sphincter activity at the pylorus or to postoperative narrowing of the pyloroplasty. Farris and Smith (1961, 1963, 1966) accepted that the cure of anatomical obstruction by the pylorus was the most important factor in the cure of gastric ulcer. These authors, however, feared that the duodenal ulcer might develop if vagotomy was not performed in addition to pyloroplasty. This does not happen if the pylorus remains wide and incompetent, and indeed duodenal ulcers also heal when the pylorus remains wide and incompetent.

III. DIARRHOEA

A. The Evidence.—Patients known to have gallstones have frequently complained of disturbance of bowel habit in association with attacks of biliary tract pain. Some patients have attacks of diarrhoea or looseness of the bowels related to the ingestion of particular foods, and most of the fat-containing foods forbidden in the F.F.D. have been incriminated in this way at one time or another. When attacks of 'biliary colic' have been controlled by the F.F.D. associated bowel symptoms also have been cured. Some of the patients who had undergone cholecystectomy complained of attacks of diarrhoea and often also of flatulent dyspepsia when they had returned to a full diet; both the diarrhoea and dyspepsia were cured by the F.F.D.

Four hundred and twenty-five of 532 dyspeptic patients seen in the past 3 years were unequivocally fat intolerant (*Table XIII*). Bowel disturbance apparently related to fat intolerance and controlled by the F.F.D. was present in 161. Looseness and increased frequency of bowel action accompanied fat-intolerant dyspeptic pain in 82 cases. Attacks of looseness or diarrhoea unrelated to any other disease or condition but sometimes occurring in patients who also suffered from flatulent dyspepsia and often precipitated by a particular fat-containing food were controlled by the F.F.D. in 24 cases. There were 12 patients in whom left iliac fossa pain, probably due to spasm in the sigmoid colon, was relieved by the F.F.D.

Barium-enema examination when carried out in these cases showed either no abnormality, or areas of transient or persistent spasm, or diverticular disease of the bowel, or a tube-like appearance of the bowel with loss of haustrations called 'colitis' by radiologists (*Table XIII*). Spasm and loss of haustrations were sometimes found in the same patient, while diverticular disease occurred in isolation or in association with spasm, or with loss of haustrations, or with both. Motions were watery, often containing slime or mucus, and were passed one to six or more times in 24 hours. They were often 'explosive' and urgent, preceded by large-bowel colic; several motions were passed in quick succession in some patients, while the action of eating precipitated bowel movement in others.

B. Discussion.—In all the cases described above the bowel symptoms were cured when the patient adhered to the F.F.D. which was in many cases prescribed primarily for the dyspeptic symptoms. It became apparent that the symptoms and signs of bowel disturbance were in fact a syndrome of fat intolerance, and the F.F.D. was prescribed and was effective treatment for those cases of fat-intolerant diarrhoea in which dyspeptic symptoms did not require it.

The barium-enema examination showed progression of changes. The earliest evidence of abnormality was spasm, transient or persistent, affecting the sigmoid colon most frequently and seen at sigmoidoscopy invariably to affect the rectosigmoid junction. When diverticular disease was present with hypertrophy of the circular muscle layer and some loss of ability of the bowel to relax, areas of spasm were often also demonstrated radiologically. It is likely that hypertrophy is the result of repeated or persistent spasm. Loss of haustrations was also frequently associated with areas of spasm. In ulcerative colitis shortening of the colon and loss of haustrations are the result of a muscle abnormality which Morson (1968) described as more in the nature of a contracture or a maintained contraction than a spasm, while strictures in ulcerative colitis are due to thickening of the muscularis mucosae as well as the muscularis propria and are found in any part of the rectum and colon (Goulston and McGovern, 1969; Morson, 1970).

Table XIII.—BOWEL DISTURBANCE IN 'FAT-INTOLERANT' PATIENTS, 1969-71

TYPE OF BOWEL DISTURBANCE	TOTAL NO. OF CASES	TYPE OF FAT-INTOLERANT DYSPEPSIA			BARIUM-ENEMA EXAMINATION FINDINGS						OTHER COEXISTING DISORDERS								
		Gall-stones proved	Post-cholecystectomy	Fat-intolerant Dyspepsia: Cholecystogram negative	Not done	N.A.D.	Spasm	Loss of Haustration	Proctocolitis	Diverticular Disease	Previous Vagotomy and Pyloroplasty for D.U.	Dyspepsia but not investigated	Hiatus Hernia	Gall-stones proved	Hypertrophy of Sphincter of Oddi	Duodenal Ulcer	Abnormal Duodenal Cap	Gastric Ulcer	Diabetes
Looseness of bowel or diarrhoea associated with 'attacks' of dyspeptic pain	27	178	—	—	24	—	—	1	—	—	2	—	13	—	2	7	14	2	3
	14	—	77	—	5	2	3	2	—	2									
	41	—	—	170	28	—	6	—	—	7									
Principal complaint looseness of bowels or diarrhoea	24	—	—	—	5	4	7	6	2	—	—	4	—	2	—	—	2	—	1
Diverticular disease of bowel (not included in above cases)	43	—	—	7	—	—	—	—	—	43	—	3	7	5	—	—	1	—	—
Left iliac fossa pain	12	—	—	—	2	4	4	2	—	—	—	1	—	—	—	—	1	—	2
Total	161	—	—	—	64	10	20	11	2	54	—	—	—	—	—	—	—	—	—

Looseness of the motions or diarrhoea is 'triggered' by a high dietary fat intake and occurs in 37 per cent of patients who are recognized on other evidence as fat-intolerant. The bowel symptoms and signs are cured by the F.F.D. Spasm of circular smooth muscle in the bowel wall, especially in the area of the rectosigmoid junction but also elsewhere, is the earliest abnormality seen; this spasm is no longer present when the patient has been cured by the F.F.D. There is no clear-cut line between these patients and those with loss of haustrations or with established diverticular disease of the bowel. Even in the presence of diverticular disease with hypertrophy of the circular muscle and some rigidity and loss of distensibility of the bowel, patients are usually cured by the F.F.D. If they are not, Reilly's operation of sigmoidomyotomy is necessary (Reilly, 1966).

I have not had enough experience of the use of the F.F.D. in florid cases of ulcerative colitis to draw firm conclusions. It is very difficult, however, to separate from a true ulcerative colitis the fat-intolerant 'colitis' with spasm, loss of haustration, and a 'tube-like' radiological appearance of the bowel in which the mucosa is oedematous and pouring forth a copious mucoid and watery fluid. It could be significant that Truelove (1967) found that 9 per cent of cases were 'sensitive' to milk and derivatives of milk; he suspected that the protein of milk was responsible but was never able to detect any antibodies. I think that in any patient suffering from ulcerative colitis a prolonged trial of the effect of the F.F.D. must be carried out.

IV. FAT-INTOLERANT CHILDREN

Children as well as adults can eat too much fat. During the past 3 years I have seen 17 cases in which abdominal pains were associated with excess dietary fat intake. Ten of these children have been on the F.F.D. for more than 6 months and no longer suffer recurrent attacks of pain; 5 others have had no further pain during 3 to 6 months' follow-up.

All the children, 11 boys and 6 girls, aged 7 to 16 years (14 cases were aged 10–15 years), were 'plump' and 3 were much overweight. Pain had occurred in 'attacks' on and off for periods of a few months to 4 years but had recently become more frequent and even daily in some cases. In 3 cases fat had been identified as the cause of pain, which in 13 of the 17 cases was primarily epigastric, radiating as shown in *Table XIV*. The pain was described as aching in 5, colicky in 4, and both aching and colicky in 8 cases. Other symptoms are listed in *Table XIV*. The gall-bladder was markedly tender on palpation in 3 cases. The excess dietary fat intake was high in all the cases; in 1 it was more than 1250 cal. per day, and in 3 other cases was more than 800 cal. per day.

This group of patients is important because the children had often been labelled 'emotionally disturbed'. There was lethargy and 'lack of interest' in almost all of the children, but when the F.F.D. had cured them of their pain they became normal once more. In 8 of the cases the mothers commented spontaneously that their children were brighter and more lively. The provisional diagnosis is made on the history and clinical presentation. There may be some dyspepsia or disturbance of the bowels and even recognized fat intolerance. The diagnosis can only be confirmed by prescribing the F.F.D. and assessing the benefit after at least 3 months.

V. DIETARY FAT INTAKE AND GLUCOSE TOLERANCE

The effect of the F.F.D. on glucose tolerance (G.T.) has been investigated in 134 patients who required treatment by the F.F.D. An initial oral glucose-tolerance test (G.T.T.) was performed on each patient before prescribing the F.F.D. and was

Table XV.—INDICATIONS FOR F.F.D. IN THE 65 CASES INCLUDED IN THE SERIES OF G.T.T.S WHICH WAS SUBMITTED TO STATISTICAL ASSESSMENT

DIAGNOSIS ON WHICH F.F.D. WAS PRESCRIBED	NO. OF CASES	OTHER CONDITIONS COEXISTING
Overweight	12	Inguinal hernia, 4. Dyspepsia, 2. Varicose veins, 1. Migraine, 1. Nodular goitre, 1. Diabetes, 2
Gall-stones	12	Diverticulitis, 1. Diabetes, 2. (Cholangitis positive bile-culture)
Post-cholecystectomy symptoms	7	'Colitis', 1. Diabetes, 1. Stone in common bile-duct, 1. 'Stenosis' of sphincter of Oddi, 1
Dyspepsia (including 'biliary colic' in 3 cases); cholecystogram and barium-meal examinations negative	15	Previous vagotomy and pyloroplasty, 1. Diabetes, 2. Migraine, 2. Spastic, irritable duodenal cap, 1. 'Colitis', 3 (including 1 case who had been on a low-carbohydrate diet). Prepyloric muscle hypertrophy, 1. Stenosis of sphincter of Oddi, 1
Duodenal ulcer	3	
'Spasm of colon'	4	Dyspepsia, 1. Diabetic, 1 (had been on low-carbohydrate diet)
Diverticulitis	4	
Undiagnosed abdominal pain	3	One case had been on low-carbohydrate diet
Migraine	1	Post-cholecystectomy dyspepsia, 1
Fat intoxication	3	Post-cholecystectomy, 1
Diabetes	1	Presented with 'prostatic' symptoms

repeated at intervals while the patient was on the diet; 433 separate tests have been carried out (*see* Appendix 3). The change in G.T. has been analysed statistically in a series of 65 consecutive patients.

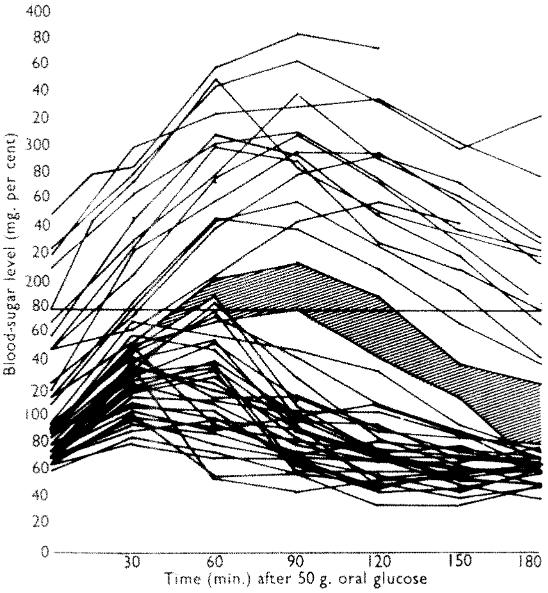

FIG. 4.—Initial G.T. curves. Representative selection (7 of 13 cases from group 1; 24 of 43 cases from group 2; 15 newly diagnosed diabetic cases) which demonstrates the 'hiatus' between high hyperglycaemic and diabetic curves, but continuous rise from 'normal' to hyperglycaemic curves.

The diseases or disorders afflicting these patients and any other coexisting diseases or disorders were representative for all the patients investigated by the G.T.T. (*Table XV*); so also was the range of variation found in the initial G.T. curves (*Fig.* 4).

A. The Results.—*Fig.* 4 shows a demarcation between diabetic and non-diabetic curves; no such 'hiatus' exists between any of the non-diabetic curves and it is impossible to define a level at which a normal G.T. curve becomes hyperglycaemic. A visual survey of all the initial and final G.T. curves in the 'statistical series' showed that if the initial curve rose at any point above the 100 mg. per cent level the G.T. increased on the F.F.D.; if the initial curve never rose above 100 mg. per cent changes in the G.T. showed no constant trend. The initial curves were therefore divided into three groups:—

Group 1 (13 cases; average age, 42 years): Not hyperglycaemic. Initial G.T. curve never rose above 100 mg. per cent.

Group 2 (43 cases; average age, 52 years): Hyperglycaemic. Initial G.T. curve rose above 100 mg. per cent but not above 180 mg. per cent (i.e., not diabetic).

Group 3 (9 cases; average age, 59 years): Diabetic.

Clinically it had proved to be impossible to assess the effect of the F.F.D. on symptoms in less than 3 months on the diet. There was often an immediate benefit, but this might not be noticeable for 2 or 3 weeks and the full effect was sometimes more delayed. Likewise, no fixed interval between the initial and final G.T.T. could be laid down as standard; th longer a patient adhered to the F.F.D. the mor certain it was that the G.T. would increase. Othe factors such as initial level of G.T., activ weight-loss, strictness of adherence to the diet, an intercurrent infection or disease all influenced tl time needed.

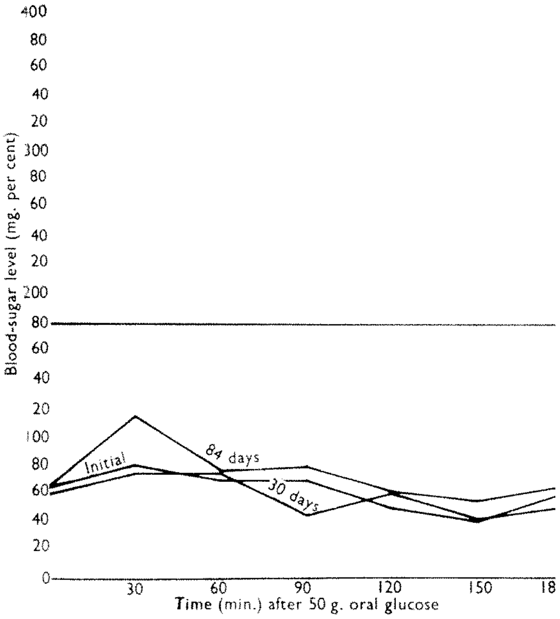

FIG. 5.—*Case* 1. Female, aged 47 years, with gall-stones. Dietary intake before F.F.D.: fat, 800 cal. per day; carbohydrate, 500 cal. per day. After F.F.D.: carbohydrate, plus 100 cal. per day. Initial weight was 126 lb.; after 30 days, 121 lb.; and after 84 days, 114 lb.

1. *Statistical Assessment of Change in G.T. wh on the F.F.D.* (*see* Appendix 4).—The G.T. curv of 65 consecutive patients before and after they ha been on the F.F.D. were assessed statistically b Mr. Niall Clinton, Lecturer in Statistics, Plymout Polytechnic. The series was divided on the basis the initial G.T. curves into the groups defined abov Mr. Clinton concluded:—

'The area under a G.T. curve (which is, in fact, broken-line graph) appears to be a reasonable ar objective measure of the glucose tolerance. If v accept this area as a measure of G.T., then tl following points emerge:—

1. The G.T. of patients in group 1 has not chang significantly.
2. The G.T. of patients in both groups 2 and has increased significantly (at 1 per cent level significance).
3. The G.T. of patients in group 3 has increas more than that in group 2.
4. The reactions of patients in group 3 are mo variable than the reactions of patients in either of tl other groups. However, there is a small number people in group 3, and there are large variations the reactions of patients within all the group Possibly these large variations are due to lar variations in weight changes, days between test etc.

'In short, using the area under the G.T. curve as measure of G.T., we conclude that the patients in roups 2 and 3 have significantly increased their .T. after being on the F.F.D.' (*Table XVI.*)

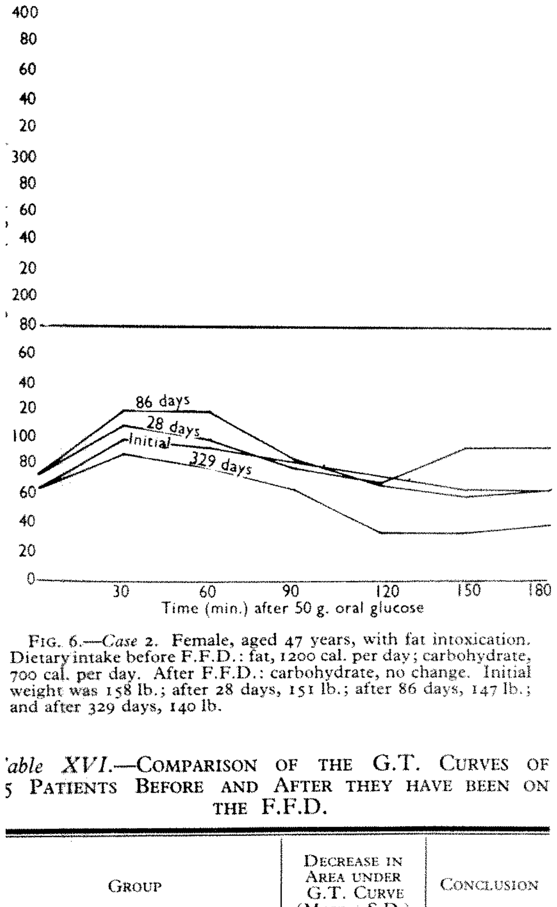

FIG. 6.—*Case* 2. Female, aged 47 years, with fat intoxication. Dietary intake before F.F.D.: fat, 1200 cal. per day; carbohydrate, 700 cal. per day. After F.F.D.: carbohydrate, no change. Initial weight was 158 lb.; after 28 days, 151 lb.; after 86 days, 147 lb.; and after 329 days, 140 lb.

able XVI.—COMPARISON OF THE G.T. CURVES OF 5 PATIENTS BEFORE AND AFTER THEY HAVE BEEN ON THE F.F.D.

GROUP	DECREASE IN AREA UNDER G.T. CURVE (Mean ± S.D.)	CONCLUSION
13 cases. Blood-sugar never more than 100 mg. per cent in initial curve	28·27 ± 86·37	No significant difference
43 cases. Blood-sugar level rose to more than 100 mg. per cent but never more than 180 mg. per cent in initial curve	89·59 ± 79·48	Difference significant ($P = 0·01$)
9 cases. Initial curve was a diabetic curve	449·16 ± 203·99	Difference significant ($P = 0·01$)

Conclusion of statistical analysis of the results by Mr. Niall Clinton, .Sc., Lecturer in Statistics, Plymouth Polytechnic.

2. *Individual Cases illustrating the Effect of the .F.D. on G.T.*

a. Group 1.—No increase in G.T. was expected these cases because they showed no initial impairent. In *Case* 1 an initial curve of group 1 type ecame group 2 type after 84 days (*Fig.* 5). The me change occurred in *Case* 2 after 86 days, but e G.T. was greater after 329 days than it had been initially (*Fig.* 6). *Case* 3 shows impaired G.T. at 28, 86, and 140 days, but little change from the initial level after 205 days (*Fig.* 7). The G.T. in all these cases was impaired during a period of active and appreciable weight-loss and recovered when the weight was stabilized.

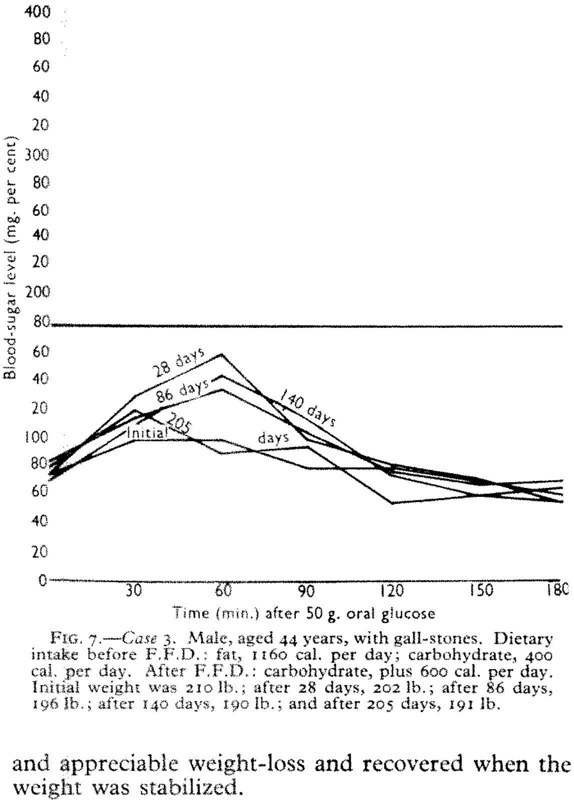

FIG. 7.—*Case* 3. Male, aged 44 years, with gall-stones. Dietary intake before F.F.D.: fat, 1160 cal. per day; carbohydrate, 400 cal. per day. After F.F.D.: carbohydrate, plus 600 cal. per day. Initial weight was 210 lb.; after 28 days, 202 lb.; after 86 days, 196 lb.; after 140 days, 190 lb.; and after 205 days, 191 lb.

b. Group 2.—The G.T. was impaired during active weight-loss in some cases in this group but there was finally always an overall increase in G.T. In *Cases* 4 and 5 initial curves of group 2 type were converted to group 1 type (*Figs.* 8, 9). Initial impairment in G.T. was not always detected and *Cases* 6–11 showed increased G.T. when the patients were on the F.F.D. (*Figs.* 10–15). In *Cases* 12–14 the initial G.T. curves were markedly hyperglycaemic; the longer the patients adhered to the F.F.D. the greater was the increase in G.T. (*Figs.* 16–18). After an initial weight-loss *Case* 14 gained weight but the G.T. showed a further increase despite this (*Fig.* 18).

c. Group 3: *diabetic patients.*—*Cases* 15–17 are diabetic patients who were cured by the F.F.D. (*Figs.* 19–21). *Case* 15 now weighs the same as when treatment started although her weight had decreased at one period. The G.T. is increasing steadily on the F.F.D. in *Cases* 18 and 19 (*Figs.* 22, 23), and *Case* 20 also shows an increase (*Fig.* 24). *Cases* 15–20 were diabetic and were treated only by the F.F.D.

Case 21 is an example of 'cure' of 'diabetes' by the F.F.D. in a patient who had been on chlorpropamide, 250 mg. daily, and a 12-portion diet for 8 years (*Fig.* 25). He was instructed to stop doing so. When, 75 days after starting the F.F.D. the G.T.T. was performed on *Case* 22 the patient was still in error taking tolbutamide. His G.T. initially became impaired, but after 252 days his G.T. curve was hyperglycaemic only. The impairment present again at 371 days was due to non-adherence to the F.F.D. (*Fig.* 26). *Case* 23 also illustrates the effect of dietary fat intake on G.T. The curve at 189 days shows no improvement over that at 77 days; the patient had been eating butter, bacon, cake, and fish paste (*Fig.* 27). In *Case* 24 impairment of G.T. between 229 and 320 days was due to fat-containing foods ingested at Christmas, while that between 460 and 579 days was due to a 3-week holiday in a bed-and-breakfast boarding house when no control over diet

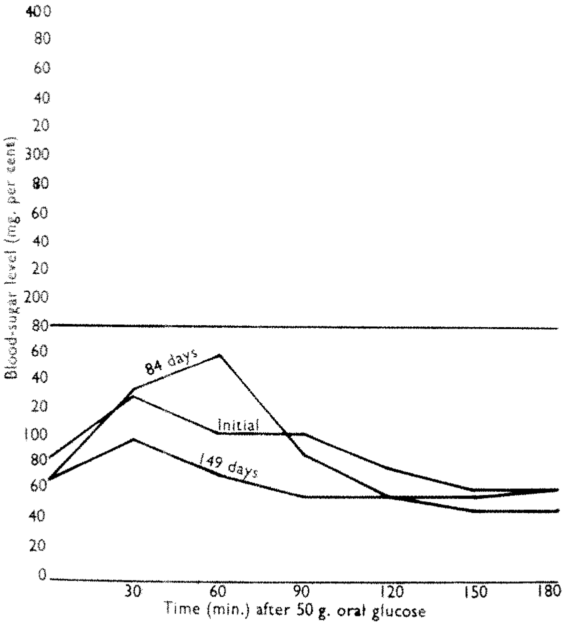

FIG. 8.—*Case* 4. Male, aged 32 years, with a duodenal ulcer. Dietary intake before F.F.D.: fat, 950 cal. per day; carbohydrate, 950 cal. per day. After F.F.D.: carbohydrate, no change. Initial weight was 149 lb.; after 84 days, 139 lb.; and after 149 days, 137 lb.

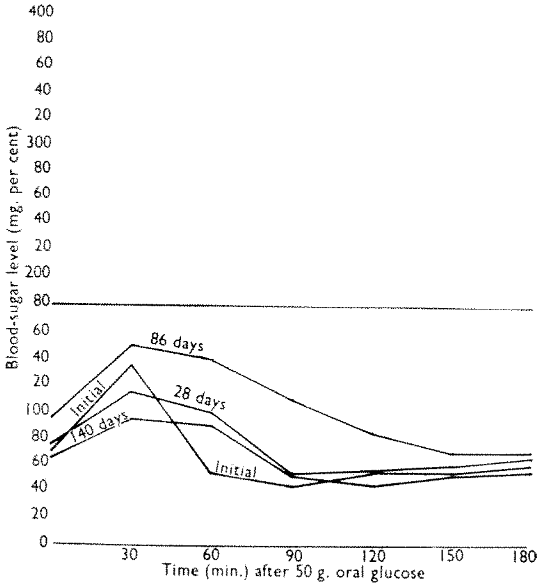

FIG. 9.—*Case* 5. Male, aged 45 years, with gall-stones. Dietary intake before F.F.D.: fat, 1200 cal. per day; carbohydrate, 720 cal. per day. After F.F.D.: carbohydrate, plus 130 cal. per day. Initial weight was 157 lb.; after 28 days, 140 lb., after 86 days, 135 lb.; and after 140 days, 136 lb.

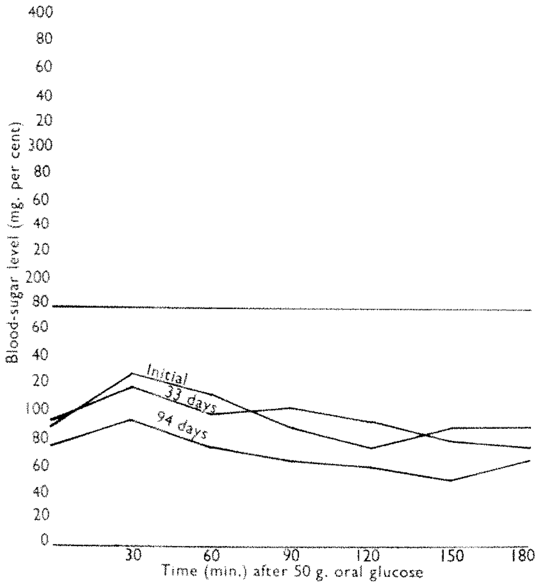

FIG. 10.—*Case* 6. Female, aged 49 years, with 'biliary colic'. The cholecystogram was negative. Dietary intake before F.F.D.: fat, 700 cal. per day; carbohydrate, 160 cal. per day. After F.F.D.: carbohydrate, plus 400 cal. per day. Initial weight was 138 lb.; after 33 days, 135 lb.; after 94 days, 130 lb.

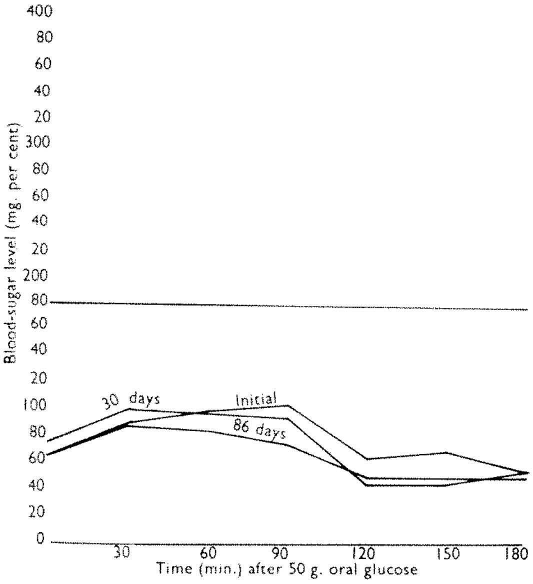

FIG. 11.—*Case* 7. Female, aged 37 years, with gall-stones. Dietary intake before F.F.D.: fat, 720 cal. per day; carbohydrate, 320 cal. per day. After F.F.D.: carbohydrate, plus 160 cal. per day. Initial weight was 138 lb., and after 86 days, 119 lb.

was possible (*Fig.* 28). The G.T. of *Case* 25 was increased after 60 days on the F.F.D.; at 119 days it was decreased after eating 12 eggs per week and other fat. There was improvement after 208 days, but by 327 days the curve reflected the fact that she was again eating fat (*Fig.* 29). The wife of *Case* 26 was a diabetic under orthodox treatment; my patient's G.T. had improved after 120 days on the F.F.D. but he had to abandon the diet to keep the peace at home, and his G.T. returned to its original level (*Fig.* 30).

Ten out of 23 patients who were diabetic when they started on the F.F.D. diet are no longer diabetic.

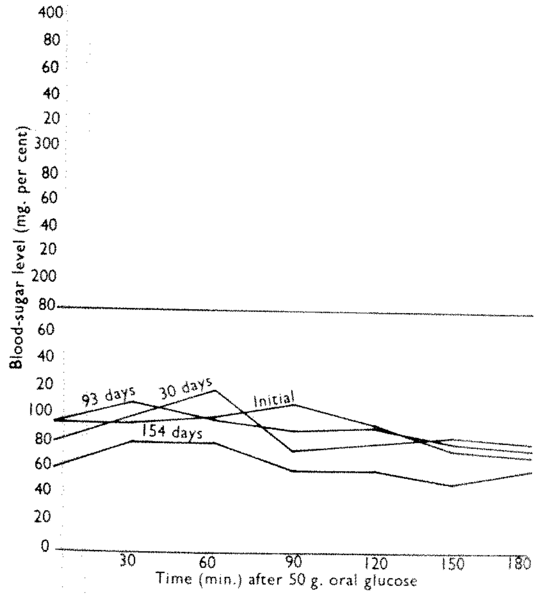

FIG. 12.—*Case* 8. Female, aged 57 years, with hypertrophy of the sphincter of Oddi and of the prepyloric muscle. Dietary intake before F.F.D.: fat, 1080 cal. per day; carbohydrate, 600 cal. per day. After F.F.D.: carbohydrate, plus 300 cal. per day. Initial weight was 126 lb.; after 30 days, 119 lb.; after 93 days, 105 lb.; and after 154 days, 98 lb.

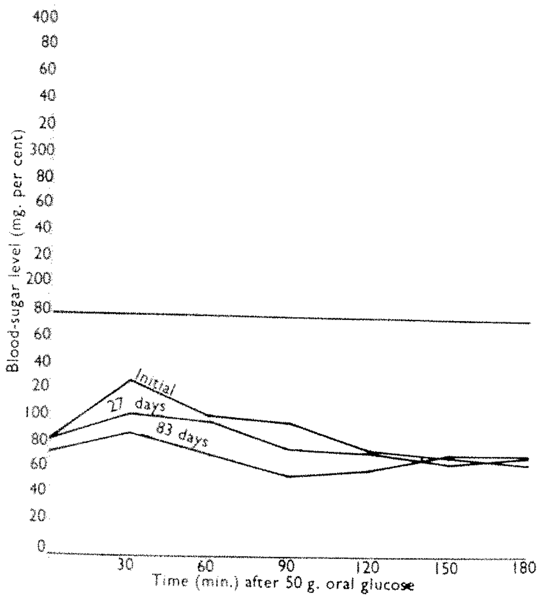

FIG. 13. *Case* 9. Male, aged 44 years, who was overweight. Dietary intake before F.F.D.: fat, 800 cal. per day; carbohydrate, 920 cal. per day. After F.F.D.: carbohydrate, plus 100 cal. per day. Initial weight was 189 lb.; after 27 days, 182 lb.; and after 83 days, 169 lb.

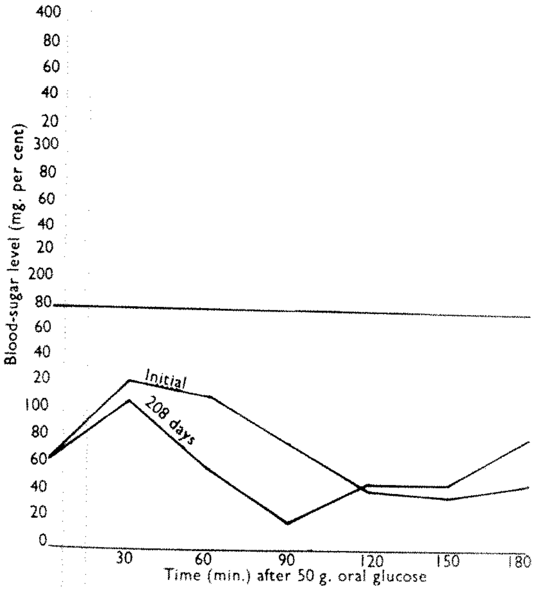

FIG. 14.—*Case* 10. Male, aged 19 years, with flatulent dyspepsia and who was overweight. Initial weight was 196 lb., and after 208 days 189 lb.

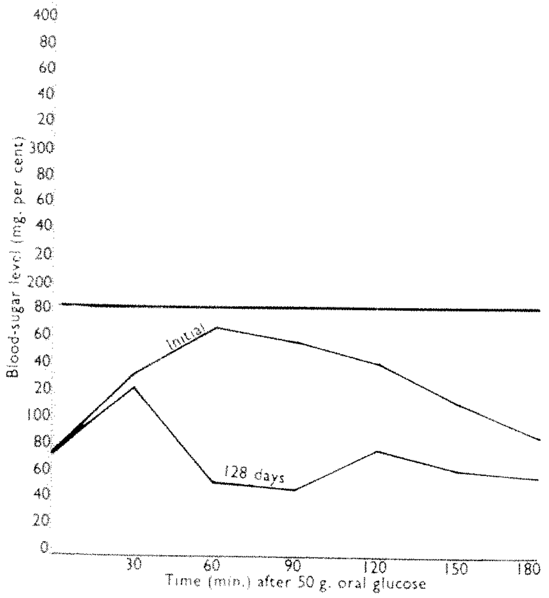

FIG. 15.—*Case* 11. Male, aged 58 years, with occasional glycosuria and an inguinal hernia. Initial weight was 168 lb., and after 128 days, 161 lb.

Three have at some time been hyperglycaemic only but have reverted to diabetic curves after taking fat. Two others whose G.T. had improved while they adhered to the F.F.D. reverted to their previous impairment when they took fat again. It is too early to assess the results in 6 patients; in 2 cases the G.T. is at present increased, in 2 it is impaired, and in 2 only the initial test has been performed. In 2 cases after initial improvement there has been no further increase in G.T.: 1 case appears to have reached the limit of increase in G.T.; the other patient does not adhere strictly to the F.F.D. (*Table XVII*).

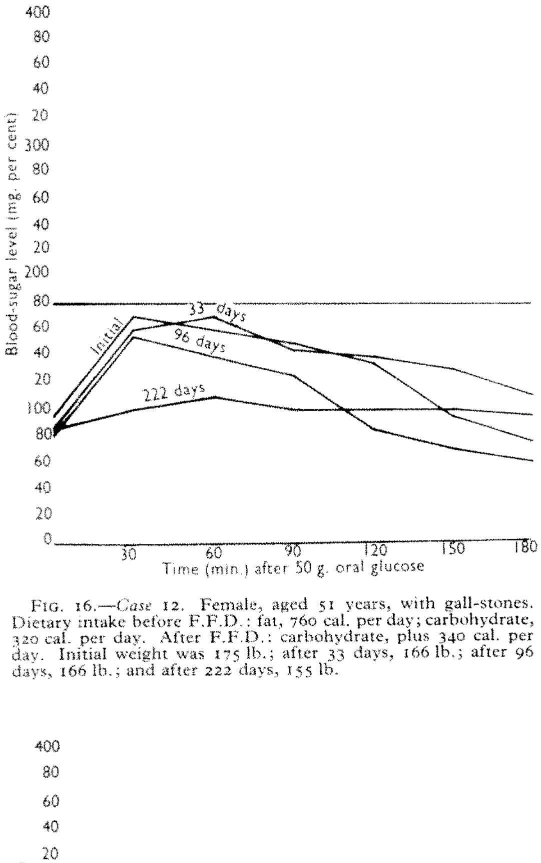

FIG. 16.—*Case* 12. Female, aged 51 years, with gall-stones. Dietary intake before F.F.D.: fat, 760 cal. per day; carbohydrate, 320 cal. per day. After F.F.D.: carbohydrate, plus 340 cal. per day. Initial weight was 175 lb.; after 33 days, 166 lb.; after 96 days, 166 lb.; and after 222 days, 155 lb.

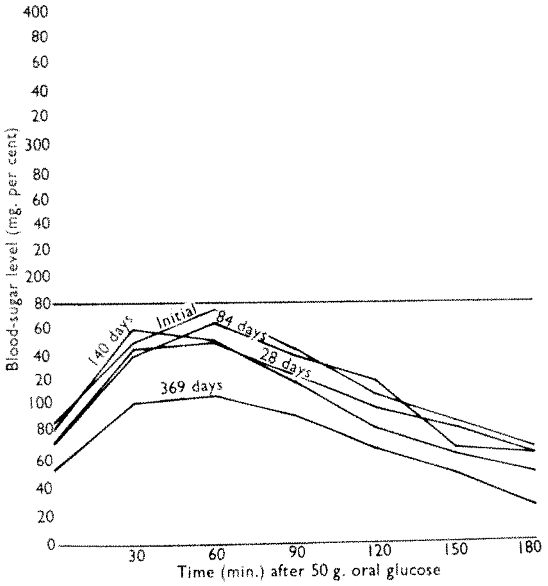

FIG. 17.—*Case* 13. Female, aged 71 years, with postcholecystectomy symptoms. Dietary intake before F.F.D.: fat, 500 cal. per day; carbohydrate, 720 cal. per day. After F.F.D.: carbohydrate, plus 100 cal. per day. Initial weight was 108 lb.; after 28 days, 102 lb.; after 84 days, 97 lb.; after 140 days, 93 lb.; and after 369 days, 88 lb.

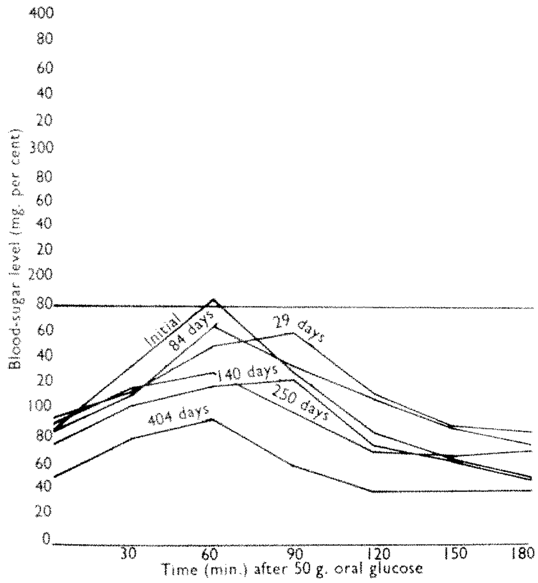

FIG. 18.—*Case* 14. Male, aged 53 years, post-cholecystectomy, with fat intoxication. Dietary intake before F.F.D.: fat, 1350 cal. per day; carbohydrate, 400 cal. per day. After F.F.D.: carbohydrate, plus 650 cal. per day. Initial weight was 205 lb.; after 84 days, 199 lb.; after 140 days, 194 lb.; after 250 days, 194 lb.; and after 404 days, 199 lb.

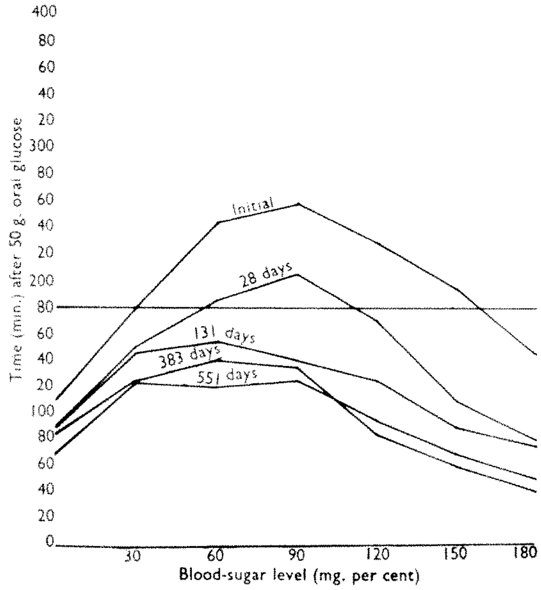

FIG. 19.—*Case* 15. Female, aged 59 years, with gall-stones and diabetes. Dietary intake before F.F.D.: fat, 1450 cal. per day; carbohydrate, 800 cal. per day. After F.F.D.: carbohydrate, plus 400 cal. per day. Initial weight was 125 lb.; after 28 days, 119 lb.; after 131 days, 113 lb.; after 383 days, 125 lb.; and after 551 days, 123 lb.

B. Discussion.—The F.F.D. resulted in increased G.T. in all the patients who adhered to it strictly, provided that it was possible to demonstrate impairment of G.T. initially. It has been impossible to define the level of a normal G.T. curve; in some cases with group 1 type initial curves the only change demonstrated after 80–100 days on the F.F.D. was slight impairment of G.T., but in all the cases from this group which were tested after a much longer period on the diet (more than 200 or even 300 days) no change or even increased tolerance was found. However, the frequency with which it has been

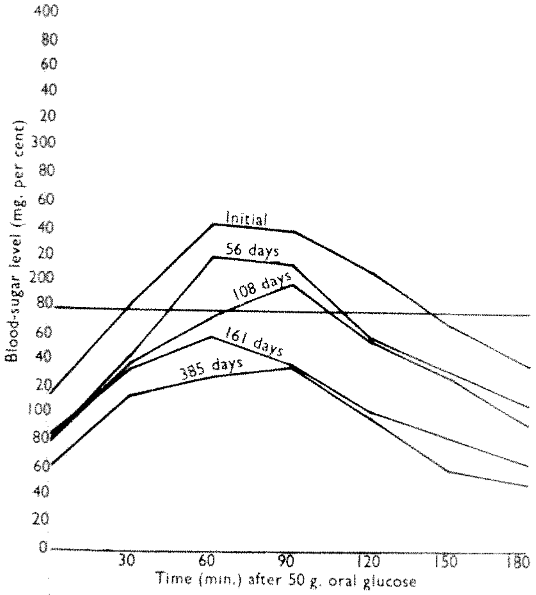

FIG. 20.—*Case* 16. Male, aged 27 years, who was overweight. He had an inguinal hernia and diabetes. Dietary intake before F.F.D.: fat, 720 cal. per day; carbohydrate, 790 cal. per day. After F.F.D.: carbohydrate, plus 50 cal. per day. Initial weight was 152 lb.; after 56 days, 150 lb.; after 108 days, 147 lb.; after 161 days, 143 lb.; and after 385 days, 140 lb.

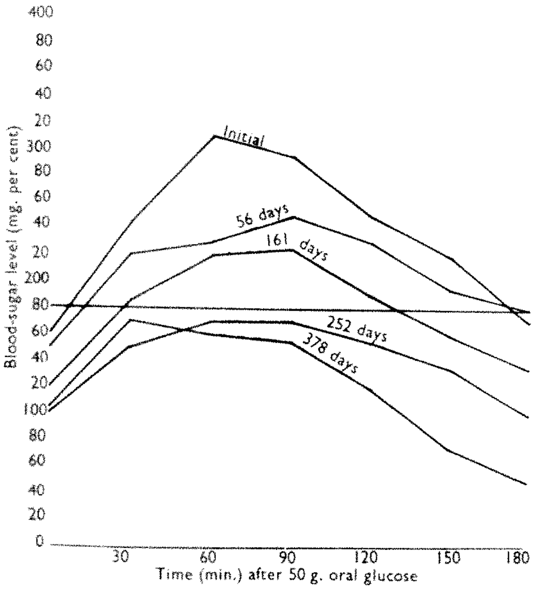

FIG. 21.—*Case* 17. Female, aged 64 years, with spasm in the colon and diabetes. Dietary intake before F.F.D.: fat, 860 cal. per day; carbohydrate, 650 cal. per day. After F.F.D.: carbohydrate, plus 150 cal. per day. Initial weight was 188 lb.; after 56 days, 176 lb.; after 161 days, 168 lb.; after 252 days, 157 lb., and after 378 days, 149 lb.

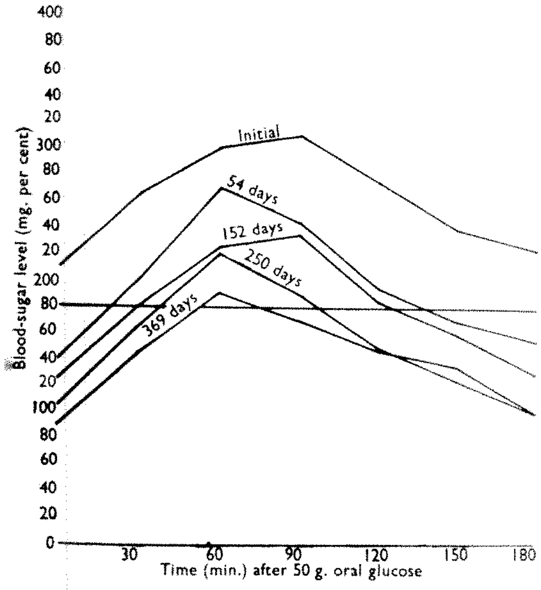

FIG. 22.—*Case* 18. Male, aged 57 years, with an inguinal hernia and diabetes. Dietary intake before F.F.D.: fat, 1030 cal. per day; carbohydrate, 1160 cal. per day. After F.F.D.: carbohydrate, no change. Initial weight was 206 lb.; after 54 days, 194 lb.; after 152 days, 196 lb.; after 250 days, 180 lb.; and after 369 days, 183 lb.

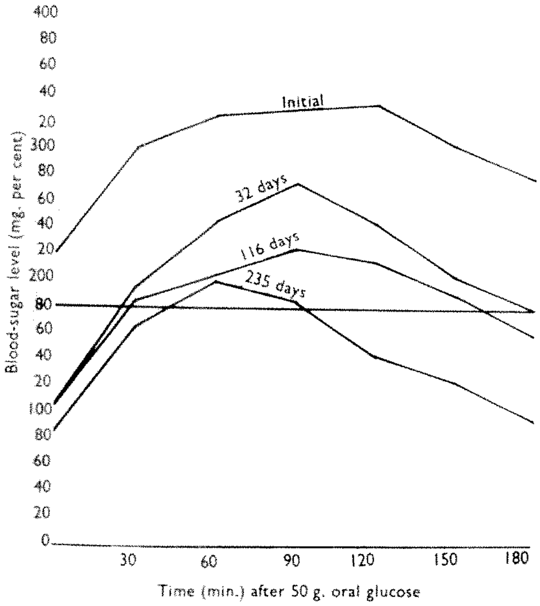

FIG. 23.—*Case* 19. Female, aged 70 years, with polycystic disease of the kidneys and diabetes. Initial weight was 195 lb.; after 32 days, 187 lb.; after 116 days, 168 lb.; and after 235 days, 164 lb.

possible to show increased G.T. is important. Analysis of 65 consecutive cases in which the F.F.D. was necessary treatment showed that the increase in G.T. was statistically significant in all except the 13 cases in group 1, which were not considered to have any impairment of G.T. when they w placed in this group.

There is no constant duration of the F.F which results in increase in G.T., but the longe patient is on the diet the more the G.T. increa

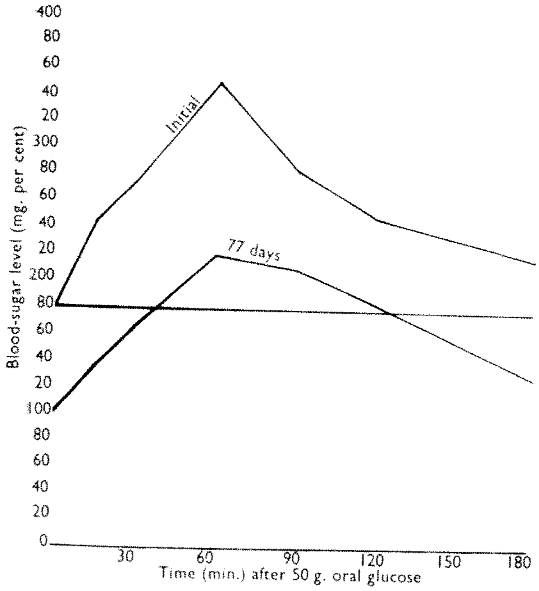

FIG. 24.—*Case* 20. Male, aged 60 years, with prostatic hypertrophy and diabetes. Initial weight was 132 lb., and after 77 days, 126 lb.

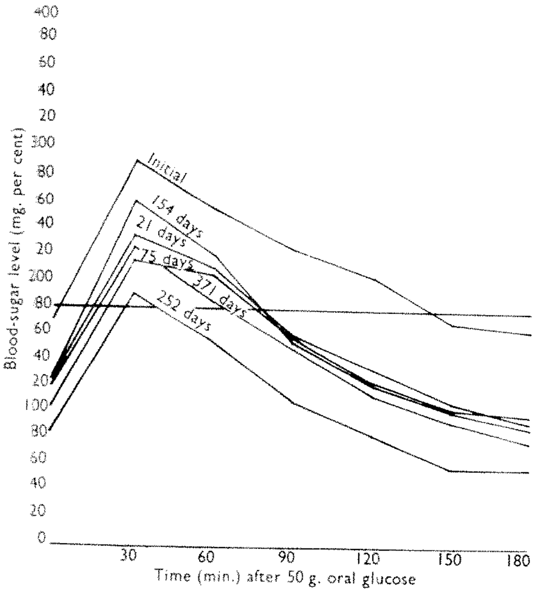

FIG. 26.—*Case* 22. Male, aged 51 years, with 'biliary colic', jaundice, diarrhoea, and diabetes. The diabetes had been diagnosed 6 years earlier on the occasion of vagotomy and pyloroplasty for a duodenal ulcer. The patient has suffered three myocardial infarcts since then. The diabetes had been treated initially by chlorpropamide, 250 mg. daily, and a 12-portion diet. Recently tolbutamide had been prescribed. Random blood-sugar had been 115–145 mg. per cent, and the weight 160–170 lb. The initial weight at the present time was 151 lb.; after 21 days, 143 lb.; after 75 days, 143 lb.; after 154 days, 131 lb.; after 252 days, 135 lb.; and after 371 days, 144 lb.

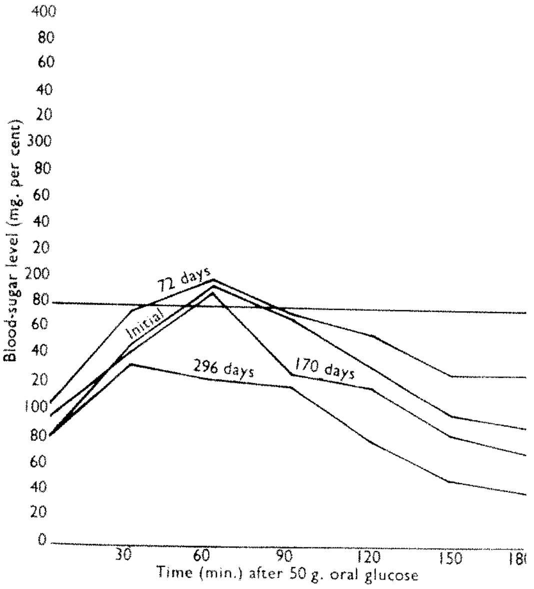

FIG. 25.—*Case* 21. Male, aged 63 years, with 'colitis' and diabetes. The diabetes had been diagnosed 8 years earlier and had been treated by chlorpropamide, 250 mg. daily, and a 12-portion diet. Random blood-sugars had been 210–250 mg. per cent and the weight 167–176 lb. The initial weight at the present time was 167 lb.; after 72 days, 145 lb.; after 170 days 138 lb.; and after 296 days, 126 lb.

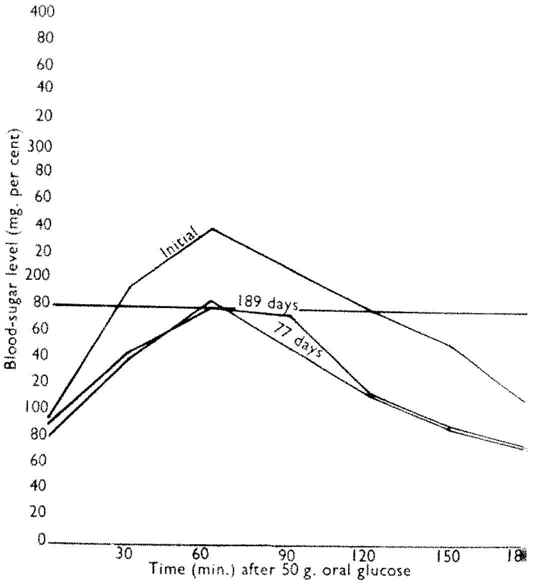

FIG. 27.—*Case* 23. Male, aged 58 years, post-cholecystectomy, with diabetes. The diabetes had been diagnosed 1 year earlier (after cholecystectomy). Previously he had been on steroids for arthritis. He had been weaned from these and prescribed a 10-portion diet. Random blood-sugars had been 105–200 mg. per cent and the weight 200–203 lb. The initial weight at the present time was 203 lb.; after 77 days, 196 lb.; and after 189 days, 197 lb

towards whatever can be termed a normal level, while there may be initial impairment before increased tolerance is established. Such impairment has been demonstrated during periods of active weight-loss. This could be due to catabolism of the patient's own adipose tissue flooding the body with fatty acids; the same process could explain occasional complaints while on the F.F.D. of 'attacks' of biliary tract pain during the period when patients are still losing weight. Initial impairment of G.T. was most obvious in the patients whose tolerance was already good, and much less evident in those whose initial G.T. curves were markedly hyperglycaemic or even diabetic. In the latter, increase in G.T. may be slow to appear; it may require 222 days (*Case* 12, *Fig.* 16), 399 days (*Case* 13, *Fig.* 17), or 404 days (*Case* 14, *Fig.* 18) to become normal.

Increase in G.T. has not been dependent upon a loss of body-weight. *Case* 15, a diabetic who became non-diabetic on the F.F.D., is the same weight now as when treatment started although she did lose weight initially. In the majority of cases the patients lost weight; during a period of active weight-loss G.T. might be impaired, but it increased when the weight became stabilized and continued to increase even when weight was gained while the patient was on the F.F.D. Obesity cannot be other than as

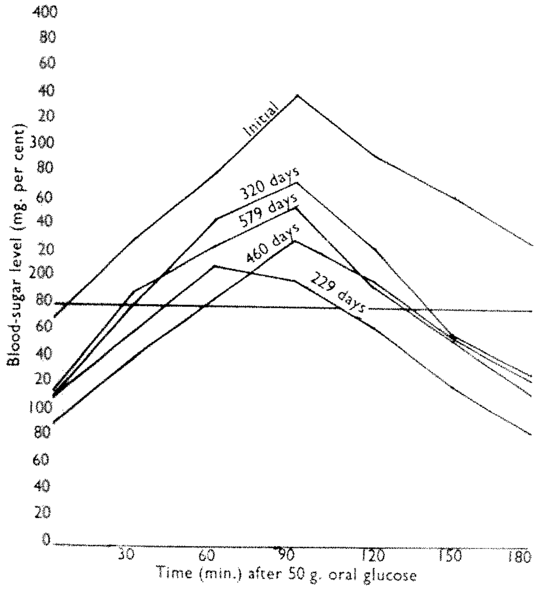

FIG. 28.—*Case* 24. Female, aged 74 years, with spasm in the colon and diabetes. Dietary intake before F.F.D.: fat, 1450 cal. per day; carbohydrate, 860 cal. per day. After F.F.D.: carbohydrate, plus 260 cal. per day. Initial weight was 149 lb.; after 229 days, 135 lb.; after 320 days, 146 lb.; after 460 days, 130 lb.; and after 579 days, 130 lb.

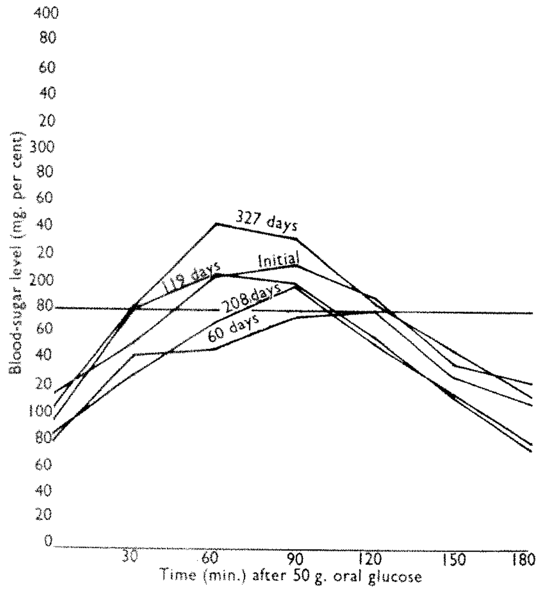

FIG. 29.—*Case* 25. Female, aged 58 years, with urinary infection and diabetes. Dietary intake before F.F.D.: fat, 1600 cal. per day; carbohydrate, 1800 cal. per day. Initial weight was 173 lb.; after 60 days, 168 lb.; after 208 days, 170 lb.; and after 327 days, 173 lb.

Table XVII.—RESULTS OF TREATMENT OF DIABETES BY F.F.D.

Results		*No. of Cases*
No longer diabetic		10
Low hyperglycaemic curve	6	
High hyperglycaemic curve	4	
Still diabetic		13
Have been hyperglycaemic only	3	
Improved G.T., now reverted	2	
'Stuck'—won't stay on F.F.D.	1	
Just 'stuck'	1	
Too early to assess	6	
G.T. impaired	2	
G.T. improved	2	
Only 1 G.T.T.	2	
Total No. now under treatment		23

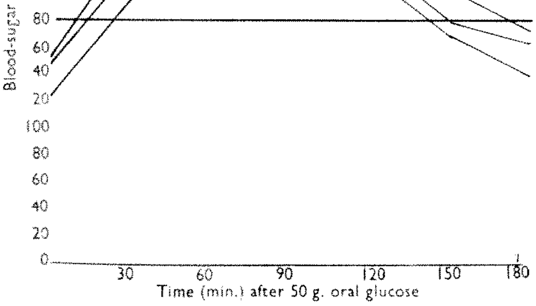

FIG. 30.—*Case* 26. Male, aged 60 years, with symptoms of prostatism and diabetes. Dietary intake before F.F.D.: fat, 1000 cal. per day; carbohydrate, 560 cal. per day. After F.F.D.: carbohydrate, plus 200 cal. per day. Initial weight was 147 lb.; after 120 days, 138 lb.; and after 351 days, 146 lb.

much a symptom of fat intolerance as is impaired G.T. There are at least two types of obesity:—

i. Obesity due to excess dietary fat intake and associated with impairment of G.T. In this type of obesity impairment of G.T. and loss of normal weight regulation are both corrected by the F.F.D.

ii. Obesity not associated with excess dietary fat intake. There is no impairment of G.T. in these cases. These patients do not complain of symptoms of the diseases and disorders discussed earlier in this paper. This type of obesity is not apparently of any sinister import, and if weight must be lost in these patients the calorie intake must be decreased dramatically.

Increase in G.T. on the F.F.D. is not related to previous carbohydrate intake (*Fig.* 1), although there is some evidence that the G.T. is more likely to have been impaired if the carbohydrate intake has been low because in such a diet the fat intake is proportionally higher. At least 3 of the 65 patients in the statistical series presented with symptoms directly attributable to their having attempted to lose weight on a low-carbohydrate diet (*Table XV*). Increase in G.T. on the F.F.D. was independent of change in the carbohydrate intake. There have been no restrictions of or instructions concerning carbohydrate intake on the F.F.D.; in the majority of cases it was increased (*Fig.* 2).

The total number of patients in each of the three different groups of the 'statistical' series was too small for accurate assessment of the relationship of the type of the initial G.T. curve and age. However, the average age of group 1 cases was 42 years, of group 2 52 years, and of group 3 59 years. There were some anomalous cases, but in the series of cases as a whole there appeared to be greater impairment of G.T. as the age of the patient increased. The dietary fat intake tended to be higher in many of the older patients and in those with the greater impairment of G.T.

Himsworth (1933) clearly always suspected that dietary fat played an important part in the causation of diabetes. It is unfortunate that in his studies of the influence of different diets on G.T. he only allowed 5 days for adjustment to diets. It is necessary to allow as long as is necessary for the G.T. to increase on the F.F.D. Himsworth (1935b) suggested that prediabetic obesity was an effect of the type of diet eaten. Himsworth and Marshall (1935) found that diabetics ate more fat than non-diabetics and concluded that this was because they were diabetic. In fact, my findings indicate that they are diabetic because they eat more fat. Himsworth (1935b) suggested that a relatively low carbohydrate diet was a factor determining the onset of diabetes in individuals with a predisposition to the disease, and that if a high-carbohydrate diet was taken a considerable proportion would not develop the disease. However, he concluded that the sugar tolerance of the healthy individual was determined solely by the carbohydrate content of the diet that he received; unfortunately again he only allowed 1 week for a diet to produce an effect (Himsworth, 1935a). In 1939 he stated that the sole dietary factor governing sugar tolerance was the absolute amount of carbohydrate in the preceding diet (Himsworth, 1939). In 1949 he reconsidered the role of fat. He pointed out that the diabetic death-rate tended to fall during wars owing to the food shortage. He could not say that fat was the deleterious factor but found that fat consumption was the dietetic factor most closely related to diabetic mortality (Himsworth, 1949).

My own studies demonstrate that diabetic patients become non-diabetic when they adhere to the F.F.D. and that they revert to the diabetic state when they take fat again. It appears that it is the dietary fat intake that is significant; it does not matter whether the fat is of animal or vegetable in origin because both animal and vegetable fats impair G.T. The length of time during which a high dietary fat intake is present appears to be significant. Butterfield, Hanley, and Whichelow (1965) concluded that obesity was an important factor in the development of diabetes and that carbohydrate tolerance diminished as the duration of obesity increased. However, evidence from the investigation of G.T. reported above points to obesity as merely another symptom of excess dietary fat intake and the duration of obesity must therefore be a measure of the duration of excess dietary fat intake; thus carbohydrate tolerance diminishes as the duration of the excess dietary fat intake increases. This is consistent with my own findings that impairment of G.T. tends to increase with age.

Maturity-onset of diabetes mellitus as seen in this series appears to be an acquired disorder of the metabolism resulting from an excess dietary fat intake over a period of time. It has proved to be reversible if the patient adheres to the F.F.D. and the most dramatic results are those in diabetics who have not had any previous treatment (*Figs.* 19–24). It appears from my investigation in 134 patients that as a consequence of prolonged excess dietary fat intake, probably over many years, with the fat intake also possibly increasing as the years pass, the G.T. gradually becomes more and more impaired till it reaches the stage shown in the initial curve of *Case* 14 (*Fig.* 18). There can be little doubt that if he had continued his high dietary fat intake this patient would have 'jumped the hiatus' noted in *Fig.* 3 and would have become diabetic. At some point a 'breakdown' of some kind must occur (perhaps a switch in metabolic pathways or a change from glucose to fatty acid as the substrate for oxidation—*see below*) and the hyperglycaemic non-diabetic becomes diabetic. No such 'hiatus' in the distribution of the G.T. has been seen during the recovery process when diabetics are becoming non-diabetics.

VI. DISCUSSION

Yudkin (1963) concluded that all species of animals are adapted anatomically, physiologically, and biochemically to a particular sort of diet, i.e., to a particular combination of foods, and that 100,000 years was too short a time for measurable adaptive change from man's early diet. He suggested that a surfeit of calories resulting from increased consumption of carbohydrate was a factor causative of obesity and other diseases in man. Cleave, Campbell, and Painter (1969) blamed refined carbohydrates. Howell and Wilson (1969), however, were not convinced by the evidence and considered that other foodstuffs must play an important role. The evolutionary approach of Yudkin (1963) and of Cleave and others (1969) is attractive and acceptable, but among the patients suffering from dyspepsia, diarrhoea, and lately diabetes whom I have seen and treated carbohydrate was not a causative factor in any. It has always been fat which has caused symptoms or precipitated 'attacks' of pain, and the F.F.D. which has cured symptoms, prevented attacks of pain, been accompanied by weight-loss, has increased G.T. and cured diabetes. In this country for several years before the Second World War fat provided 39 per cent of the total energy of the diet. During the war this figure fell and was 33 per cent in 1947; it rose to 39 per cent in 1954 and to 42 per cent in 1967 (Davidson and Passmore, 1969). The F.F.D. removes on average at least 950 calories of excess dietary fat from the diet per day, while the carbohydrate intake may be unchanged or decreased, but is usually increased. Eighty-six per cent of the excess fat withdrawn from the food intake by the F.F.D. is derived from two domesticated animals, the cow and the pig. The cow has been selectively bred to give a high butter content in milk, and the pig to be fat. These two animals provide a relatively cheap source of energy, and when this is available the human animal takes much more than its metabolic pathways and enzyme systems have been evolved to deal with. Too much vegetable fat is just as poisonous to the human animal; G.T. is impaired and symptoms of dyspepsia and diarrhoea are caused as readily by vegetable fats as by animal fats.

Shipp, Opie, and Challoner (1961) showed that glucose was replaced by fats as the substrate for oxidation in the perfused beating heart when the fatty-acid concentration in the perfusing fluid was raised. Fritz, Davis, Holtrop, and Dundee (1958) found that the rate of oxidation of fatty acids by liver and muscle *in vitro* was roughly proportional to the concentration of fatty acids in the medium. Nestel and Steinberg (1963) demonstrated a similar relation between the concentration and rate of oxidation of fatty acids in the perfused liver, while Challoner and Steinberg (1966) showed the same relationship in the perfused heart. Myant (1968), writing on the subject of the control of cell metabolism, pointed to 'the many cases in higher organisms where enzyme formation is modified by hormones, or by substances which evoke the secretion of hormones, or by metabolites unrelated to the pathway in which the enzyme operates'. He referred to the true induction or repression of many enzymes in animal tissues known to occur in response to changes in the diet, or in the amount of substrate present, or in the balance of hormones. He indicated that the rate of a metabolic process may be influenced by competition between two or more substrates for the same cofactor, and suggested that fatty acids and glucose may compete for a common cofactor. The withdrawal of at least 950 calories of fat (more than 100 g.) from the metabolism each day must clearly have a marked effect on the rate and direction of metabolic reactions and on the availability of pathways. This is the effect of the F.F.D. It must be remembered that the opposite change has taken place, perhaps more gradually, as the excess dietary fat intake was built up.

Clinically, the effect of the F.F.D. is marked by the cure of symptoms, as described earlier in this paper, by appreciable weight-loss in most patients, an average loss of 9 kg. per patient occurring in a series of 50 patients who suffered from gall-stones, and by increased G.T. The patient experiences a subjective 'change' often ascribed to but not satisfactorily accounted for by weight-loss; this 'change' occurs in those who do not lose weight and consists of loss of 'tired feeling', of 'feeling more alive', and of 'feeling better in all ways and able to do and cope with more'. I have investigated only a very small part of the whole metabolism and have shown that G.T. is increased by the withdrawal of excess dietary fat. All metabolic processes are interdependent to a greater or lesser extent, and this change in carbohydrate metabolism must reflect a change in the whole balance of metabolism. As has already been mentioned, there must be a chain reaction of changes throughout the metabolic processes of the whole body until a new state of homeostasis with the new G.T. is reached. The extent of change in each individual must depend upon that individual's gene constitution and the adaptability of metabolic control mechanisms. How far G.T. returns to normal must depend to some extent upon what permanent damage has been done during the period of impaired tolerance and disturbed metabolism, what enzymes have been suppressed, and perhaps how quickly enzymes can be synthesized. Change in the metabolism may act upon control mechanisms by altering the hormone metabolism, or peripherally by altering the individual cell metabolism and perhaps thereby modifying cell function. Almost all patients who adhere to the F.F.D. rapidly lose the desire for fat; many acquire distaste for it. This constant effect of the diet indicates a change in the 'chemistry' of the patient, as does the clinical fact that when a patient who has adhered to the F.F.D. does take fat a very much smaller quantity stimulates symptoms than was the case before dieting.

It cannot be coincidental that the patients in whom I found impaired G.T. and even diabetes were those who were complaining of dyspepsia or diarrhoea or both, or that the F.F.D. cured symptoms and increased G.T. in the same patients at the same time. Nor can it be coincidence that the primary lesion in cases of dyspepsia and diarrhoea is spasm of circular smooth muscle at the site of sphincter action—at the sphincter of Oddi, the pylorus, and the recto-sigmoid junction—or hypertrophy following upon repeated or chronic spasm; or that when limited relaxation of these sphincters results from pathological changes in the muscle layer, thereby preventing complete cure by the F.F.D., a similar operation, sphincterotomy, pyloroplasty, or sigmoidomyotomy, by restoring an adequate lumen in each site cures those cases not cured by the F.F.D.

I have not discussed a series of isolated and independent diseases in this paper, for intolerance is a disorder caused by excess dietary fat intake and characterized by disturbance of the whole metabolic balance. It may present as one or more syndromes in each patient. Diabetes itself is an extreme manifestation of the disordered metabolism, perhaps, as suggested earlier, a 'breakdown' when limits of adaptability have been reached and metabolic pathways have switched or the substrate for oxidation changed. In the digestive system fat intolerance may present as flatulent dyspepsia, or with symptoms and signs referable to the biliary tract, peptic ulceration, or the lower levels of the large bowel. The onset of spasm is often sudden, as in acute attacks of biliary pain; this again suggests a 'breakdown'. (It is interesting and perhaps relevant that an essential lesion in migraine and in coronary artery disease is spasm of circular smooth muscle.) This hypothesis is compatible with the association of dyspepsia and diarrhoea with hormonal changes and with stress noted clinically in so many cases. Wynn and Doar (1966) measured impairment of G.T. caused by the 'pill'. Stress alters hormone levels, mobilizes body fats, and causes spasm (Oliver, Kurien, and Greenwood, 1968).

Treatment of these conditions should, it seems, be directed to the restoration of a more normal metabolism by restricting severely the excess dietary fat intake, rather than by administering drugs to treat individual symptoms such as raised blood-sugar, acidity, or diarrhoea. Surgery should be reserved for those cases which are not cured by the F.F.D. and should be directed at the proper lesion; no purpose is served by removing a gall-bladder if an obstructing or hypertrophic sphincter of Oddi is not also relieved, while pyloroplasty does not require the addition of vagotomy, the latter being merely an attack upon a symptom, and is unnecessary if obstruction at the pylorus is efficiently relieved.

The human animal is adaptable, but there is a limit to adaptation. Farmers have changed the cow and the pig from the animals they once were. By excess dietary fat intake the human animal has been changed from the animal it should be. In the case of the cow and the pig genetic selection has produced new animals. The excess dietary fat-eating human has been changed chemically and not genetically and can only adapt so far and for a time; when the limit of adaptability is reached the diseases and disorders that I have discussed in this paper become apparent.

CONCLUSIONS

1. Fat intolerance is a metabolic disorder associated with impairment of G.T. and caused by excess dietary fat intake.
2. The syndromes of fat intolerance are not different diseases but are due to dysfunction in different parts of the body in response to the same metabolic abnormality which may present as flatulent dyspepsia, surgical disease or disorder in the biliary tract, peptic ulceration, diarrhoea (associated with spasm of the colon, colitis, or diverticular disease), abdominal pain (in children), or diabetes mellitus. One, two, or more of these syndromes may occur in the same patient at the same or different times.
3. The F.F.D., as defined, cures symptoms in the majority of cases and the G.T. is significantly increased on it.
4. The abnormal metabolism of fat intolerance causes spasm of smooth muscle and affects especially the circular muscle-fibres at sphincter sites—the sphincter of Oddi, the pylorus, and the rectosigmoid junction. Spasm is reversible by the F.F.D. When permanent restriction of relaxation is caused by hypertrophy or fibrosis, surgery is necessary for a cure. If hypertrophy or fibrosis of the sphincter of Oddi interferes with the emptying of the gall-bladder or the free drainage of the common bile-duct, sphincterotomy of the sphincter of Oddi is required. When surgical treatment is required for duodenal or gastric ulcer, pyloroplasty alone cures the ulcer. Vagotomy is unnecessary and can be detrimental to the patient.
5. Increase in G.T. results from decrease in dietary fat intake and is independent of the previous carbohydrate intake, of change in the carbohydrate intake, and of weight change. In many cases obesity is only another symptom of fat intolerance.
6. Ten out of 23 diabetic patients have, to the present date, become non-diabetic on the F.F.D. without any other treatment. Diabetes mellitus (maturity-onset) appears to be an acquired metabolic disorder caused by excess dietary fat intake and is reversible; glucose tolerance increases progressively on the F.F.D., and the extent to which recovery is retarded or limited is dependent only on the previous duration of the diabetes and previous treatment by drugs provided that the patient adheres to the diet.
7. Eighty-six per cent of the excess dietary fat intake is derived from cow's milk and the pig which have been selectively bred to produce a high butterfat content in milk and a 'fat' animal respectively.
8. Vegetable fat causes fat intolerance and all its syndromes as readily as animal fat.
9. No evidence has been found that carbohydrate in any form is the cause of symptoms or disease.

Acknowledgements.—I extend my sincere thanks to Dr. Peter Goddard and his technical staff for their help with blood-sugar estimations; Dr. E. A. Waldron and Dr. W. Homer Smith for their radiological studies; Dr. Geoffrey Steed for allowing me to 'take over' the care of a number of diabetic patients we shared; Miss Easton of the Hospital Photographic Department, Miss Jean Horswill, personal secretary, and the staff of the Medical Records Department; my ward and theatre sisters and their staffs; and finally to the many patients who have co-operated so willingly and often at great personal inconvenience, without whom this paper could not have been written.

APPENDIX 1: TECHNIQUE OF SPHINCTEROTOMY OF THE SPHINCTER OF ODDI

The following technique has proved to be simple to perform, effective, and free from complications.

The duodenum is mobilized, if necessary, by incising the peritoneum on its lateral border. A longitudinal incision is made in the common bile-duct just below the junction with the cystic duct in the free border of the lesser omentum. A 6/10 urethral sound (Clutton's) is passed down the duct and is gently levered so that the ampulla of Vater, or the tip of the sound if it actually passes through the sphincter and ampulla, can be readily identified through the anterior wall of the second part of the duodenum. An oblique incision, 2·5 cm. long, is made in the anterior wall of the duodenum over the ampulla, which is then delivered by further gentle leverage on the sound. The duodenal mucosa is incised over the tip of the sound; if the tip is already presenting the opening in the mucosa is enlarged by incising against the sound on its right anterolateral aspect for a distance of 2–3 mm. Gentle retraction of the mucosa by dry gauze will then expose the lowermost fibres of the sphincter stretched upon the sound. These fibres are incised against the sound on the right anterolateral aspect until the sound slips through easily. The sound is then withdrawn and replaced by one of size 8/12. Further fibres of the sphincter are incised as above, and the manœuvre is repeated with larger sizes of sounds until a 16/20 sound can slip through the sphincter easily. The lumen is then more than 5 mm. in diameter and the sphincterotomy is complete. The sound is withdrawn, the incision in the duodenum is closed by a single layer of interrupted Dexon sutures, and the incision in the common bile-duct is closed around a T-tube.

If pyloroplasty is necessary at the same operation the sphincterotomy can be performed through the pyloroplasty incision.

APPENDIX 2: TECHNIQUE OF PYLOROPLASTY

The following technique has been found to be most satisfactory.

The duodenum is mobilized, if necessary, by incising the peritoneum along its right lateral border. A long incision is made through all the layers on the anterior surface of the pylorus extending far enough on to the antrum and the duodenum to divide any rigid or constricting segment to decompress the antrum and to prevent duodenal cap systole. The incision is centred on the pyloric ring and extends an equal distance proximally and distally to it. The incision is sewn up transversely (in relation to the lumen) with a single layer of interrupted Dexon sutures placed 0·32–0·64 cm. apart. The lumen of the resulting pyloroplasty must 'take three fingers' when completed. Omentum should be interposed between the pyloroplasty and the under-surface of the liver and the gall-bladder or the gall-bladder bed.

APPENDIX 3: THE ORAL GLUCOSE-TOLERANCE TEST

The test was performed as an out-patient investigation in most cases. The patients were instructed not to eat or drink anything after 9.00 p.m. on the evening before the test. They attended hospital at 8·45 a.m. on the day of the test, and a specimen of blood (for the fasting blood-sugar level) was taken just before 9·00 a.m. Each patient then drank, in turn, a solution of 50 g. glucose dissolved in 500 ml. water. Specimens of blood were taken from each patient at 30-minute intervals for the next 3 hours. Each blood specimen was taken by venepuncture, and estimation of the blood-sugar level was carried out on a Technicon Auto-Analyser by the alkaline ferricyamide technique.

APPENDIX 4: A COMPARISON OF THE GLUCOSE TOLERANCE CURVES OF PATIENTS BEFORE AND AFTER THEY HAVE BEEN ON A FAT-FREE DIET

BY NIALL CLINTON
LECTURER IN STATISTICS, PLYMOUTH POLYTECHNIC

Two G.G.T.s were carried out on each of 65 patients. For each patient test 1 was carried out before the patient went on the F.F.D. and test 2 was performed after the patient had been on the diet for some time.

The patients were divided into three groups. Group 1 contained 13 patients whose G.T. at test 1 was considered normal, while group 2 contained 43 patients whose G.T. at test 1 was low, and group 3 contained 9 patients who were diabetic at the time of test 1.

It is required to determine if the F.F.D. has increased the G.T. of the patients and also if the patients in the different groups respond differently to the diet.

Analysis.—A quantity proportional to the area under the G.T. curve was found for each test as it affords a measure that takes into account all the readings of a test. If x_1, x_2, x_3, x_4, x_5, x_6, x_7 are the readings of a test (in the order in which they are obtained), then the quantity found was

$$A = x_2 + x_3 + x_4 + x_5 + x_6 + \tfrac{1}{2}(x_1 + x_7).$$

Since the time interval between each adjacent pair of readings is the same (30 minutes) for comparison

purposes the use of A is equivalent to the use of the actual areas under the G.T. curves, and in the following we shall refer to A as the area.

For each patient the results of test 2 were subtracted from the corresponding results of test 1, giving eight scores for each patient. Thus, the first score for a particular patient is the decrease in the fasting blood-sugar level over the period that the patient was on the diet, the second score is the decrease in the blood-sugar level at the 30-minute stage of the tests, etc., and the eighth score is the decrease in the area under the patient's G.T. curve. Of course a negative decrease is an increase. The scores for all the patients are given in *Table IA* and the means and standard deviations of the scores for each group are given in *Table IIA*.

2 and 3	C = 0·948 V = 6·104	4·990	4·359	C = 0·947 V = 5·092	C = 0·979 V = 3·824	C = 0·980 V = 4·061	C = 0·986 V = 4·412	C = 0·979 V = 5·440

To test for differences between the three groups a one-way analysis of variance was performed for each of the eight scores. The mean square ratios in all of these were very large, indicating that there were in fact differences for all of the scores. The groups were then compared in pairs and for this it was decided to test the hypotheses that the means for group 2 were significantly larger than those for group 1, and that the means for group 3 were significantly larger than those for group 2. First, the appropriate variance ratios were found and these are given in *Table IIIA*, the starred ratios being those that are significantly different from unity. To compare the means of the pairs associated with the starred ratios Welch's test was used, and for the means of the pairs associated with the other variance ratios, which were not significantly different from unity, t tests were used. The required test statistics are shown in *Table IVA*. Where Welch's test has been used the notation is that used by *Biometrika Tables for Statisticians* (Pearson and Hartley, 1966). The tests show that we can accept the above hypotheses at the 5 per cent level of significance.

The question still remains as to whether the average scores for each group are significantly greater than zero. Here again t tests were used, all at the 1 per cent level, and the test statistics are given in *Table VA*. It was found that none of the scores for group 1 was significantly greater than zero. Since it was considered that the patients in this group had normal G.T. curves initially it may be more appropriate to test the hypotheses that the average scores are different from zero rather than just greater than zero. The result was still not significant for this test. It was found, however, that all the mean scores for both group 1 and group 2 were significantly greater than zero.

Conclusion.—The above tests indicate that while the fat-free diet appears to have had little or negligible effect on the blood-sugar levels of the patients whose G.T. was normal, there is strong evidence to suggest that the patients whose initial G.T. was low had increased their G.T. significantly after they had been on the diet. Moreover, greater increases in G.T. were shown by the diabetic patients. Also the diabetic patients showed more variability in their reactions to the diet than did the other groups of patients.

The question arises as to what constitutes an increase in G.T. Possibly the best measure of G.T. is the area under the G.T. curve and then an increase in the G.T. is represented by a decrease in the area under the curve. There may be a dilemma if some of the first seven scores are significantly greater than zero and some are not, because the interpretation of the results then becomes difficult if it is considered that these seven scores are the important ones. However, the problem does not arise here as all the eight scores give the same result.

APPENDIX 4A: ANALYSIS WITH NEW DATA

Table VIA gives the new scores for the patients with additional data. *Table VIIA*, which corresponds to *Table IIA* of the previous analysis, gives the new means and standard deviations for the scores in the three groups. The other tables of test statistics, etc., have also changed but these have not been included as I feel that a statement of the procedures adopted and not all the details of them is sufficient.

Analysis.—The same procedures as before were used with the new data. To test if the mean scores of each group were greater than zero t tests were used. Also as before t tests and Welch's test were used to compare the mean scores of the groups.

Conclusions.—The conclusions have not changed, but for the sake of clarity let us go into these in a little more detail.

It was pointed out before that the area under the G.T. curve (which is, in fact, a broken-line graph) appears to be a reasonable and objective measure of G.T. Then the area under a patient's before F.F.D. curve minus the area under the patient's after F.F.D. curve is a measure of the patient's increase in G.T. after being on the diet. This measure is, in fact, score 8 in the tables. If we do accept the area as a measure of G.T., and it seems difficult not to, then the following points emerge:—

1. The G.T.s of patients in group 1 have not changed significantly.
2. The G.T.s of patients in both groups 3 and 2 have increased significantly.
3. The G.T.s of patients in group 3 have increased more than those of patients in group 2.
4. The reactions of patients in group 3 are more variable than the reactions of patients in either of the other groups. However, there is a small number of people in group 3 and there are large variations in the reactions of patients within all the groups. Possibly these large variations are due to the large variations in weight changes and days between tests, etc.

In short, using the area under the G.T. curve as a measure of G.T. we conclude that the patients in groups 2 and 3 have significantly increased their G.T.s after being on the F.F.D.

It is notable also that the same conclusions are reached even if it is demanded that significant results should be obtained for each of the first seven scores.

Note on the New Data.—The conclusions have not changed with the new data, as was mentioned above, except that the results for some individual patients are more encouraging. The differences we are trying to detect were marked with the original data, so that the new results on a few patients have not had any large affect.

It is surprising to note that patient 56 has indicated an even greater decrease in G.T. after the longer period on the F.F.D.

Possibilities for Further Analysis.—It would be interesting to pursue the idea that there might be relations between the variables measured on each patient. Also for the patients on which a series of G.T. tests have been done it may be possible to find relations between G.T. and the time on the F.F.D. and to compare these for different patients.

Acknowledgement.—I would like to thank E. C. Tapper, B.Sc., A.F.I.M.A., for the computer programming he has done in connexion with this work.

THE ORIGIN OF PHLEBOLITHS

BY PHILIP SHEMILT
SALISBURY GENERAL HOSPITAL

SUMMARY

Phleboliths originate as thrombi in the pelvic veins and are the result of injury to the vein wall.

Although in children the pelvic veins and venous plexuses may be protected by valves, these have disappeared in adult life. In 20 dissections in adult cadavers remnants of osteal valves were sometimes seen, but a functioning bicuspid valve was noted only once.

These unprotected veins are subjected to large and abrupt rises in pressure during normal acts of coughing and straining. Because of this the veins are distended and damage to the intima with the formation of a protective thrombus can occur.

A locally high concentration of phosphatase in the perivesical tissues would explain why these thrombi become calcified in the pelvis and why phleboliths are so rarely found elsewhere.

PHLEBOLITHS are commonly seen in radiographs of the pelvis but their origin has so far remained a mystery. That they are calcified thrombi inside pelvic veins has been known for many years, but what causes such frequent thrombi and why they should become calcified has never been explained.

The aim of the present study was first to ascertain whether the pelvic veins had the protection of valves. Having verified their absence, the next objective was to discover whether there were sufficient pressure changes inside the pelvic veins to damage the vein wall and thus initiate a thrombus. Finally an explanation of why thrombi once formed at this site should, so unusually, become calcified was sought.

HISTORICAL REVIEW

Early anatomists and pathologists (Rokitansky, 1852; Balogh, 1861) had observed the presence of calcified intravenous nodules in their dissections of the human pelvis. Before long it was established that these phleboliths were harmless calcified thrombi in dilated veins (von Recklinghausen, 1883). From then on there was little interest in the subject and phleboliths were forgotten.

With the discovery of X-rays in the early part of the twentieth century phleboliths attracted attention once more. At first radiologists were at a loss to explain the presence of calcified rounded opacities so often seen in radiographs of the pelvis. Many theories were proposed as to their nature. Leonard (1902) suggested that they were due to intestinal concretions and foreign bodies. Von Albers-Schönberg (1906) thought that they were caused by calcification in pelvic ligaments and he mentioned the fruitless discussion on the subject at the Roentgen Congress of 1905. In 1907 a warning was given by Beckett that unnecessary operations were being carried out on phleboliths. He pointed out, as did Orton in 1908, the difficulty in distinguishing between renal stones and phleboliths and advised against operative treatment based on pelvic radiological shadow.

Clark (1909) firmly established the nature of these small opacities so frequently seen on pelvic radiographs. He proved beyond doubt that they were indeed the vein stones of the earlier pathologists. By taking radiographs of the pelvis before and after removal of the soft tissues he was able to show that the calcareous bodies lay outside the urinary tract and were inside the veins. They might be found anywhere in the pelvis but especially close to the line of the lower ureter. They were usually round or oval in shape, varying in number and size, and often bilateral. They were always intravenous, attached to the intima, and surrounded by a thin membrane. He found them to be composed of concentric calcified strata around a central kernel.

The microscopic appearances of phleboliths were described by Ribbert in 1917. He showed all the stages from freshly made thrombi in the periprostatic veins forming a central calcified nucleus to final complete calcification by layers of the whole thrombus.

Culligan reviewed the subject in 1926. He found phleboliths in 39 per cent of 1555 consecutive radiographs of the pelvis. He thought that they were more common in males, but Bützler (1934) and Dovey (1966) disputed this and there is probably little difference in prevalence between the sexes. In Culligan's (1926) series the average age of patients with phleboliths was 37 years; he found none in any patient below the age of 16. The number of phleboliths varied and up to 20 might be present. There was an average size of 4 mm. with variations between 1 and 10 mm. Culligan noted a tendency for the phleboliths to appear in chains.

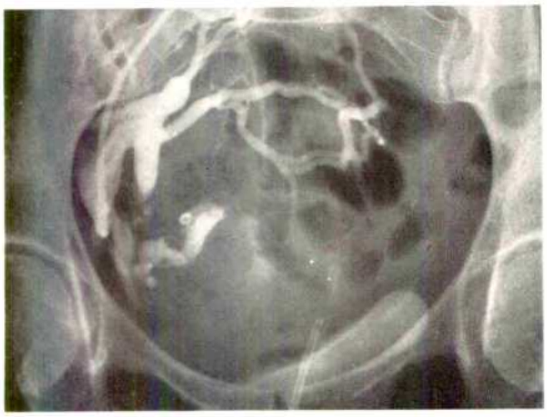

FIG. 1.—Radiograph showing contrast medium pooled in the pelvic veins.

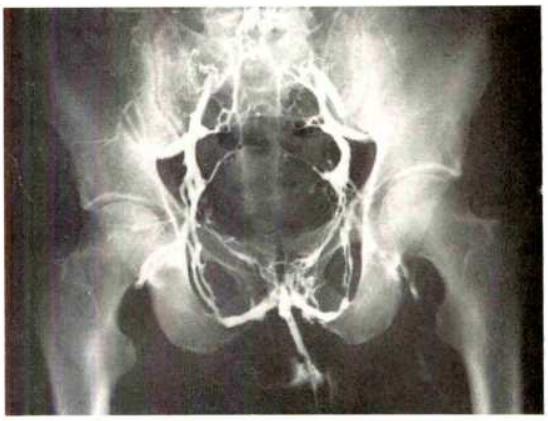

FIG. 2.—Radiograph showing the injection of contrast medium into the deep dorsal veins of the penis.

In the recent series the incidence of phleboliths in the adult population has been estimated at between 30 and nearly 50 per cent (Dillon and Cody, 1928; Dovey, 1966; Green, 1967), the prevalence increasing with age up to the sixth decade but falling slightly thereafter. Significantly Dovey (1966) found no progressive increase in the size of phleboliths in the patients that he followed for up to 9 years. Green (1967), from his estimate of the size of phleboliths at different ages, concluded that phleboliths must form as the result of a process which can occur once or perhaps repeatedly during life, but which lasts a comparatively short time.

THEORIES OF ORIGIN

From the time that they were first described there has been speculation regarding the mode of origin of phleboliths.

Slowing of the blood-stream was the explanation usually given by pathologists in the nineteenth century. Balogh (1861), having examined phleboliths in a patient who died of carcinoma, concluded that malignancy might be a cause.

Clark (1909) gave various explanations: idiosyncrasy, lowered or impaired degree of local venous circulation, congestion, changes in the vessel wall from disease or age, phlebitis, and possibly inflammatory processes in neighbouring structures. He could offer no reason why one thrombus should undergo resolution and another calcification.

Culligan (1926) pointed out that thrombi in other parts of the body only rarely formed phleboliths. It is true that they have been reported occasionally in other sites—in the spleen (Barsony and Schültz 1931), in a varicocele (Sanazzari, 1927), and occasionally in angiomata—but these are exceptional findings. Culligan (1926) believed that stasis in pelvic venous plexuses favoured thrombus formation and he thought that secondary infection from prostatic ducts might play a part. Since the area was poorly nourished the thrombus would become calcified more easily. Dillon and Cody (1928) considered that phleboliths, being rare in patients under the age of 40 years, might indicate by their presence some past disease of the sex organs. Greenburg (1949) mentioned phlebitis as a cause of pelvic thrombi and warned that phleboliths might become dislodged to form emboli. From studies on venograms Dovey (1966) concluded that valves are present in pelvic veins, and that phleboliths might form from non-specific valvulitis.

None of these explanations appears to be convincing. The fact that the blood flows slowly in the pelvic venous plexuses was confirmed during the course of the present investigations. Radio-opaque dye injected directly into the internal iliac veins of patients could be seen pooled in the plexuses for several seconds on the radiographic screen (*Fig.* 1). A sluggish blood-flow could hardly by itself initiate a thrombus, and therefore there would need to be some other factor.

It seems unlikely that infection in the pelvis or genital tract has any large influence determining phlebolith formation. This would mean an unsuspected infection in nearly half the adult population, giving rise to thrombi which are always sterile. Clark (1909) could find no bacteria in any of the phleboliths that he examined.

A theory proposing non-specific inflammation of valves in the pelvic veins implies that valves are scattered throughout the pelvic plexuses. This point was investigated by reference to the literature and by post-mortem dissection of the pelvic veins.

ANATOMY OF THE PELVIC VEINS

Standard descriptions of the pelvic veins show that they consist of a number of intercommunicating plexuses surrounding the viscera. These veins are thin walled and are contained in loose connective tissue. From the plexuses blood drains into the internal iliac veins via the vesical, uterine, vaginal, and middle rectal veins.

VALVES IN THE PELVIC VEINS

It proved unexpectedly difficult to discover from the literature whether or not the internal iliac veins and pelvic plexuses contain valves. Many of the standard works on anatomy either are contradictory or make no mention of this point. Most studies on the iliac veins and their valves seem to have concentrated only on the common and external veins.

Quain (1892) states that there are no valves in the internal iliac veins. Testut (1921) makes no mention of the presence or absence of valves in these veins. Fredreich (1881) states that valves in the common iliac vein are excessively rare, having been found in 4 subjects in 185 examinations. In *Gray's Anatomy* (1967) and Cunningham's *Textbook of Anatomy* (1964) the point is not mentioned.

Fredreich (quoted by Franklin, 1927) stated that no valves are present in the internal iliac veins but that they do exist in their ramifications, opinions differing as to their presence either at their terminations or in the path of these vessels beyond the pelvic confines. Opinions were also divided about the existence of valves in the various venous plexuses such as the middle and inferior haemorrhoidal, vesical, pudendal, and uterovaginal.

Fenwick (1885) remarked on the difficulty in obtaining anatomical preparations of the pelvic venous plexuses. He dissected the pelvic veins in 50 subjects (foetuses, children, and young adults). He insisted that after the age of 25 pathological changes set in altering the anatomy with enlargement of existing veins or the formation of new channels.

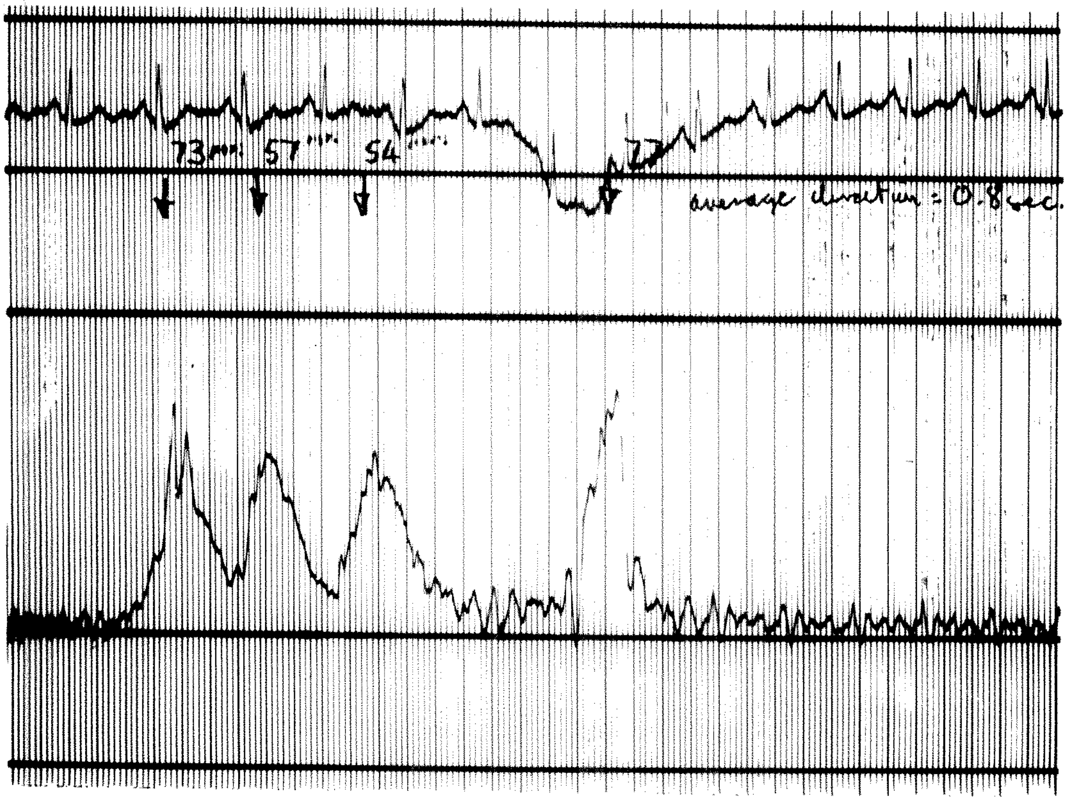

FIG. 3.—The pressure rises in the pelvic veins caused by coughing.

Fenwick concentrated on the vesicoprostatic plexuses in his young subjects and found valves in all parts; one group behind the pubis, another set guarding reflux from the internal iliac vein, and a third set which was less constant and apt to degenerate about the middle of the tract. He recorded that by the age of 38 many of the valves had atrophied and in old age the pelvic veins that he dissected were valveless.

Dodd and Cockett (1956) stated: 'Valves are not described in the internal iliac vein but are said to be found in its tributaries'.

Batson (1942) demonstrated the pelvic plexuses radiographically by post-mortem injection of radio-opaque dye into the deep dorsal vein of the penis. He saw no valves and showed that there was a flow of contrast from the deep dorsal vein into the pelvic plexuses and so into the inferior vena cava. He could not find valves when he dissected the venous plexuses in male and female subjects. His experiment, injecting contrast medium into the deep dorsal vein of the penis in post-mortem subjects, has been repeated in the present study. The radiographs (*Fig.* 2) show excellent filling of the prostatic plexus and of all the tributaries of the internal iliac veins, but no valves could be made out.

In recent years various methods have been used to demonstrate the pelvic veins radiographically. From the evidence of these radiographs it has sometimes been claimed that the internal iliac veins and their tributaries contain valves in almost all cases.

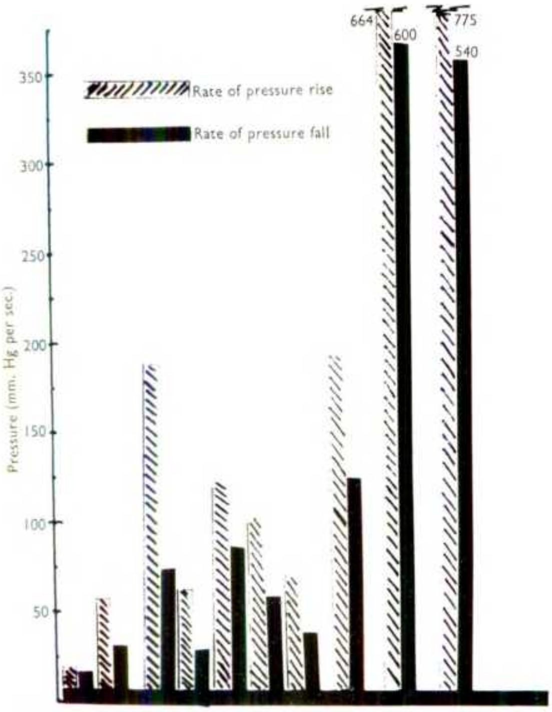

FIG. 4.—The rates of pressure changes in the pelvic veins during coughing and straining.

Helander and Lindbom (1959) injected contrast medium into the external iliac vein bilaterally in 304 patients using abdominal compression to occlude the inferior vena cava. By this means they were able to fill the internal iliac veins by back-flow. In about one-third of their cases the pelvic plexuses were filled and appeared dilated. When the contrast medium was held up in a vessel it was assumed that the block was caused by a valve. Helander and Lindbom considered valves were likely in the internal iliac veins or their branches in 85 per cent of the cases.

Dovey (1966), using retrograde inferior vena cava injection at autopsy on 10 cases, was able to fill the common and internal iliac veins. In all except 1 case the contrast would not flow beyond the internal iliac vein and its tributaries would not fill. He concluded that valves were therefore present, and demonstrated the valves in a few cases by dissecting the main draining veins.

Excellent pictures of the pelvic veins have also been obtained by intra-osseus pubic phlebography (Lea Thomas, Fletcher, Andress, and Cockett, 1967).

The recent studies of pelvic venography apparently contradict the findings of the anatomists, who were unable to demonstrate valves in the internal iliac vein or its tributaries in the pelvis in adults.

In order to settle the question the pelvic veins were dissected in 20 subjects at autopsy. The dissections were carried out mainly on elderly subjects, none being younger than 25 years.

DISSECTIONS

The inferior vena cava was opened and the dissection extended downwards into the pelvis, opening the common and internal iliac veins on each side. At this point the visceral contents of the pelvis were removed *en bloc* and the tributaries of each internal iliac vein were dissected as far as the pelvic viscera.

No valves or remnants of valves were seen in the common or internal iliac veins in any subject. Every tributary of the internal iliac vein entered it at an oblique angle, tending to provide it with a valvular type opening. Were this oblique entrance protected by a fold of intima it could act as an osteal valve. In the subjects dissected no osteal valves were seen, but sometimes a thin crescent of intima betrayed the presence of a possible osteal valve which had atrophied. In 1 subject only a bicuspid valve was discovered in the vesical tributary of the right and left internal iliac veins. No valves of any kind, osteal or bicuspid, were seen in the pelvic plexuses. These veins varied in size along their course, in some places being dilated and in others narrowed. Occasionally the intima appeared rippled or scarred, the possible site of previous intimal damage.

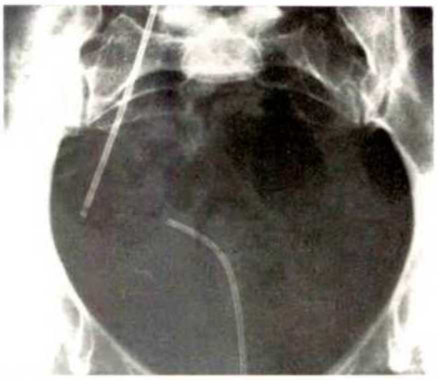

FIG. 5.—Radiograph showing catheters inside the internal iliac vein and the bladder.

It seemed likely that since in adults the pelvic venous plexuses are not protected by valves they might be subject to gross variations of intraluminal pressure.

PHYSIOLOGICAL STRESSES ON THE PELVIC VEINS

Alterations in pressure in the inferior vena cava can be transmitted directly downwards to the pelvic veins. This could not happen in the veins of the legs since the abdominopelvic venous blood-pressure is always shut off from that of the lower extremity by efficient valves (Fenwick, 1885).

Sudden alterations in venous pressure normally and frequently happen in coughing and straining. Franklin (1927) noted this in the efforts of difficult defaecation, micturition, parturition, or violent coughing. Halpern, Selman, Shaftel, Samuels, Shaftel, and Kuhn (1959) recorded the venous pressures in the limbs during the act of straining at defaecation. They observed that with controlled straining efforts the venous pressure in the extremities rose in proportion to the magnitude of the strain. Sharpey-Schafer (1960) has noted pressures reaching 400 mm. Hg in the vena cava of strong males with coughing.

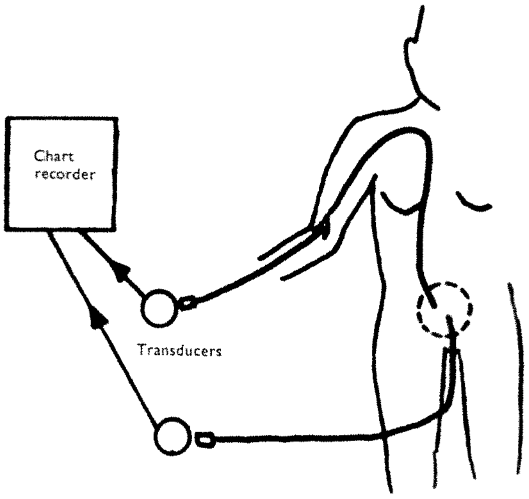

FIG. 6.—Diagram of the experiment recording pressures in the internal iliac vein and the bladder.

It seemed possible that in the pelvic veins without valvular protection, pressure changes on muscular effort might be sudden and dramatic. These veins are thin walled, tortuous, and poorly supported by the surrounding tissues. They are thus ill equipped to withstand alteration in venous pressure except by distension.

EXPERIMENTS ON PELVIC VENOUS PRESSURES

The first experiments to record pelvic venous pressures were carried out by inserting a catheter in the internal iliac vein and connecting it to a transducer. In order to achieve this a No. 7 Goodale-Lubin plastic catheter used during the course of cardiac catheterization was inserted into the right brachial vein under a local anaesthetic. The patient was supine and conscious but under light sedation. The catheter was advanced into the superior vena cava through the right auricle and down the inferior vena cava. Guiding the catheter under radiographic control the tip was seen to reach the internal iliac vein where it was arrested.

A continuous recording was made of the pelvic venous pressure with the patient supine, first at rest and then during the acts of coughing and straining (*Fig.* 3).

From the graph obtained (*Fig.* 4) it was seen:—

1. There is a sudden abrupt rise in the pelvic intravenous pressure during the act of coughing or straining.

2. The height of pressure is proportional to the magnitude of the effort, up to 140 mm per cent Hg being recorded with a violent cough.

3. As soon as the strain is over the pressure returns to normal, but the rate of descent is always slower than the rise, indicating distension of the venous bed.

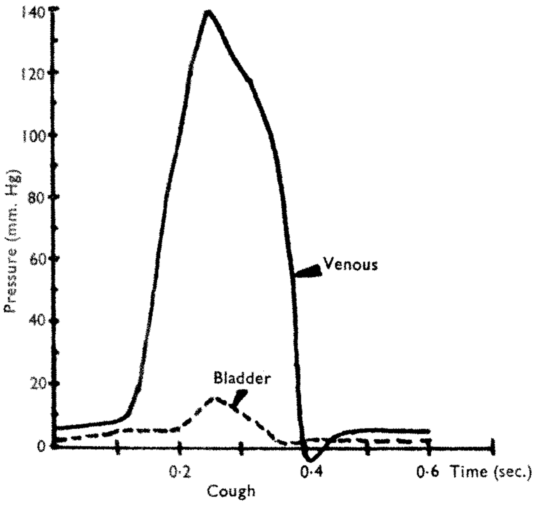

FIG. 7.—Simultaneous pressure recordings from the internal iliac vein and the bladder during coughing.

These recordings of pressure variations inside the pelvic vein give no information of the tension or pressure gradient on the vein wall since intravenous pressures might be protected by equivalent pressures in the pelvis generally. To obtain the pressure gradient on the vein wall, measurements of the pressures inside the vein must be matched with those outside in the pelvic cavity recorded simultaneously. In order to achieve this the second experiments were carried out with a catheter in position in the internal iliac vein as before, but this time with an identical Goodale-Lubin catheter in the bladder (*Fig.* 5). It was assumed that the pressure inside the undistended bladder would be that of the pelvic cavity.

In another set of experiments simultaneous pressure tracings were again taken from the intravenous and bladder catheters with the patients supine, at rest and then during acts of coughing and straining. This time twin transducers were used (*Fig.* 6).

The graph (*Fig.* 7) shows that in every case the pressure in the pelvic veins rose much higher and more quickly than that in the bladder during efforts of coughing and straining.

RESULTS

The experiments appear to prove the following:—

1. There is a large and abrupt rise in pelvic intravenous pressure during normal acts of coughing and straining.

2. There is a pressure difference across the vein wall since the pressure outside does not match the intravenous pressure.

3. The pelvic veins are distended by these pressures.

It is known that violent coughing or forcible straining at defaecation can cause overdistension and even rupture of the inferior haemorrhoidal tributaries of the rectal plexus, resulting in a visible perianal haematoma.

It seems likely that similar events occur in the intrapelvic venous plexuses as a result of sudden muscular strains. The delicate vein wall is overdistended and the intima is damaged, resulting in an intramural thrombus. The thrombus formation is a protective reaction to a wound inflicted upon the vascular wall, and the characteristic of the condition is that the thrombus remains localized and does not increase in size (Franklin, 1927).

Thrombi are frequently formed in the pelvic venous plexuses, and the most likely cause would appear to be venous damage brought on by straining at defaecation, by violent coughing, or at parturition. The thrombus may be large or small but it is symptomless and it would form only in adults since in children the pelvic veins have the protection of osteal valves.

CALCIFICATION

It has never been explained why the thrombi in the pelvic veins become calcified. Clots in this situation apparently remain localized and exhibit dystrophic calcification. This deposition of lime in dead and dying tissue is dependent on local conditions and is not initiated by the state of calcification in the circulating blood (Barr, 1932).

Of the many theories suggesting a cause for dystrophic calcification, that of a locally high concentration of phosphatase (Robinson, 1923) would best explain the formation of phleboliths.

Huggins (1931) found that transplants of bladder mucosa stimulated bone formation in the connective tissues of dogs and rabbits. This did not happen when other tissues were transplanted. He showed also that when cysts were formed by bladder-mucosa transplants the cyst fluid contained much more calcium and phosphorus than did the blood-serum. Huggins explained this by assuming the presence of a phosphatase in higher concentration in the bladder mucosa and perivesical tissues than elsewhere.

If, as Huggins's (1931) experiments appear to show, there is an increased amount of phosphatase in the tissues near the bladder this would account for the surprisingly regular deposition of calcium in the thrombi in the pelvic veins.

Acknowledgements.—I am indebted to Dr. Alan Johnson for allowing me to make recordings during the course of cardiac catheterization, and I am grateful to those patients who gave their informed consent for the additional tests to be carried out. I also wish to thank Mr. Robert David Chase, of the department of Electronics, Southampton Chest Hospital, for his help with the preparation of graphs and diagrams.

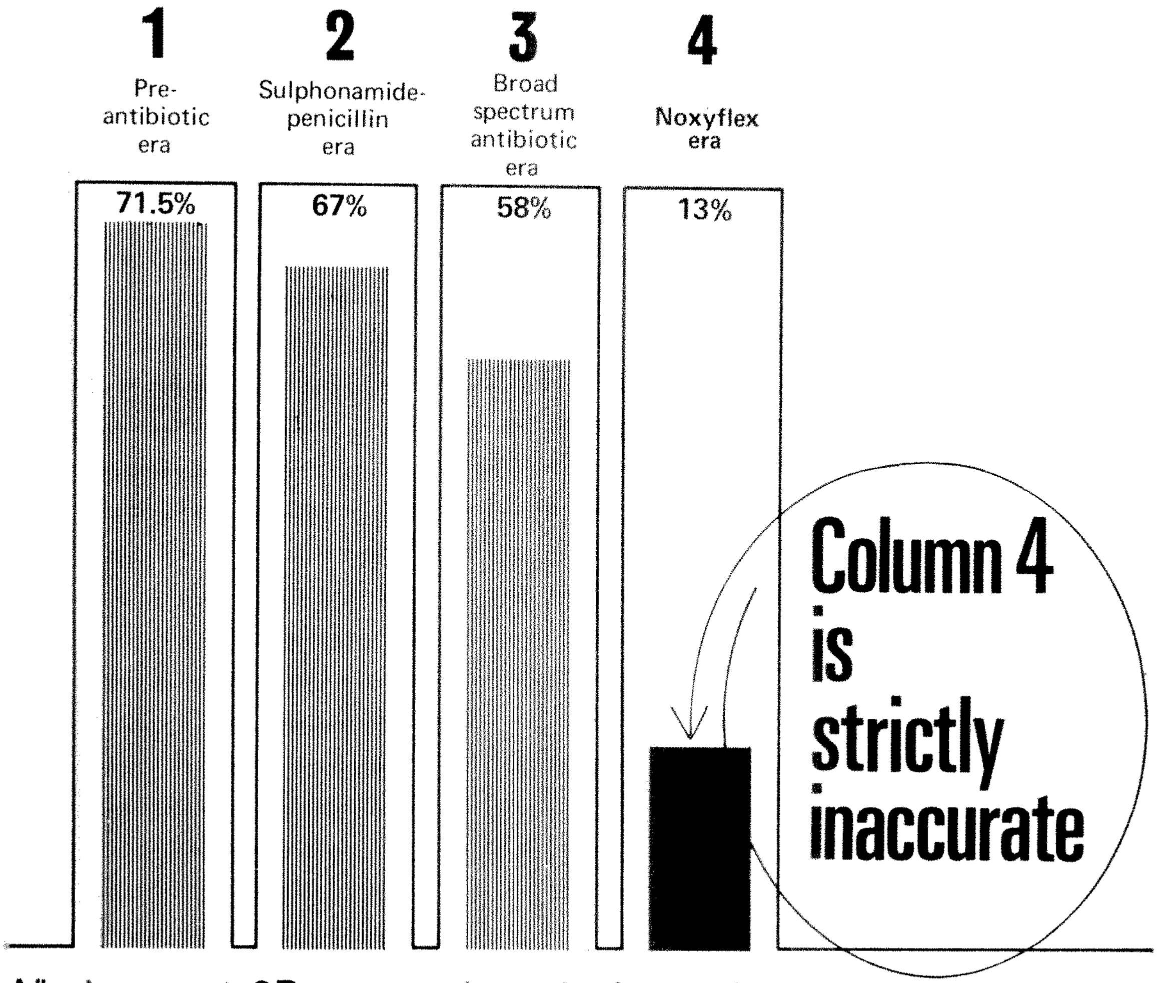
The graph below compares mortality rates due to faecal peritonitis, era by era.
It is not pedantically accurate because its sources differ. But the point is fairly made.



Column 4 is strictly inaccurate

Why inaccurate? Because column 4 refers to 23 cases of faecal eritonitis which were treated successfully with Noxyflex. But the 3 deaths which occurred were due to causes other than peritonitis - s post-mortem revealed. **The mortality rate due to peritonitis an therefore be regarded as zero.**

The whole graph, and the causes of the deaths referred to are the subject of the new Noxyflex folder "Why three deaths?" You will receive at least one copy!

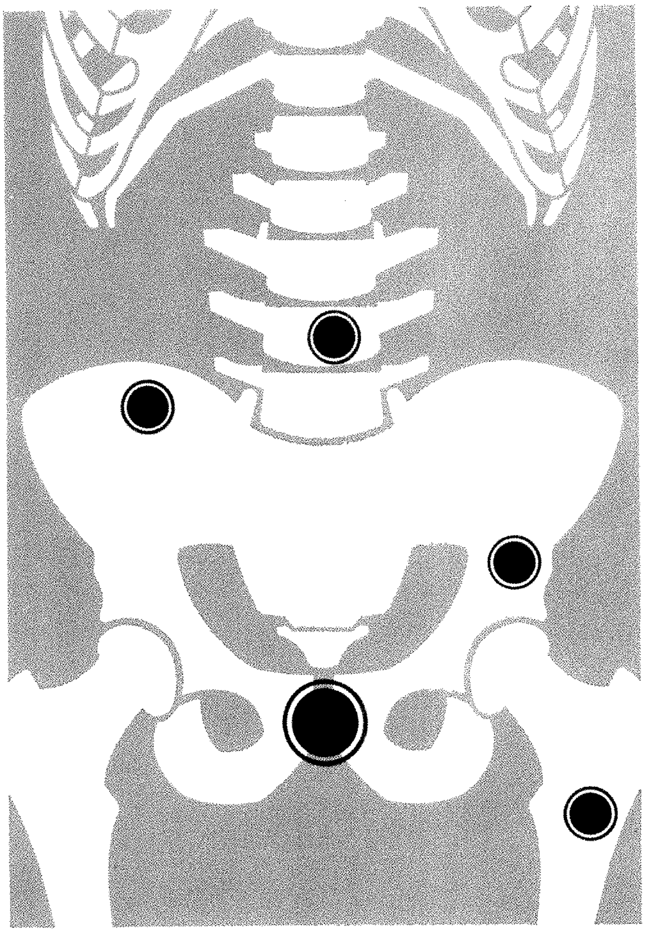
When bacterial contamination f the peritoneum is iagnosed or suspected: Noxyflex

Geistlich Chester

Honvan fosfestrol

Honvan is pharmacologically inert until dephosphorylated. It is selectively activated by tissues rich in acid phosphatase, notably the prostate, where it exerts a local cytotoxic action.

Regression of prostatic tumours and metastases is observed in most patients, including a majority of those unresponsive to standard oestrogen therapy.



Response is rapid. **Honvan** is a practical alternative to surgery in acute urinary retention caused by prostatic carcinoma.

Gastric tolerance of **Honvan** is good and side effects comparatively rare.

Honvan is available for both intravenous and oral administration.

a selective cytotoxic action – in prostatic carcinoma

FEMORO-FEMORAL CROSS-OVER GRAFTS

A REPORT OF 7 CASES

By R. BAKER and E. J. C. PARKER
SURGICAL UNIT, THE LONDON HOSPITAL

SUMMARY

Seven patients who had femoro-femoral by-pass grafts are reported and the results are noted.

The value of the operation in poor-risk patients with unilateral disease and ischaemic rest pain is confirmed. It is suggested that the indications for doing this procedure could be extended.

FEMORO-FEMORAL cross-over grafts using either a Dacron prosthesis or autogenous saphenous vein have been successfully employed in a small number of patients over the past 10 years. They represent a useful palliative procedure in patients with unilateral iliac artery obstruction in whom poor general condition or the presence of local pathology renders major abdominal surgery unduly hazardous. This paper presents 7 patients who had cross-over grafts and suggests that the indications for the procedure might be extended.

TECHNIQUE

Under general anaesthesia both common femoral arteries were exposed and their branches controlled. A pre-clotted 8- or 10-mm. Dacron prosthesis or autogenous saphenous vein was passed subcutaneously above the pubis from one femoral artery to the other, and end-to-side anastomosis was performed using continuous 00000 Dacron. *Fig.* 1 shows a Dacron graft in situ.

RESULTS

The patients selected for the procedure all had ischaemic disease of the legs of a predominantly unilateral distribution. *Fig.* 2 shows the angiograms of *Case* 5, demonstrating a complete block of the left common iliac artery with comparatively little disease on the right side. All the surviving patients were seen for the purpose of this survey and the results are given in *Table I.* A graft was considered successful if it improved the perfusion of the affected limb without prejudicing the circulation in the donor limb. The graft produced a successful result in 5 patients, although in 1 of these (*Case* 3) infection and secondary haemorrhage necessitated its removal 5 months later. In a sixth patient (*Case* 1) the graft failed to maintain an effective circulation and this necessitated the only amputation in the series. It is possible that the insertion of the graft allowed this to be below the knee rather than above the knee. In only 1 patient (*Case* 7) did the graft have an adverse effect on the donor limb. In this man the recipient limb became warm and the rest pain was relieved although no pulses returned. The donor limb, however, developed severe rest pain on the sixth postoperative day which resolved over the succeeding 3 days. When seen in the out-patients' department 6 months postoperatively the recipient limb was symptom-free and had an ankle pressure of 130 mm. Hg with a systolic pressure of 160 mm. Hg, but no pressure could be recorded in the donor limb which claudicated at 10 yards.

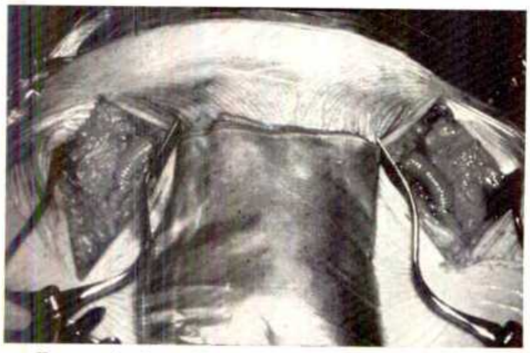

FIG. 1.—An 8-mm. Dacron femoro-femoral graft in situ.

DISCUSSION

History.—Since McCaughan and Khan recorded 2 successful cross-over grafts in 1960 this procedure has been recommended by a number of writers (Vetto, 1962; Papadopoulos, 1966; Warren and Fomon, 1966; Chavez, Hardy, and Tucker, 1967; Parsonnet, Alpert, and Brief, 1970) as a palliative procedure in poor-risk patients with unilateral disease of the lower limb.

The value of the procedure rests in the fact that it is a relatively minor operation which may be completed within an hour, especially if the two anastomoses are performed synchronously.

Indications.—These consist of the systemic conditions of previous cardiac infarction, severe bronchitis and emphysema, old age and debility, and the local problems of previous aorto-iliac surgery and retroperitoneal disease. It is also useful to revascularize the remaining limb of an amputee, provided that the femoral pulse is still present on the side of the amputation (Wertheimer, Sautot, Sisteron, and Descotes, 1963).

The Assessment of Patients.—Patients with arteriosclerosis rarely have unilateral disease, although its disposition is sometimes predominantly unilateral.

The major difficulty when considering a patient for this procedure lies in assessing the state of the circulation in the donor limb. It is of little value to revascularize one limb at the expense of the other, as happened to some extent in the present *Case* 7.

This 'steal' phenomenon cannot occur in health. Parsonnet and others (1970) have shown experimentally that the normal rate of flow through a healthy artery is capable of a tenfold increase; they have also demonstrated that if a recipient limb having the same flow resistance as a donor limb is connected to the donor inflow vessel, then the peripheral resistance presented to that vessel is halved and its flow rate doubled.

Clearly, however, it seems reasonable to accept some degree of proximal iliac disease on the donor side; the difficulty lies in determining how much is acceptable and in assessing the situation in the individual patient. Wertheimer and others (1963) stress the danger if the circulation of the donor limb is suspect, and Foley, Dow, and Fry (1969) report a failure in which the donor limb showed ischaemic changes preoperatively. The present *Case* 7 also demonstrates the dangers of a poor circulation in the donor limb. Preoperatively this man was noted to have no pulses

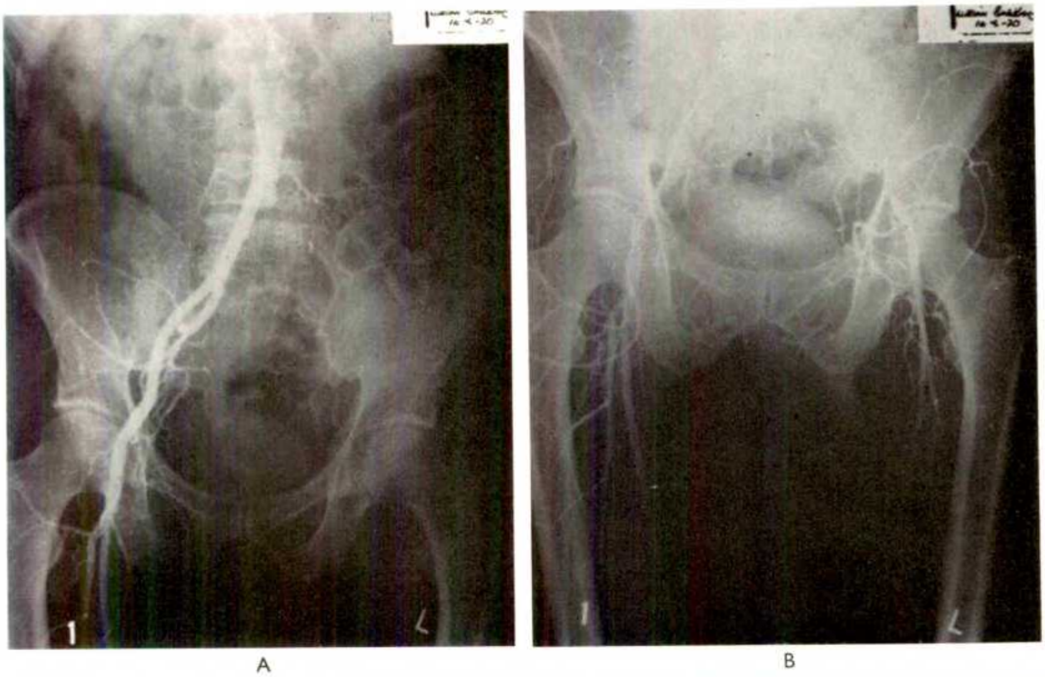

FIG. 2.—*Case* 5. Angiograms showing a complete block of the left iliac artery with retrograde filling of the left common femoral artery and comparatively little disease on the right side.

Table I.—DETAILS AND RESULTS IN

CASE NO. AND SEX	AGE AT OPERATION (years)	INDICATION FOR CROSS-OVER GRAFT RATHER THAN AORTO-ILIAC SURGERY	DISEASE OF RECIPIENT LIMB	DISEASE OF DONOR LIMB	RESULT
1 F.	54	Poor general condition	Total block of common iliac artery	Nil significant	Failure to preserve li knee amputation
2 M.	64	Ischaemic heart disease; cerebral emboli	Total embolic block of common iliac artery	Nil significant	Success
3 F.	57	Previous retroperitoneal disease and deep X-ray therapy to para-aortic nodes (secondary carcinoma of cervix)	Total block of common iliac artery (probably extrinsic)	Nil significant	Success (became infec to secondary haemo
4 F.	57	Ischaemic heart disease and previous aorto-iliac surgery	Stenosis of common iliac artery	Iliac disease and block of superficial femoral artery; 1 pedal pulse present	Success (rest pain relie claudicates at 100 yc later
5 M.	55	Recent cardiac infarction	Total block of common iliac artery	Moderate iliac disease, but all pulses present and full	Success (rest pain relie pressure 95 mm. Hg sides; systemic 145
6 F.	55	Retroperitoneal fibrosis and infection; operative trauma to common iliac artery	Ligation of common iliac artery	Nil significant	Success; walks > 1 mil pressure = systolic af
7 M.	78	Previous aorto-iliac surgery; chronic bronchitis	Occlusion of common iliac and superficial femoral artery	Iliac disease and block of superficial femoral artery; no pulses distal to diminished femoral	Partial success; recipie pressure 130 mm. H ankle pressure 0; sys sure 160/90

in the donor limb distal to a diminished femoral and this probably represented a contra-indication to the procedure. The only other patient in our series with clinically detectable disease in the donor limb was *Case* 4, who had a superficial femoral block although the common femoral pulse was full and one pedal pulse was present. *Case* 5 had radiologically demonstrated donor iliac disease, but all the pulses were full on clinical examination. All the other patients had full donor pulses on clinical examination at rest. Preoperative angiograms were performed in *Cases* 2, 3, 4, and 5. Preoperative ankle pressures measured with the ultrasonic probe (Yao, Hobbes, and Irvine, 1969) were not taken, but we feel that these would have provided valuable information. Postoperative pressures in all the surviving patients are given in *Table I*.

Choice of Material.—Saphenous vein-grafts were used in 2 patients and Dacron in the remaining 5.

Saphenous vein-grafts have the advantage that there is less risk of infection and false-aneurysm formation, and the vein is more tolerant of angulation (Ehrenfeld, Levin, and Wylie, 1968). However, the vein may become involved in the occlusive process, and this may be a cause of late failure. In addition, dissection and removal of the saphenous vein increase the operating time significantly for poor-risk patients.

Dacron has the advantage that it can be put in quickly and in the series reported so far compares very favourably with saphenous vein-grafts, although the danger of infection and secondary haemorrhage is well illustrated by the present *Case* 3.

Factors which may affect Graft Survival.—Turbulence at the site of take-off and run-in of the graft may predispose to thrombosis. Ideally an angle of 15° for take-off gives the best flow pattern (Parsonnet and others, 1970), but this is technically difficult to achieve without the risk of angulation. Blaisdell (Vetto, 1966) has shown experimentally that proximal turbulence does not affect flow through the graft, which is governed more by the peripheral resistance, i.e., the run-off.

The success of these grafts may depend upon the profunda artery, which is usually patent even in severe arterial disease. Jepson, Harris, and Miller (1970) have stressed this and Vetto (1962) reports a case where a popliteal pulse reappeared following direct anastomosis of the graft to the orifice of the profunda artery.

Endarterectomy of the orifice of the profunda artery should be done if it is narrowed (Vetto, 1966). This was not necessary in any of our patients.

Despite the disadvantages of an implant of any foreign material Dacron gives good results (Parsonnet and others (1970) report no late failures in 30 by-passes), possibly because the graft is relatively short and the prosthesis is wide and grafted between major arteries. The most likely causes of early failures are inadequate run-off, as may have happened in *Case* 1, and technical errors.

Late failure may be due to progression of the occlusive process in the donor iliac vessels. The disease may also progress in the distal recipient vessels, progressively reducing run-off. However, it has been suggested that distal disease in the donor limb may even be arrested owing to the altered haemodynamics following grafting in which there is increased linear blood-flow and decreased lateral wall tension (Vetto, 1966).

CONCLUSION

A cross-over femoro-femoral graft is a good treatment for poor-risk patients with rest pain. The risk of 'stealing' from the donor limb seems much less than might be expected, even in the presence of some

FEMORO-FEMORAL CROSS-OVER GRAFT

AFT	DURATION OF PATENCY	EFFECT ON DONOR LIMB	INDICATION FOR OPERATION	COMMENT
cron	Not known	Nil of clinical significance	Rest pain	The cross-over graft may have allowed a below-knee rather than an above-knee amputation
s vein	10 months (patient died)	Nil of clinical significance	Rest pain	Graft patent at death 10 months later of unrelated cause. Incipient gangrene relieved and amputation avoided. Good result
cron	5 months (graft removed—patient died following this)	Nil of clinical significance	Rest pain	Previous para-aortic disease, together with radiotherapy, would have made any transperitoneal surgery difficult. Pedal pulses returned following graft
s vein	Blocked at 3 months	Nil of clinical significance	Rest pain	Femoro-femoral by-pass clearly benefited this patient initially, although the sustained improvement following thrombosis of the graft must have been due to the development of further collateral vessels
acron	Patent at more than 7 months	Nil of clinical significance	Rest pain	A good result. Pre-gangrene in a patient who had had a recent infarct compelled surgical intervention under unfavourable conditions
cron	Patent at more than 23 months	Nil of clinical significance	Operative trauma	The left common iliac artery was injured at operation. Previous retroperitoneal infection and adhesions around the iliac vessels precluded prosthetic graft reconstruction in this area. No other procedure would have been of value
cron	Patent at more than 6 months	Claudication at 12 yd. (minimal previous symptoms)	Rest pain	This patient ultimately derived benefit from the operation in that he was relieved of rest pain. Normally the presence of severe ischaemia in the donor limb is a contra-indication to cross-over grafting (*see* Discussion)

proximal iliac disease (e.g., *Case* 5), and, as mentioned, it may even arrest the progress of distal disease. In view of this we suggest that the indications for this procedure might perhaps be extended, and that it should be considered as an alternative primary procedure in some patients who normally would undergo aorto-iliac surgery.

Acknowledgement.—We would like to thank Mr. D. G. A. Eadie for permission to report cases under his care.

AXILLARY-FEMORAL BY-PASS GRAFTS IN THE TREATMENT OF AORTO-ILIAC OCCLUSIVE DISEASE[*]

BY A. V. POLLOCK
SCARBOROUGH HOSPITAL, YORKSHIRE

SUMMARY

Seventeen patients with aorto-iliac occlusive disease have been treated by inserting a Dacron by-pass prosthesis subcutaneously from the axillary artery to the common femoral artery, with acceptable immediate and poor late results. Only 4 grafts remained patent for more than a year.

MANY patients who present with intermittent claudication and who are found to have an absent common femoral pulse are so little disabled that they are best managed conservatively. They are encouraged to stop smoking, to take regular walking exercise, and to avoid injury to the limb. In this way they can be maintained in reasonable comfort until death as a result of the visceral lesions of the underlying arteriosclerosis.

There are, however, certain patients with an absent common femoral pulse who have incapacitating claudication, rest pain, or gangrene, and for whom the surgeon must advise operation. For the relatively young, fairly fit patient with a short iliac occlusion, laparotomy and thrombo-endarterectomy may be the best treatment. When the occlusion is more extensive it is preferable to insert a synthetic prosthesis from the aorta or an iliac artery to one or both common femoral arteries.

Some patients have an iliac occlusion which is technically operable but their general condition is so poor that a major laparotomy is dangerous. If these patients complain only of claudication, however distressing, one cannot recommend operation. If, on the other hand, the patient presents with rest pain or gangrene, operation becomes mandatory. When gross ischaemia is the problem there is nearly always a coexisting superficial femoral or popliteal artery occlusion in addition to the iliac artery occlusion, but restoration of a full flow through the profunda femoris artery always improves these patients and usually allows healing of the gangrene (Foley and Fry, 1968).

Quite apart from the patient who may die as a result of exposure of his abdominal aorta, there are a few cases in which it may be technically inadvisable or impossible to use this vessel as the starting point of a by-pass graft. The aorta (or a previously inserted prosthesis) may be infected or it may be so heavily calcified as to defy surgery.

In all these conditions it is attractive to consider the possibility of revascularizing the common femoral artery without opening the abdomen.

Blaisdell and Hall (1963) and Louw (1964) published the first accounts of the use of a prosthesis to convey blood through a subcutaneous tunnel from the axillary artery to the common femoral artery.

The present author first employed the method in November, 1969, for a patient whose respiratory function was so poor that laparotomy was inadvisable, and has now used it 17 times. The indications for this relatively minor operation were extended so that even patients who were not at risk from a laparotomy but who required surgery were offered an axillary-femoral by-pass graft as an alternative to the more serious operations.

TECHNIQUE OF OPERATION

The common femoral artery on the ischaemic side is explored through a high oblique incision. Retraction of the lower leaf of this incision allows adequate exposure of the common femoral artery and its bifurcation. Approximately 3 cm. of the lower part of the artery are cleared, encircled with tape, and clamped. The superficial femoral and profunda femoris origins are also controlled and clamped. An incision into the vessel near the bifurcation allows inspection of the profunda origin. If the lumen at this point is compromised by an atheromatous plaque this is dealt with by endarterectomy. The end of a 6-mm. knitted, crimped, Dacron prosthesis 50 cm. long is bevelled and anastomosed to the common femoral artery. The femoral clamps are removed and the prosthesis is filled with blood and clamped near its insertion into the common femoral artery (*Fig.* 1).

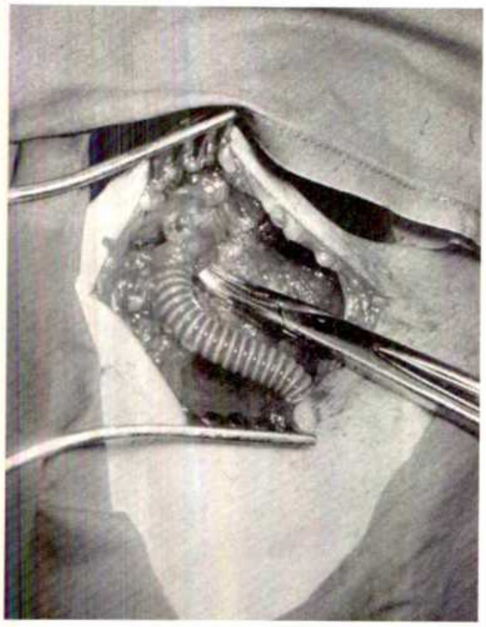

FIG. 2.—The completed anastomosis of the prosthesis to the axillary artery.

The first and second parts of the axillary artery on the same side are exposed by an infraclavicular incision. The fibres of pectoralis major are split or divided in the line of the incision and the clavipectoral fascia and pectoralis minor muscle are divided. The axillary vein is retracted and a 3-cm. length of the first and second parts of the axillary artery is cleared and controlled.

An oesophagoscope is thrust deep to the pectoralis major and through the subcutaneous tissue of the chest and abdomen until it emerges in the groin wound. The end of the prosthesis is grasped by biopsy forceps and drawn up to the axillary artery through the oesophagoscope. It must not be twisted. The oesophagoscope is withdrawn and the graft is trimmed to the correct length and anastomosed to the axillary artery (*Fig.* 2). We find that the resistance to tearing is much less in the axillary artery than in the femoral artery, though the former seldom shows signs of atherosclerosis.

As a rule heparin is not used but low-molecular-weight Dextran is infused during and after the operation. If the prosthesis clots the patient is given heparin and the clot is cleared by means of an embolectomy catheter.

The entire operation can be conducted with light general anaesthesia and spontaneous respiration. The patient soon recovers and shows little tendency to shock. Blood transfusion is seldom necessary.

After operation the graft pulse can usually be felt quite easily but sometimes it can only be detected by a stethoscope or an ultrasonic flow detector.

CASE MATERIAL

Details of the 17 cases which had an axillary-femoral by-pass graft are shown in *Table I*.

In 7 patients an embolectomy catheter had to be employed to clear a blocked prosthesis soon after operation. In each case it was successful and the graft did not immediately occlude again. One of these patients died 3 days after operation of a coronary artery occlusion, and 5 of the remaining 6 grafts occluded again within 6 months. Three patients suffered intimal damage to the axillary artery with resultant thrombosis of the artery beyond the site of the graft. There were no ischaemic manifestations in the hand in any of these patients.

RESULTS

Postoperative complications were few and there were 2 deaths. One patient became temporarily uraemic, 1 groin wound developed a minor *Escherichia coli* infection, and 3 patients had coronary thromboses from which 2 made satisfactory recoveries and 1 died on the third postoperative day. The other death was from coma due to treated cardiac arrest associated with diabetic acidosis 24 hours after operation. All except 3 patients were discharged from hospital in less than 14 days. These 3 patients were delayed up to 20, 32, and 35 days for the treatment of uraemia, pre-existing gangrene of the heel, and coronary thrombosis respectively. All the grafts were patent at the time of discharge.

The follow-up period was from 13 to 32 months.

The symptoms of claudication or rest pain and gangrene were improved in all the cases by operation. In 6 patients the graft clotted within 3 months and 5 of these were re-explored. In 1 case a further profunda endarterectomy has relieved the ischaemia of the lower limb and no further treatment is contemplated. In the others the clot was quite easily removed from the graft and the patients were maintained on heparin for a week but patency was not maintained. The sixth patient is not living in the area and further treatment was undertaken locally.

In addition to these failures 5 grafts clotted within a year without causing disabling ischaemia, and another patient had an amputation because of spread of infection from a gangrenous toe although his by-pass graft was working. A further patient had the opposite leg amputated for gangrene. Four patients have died since discharge from hospital, 3 from cardiac failure and 1 from carcinoma of the bronchus. The first graft was still patent when last seen 22 months later.

DISCUSSION

In order to make a comparison with this series of axillary-femoral grafts the author has reviewed 63 of his own cases of aorto-iliac occlusion in all of which major surgery was indicated.

Nine out of the 63 cases were rejected after cardiac and respiratory assessment. Of the remaining 54 cases, 9 females were operated on, with 1 death from shock and haemorrhage soon after operation, and 45 males with 9 deaths—1 from shock and haemorrhage soon after operation, 5 from coronary thromboses proved at post-mortem examination (on the first, fourth, ninth, twenty-eighth, and eightieth postoperative days respectively); 1 from bilateral bronchopneumonia on the eighth day, 1 from intestinal obstruction on the tenth day, and 1 from hemiplegia on the nineteenth day.

There were 23 patients under 60 years of age, 23 between 60 and 69 years, and 8 over 70 years.

Of the operations carried out, there were 2 aorto-iliac by-pass grafts, 7 iliofemoral by-pass grafts 7 aorto-femoral by-pass grafts, and 38 endarterectomies.

Postoperative complications were uraemia (2) wound infections (5), chest complications (19), fata coronary thrombosis (5), burst abdomen (14), shock and haemorrhage (2), paralytic ileus (5), and 1 each of the following: Gram-negative septicaemia, intestina obstruction, lymph fistula (groin), and hemiplegia There were 4 subsequent amputations, 12 early failures, and 5 late failures.

Twenty-five patients presented with incapacitating claudication and there were 2 deaths. Twenty-nine patients presented with rest pain or gangrene and 8 of these died.

The most important factor which influenced the mortality-rate was the preoperative condition of the heart and lungs. All the patients were assessed as good, moderate, or bad risks on the basis of the history, physical examination, electrocardiograph chest radiograph, and, in some cases, ventilatory function tests (*Table II*).

The 54 patients were divided into two groups There were 44 patients in the good or moderate cardiac and pulmonary group with 1 death, and 10 patients in the poor cardiac or pulmonary group with 9 deaths (*Table III*).

Compared with the rather dismal postoperative picture resulting from major laparotomies in poor-risk

Table II.—BASIS OF PREOPERATIVE CARDIAC AND PULMONARY ASSESSMENT

	ASSESSMENT		
	Good	Moderate	Poor
Cardiac	No history of coronary insufficiency No cardiac failure No atrial fibrillation No E.C.G. changes	One previous cardiac infarct, no residual angina No present treatment for cardiac failure Minor E.C.G. changes	Two or more cardiac infarcts Angina of effort Continuous treatment required for cardiac failure Gross E.C.G. changes
Pulmonary	No chronic cough No dyspnoea	History of recurrent bronchitis Dyspnoea on moderate exertion Ventilatory function more than half predicted normal	Chronic cough Dyspnoea on slight exertion Ventilatory function less than half predicted normal

patients, axillary-femoral by-pass grafts cause few major complications, but the incidence of graft clotting is much higher in the prostheses which are seldom less than 40 cm. long.

Table III.—A COMPARISON OF THE MORTALITY RATES OF AORTO-ILIAC SURGERY AND AXILLARY-FEMORAL BY-PASS GRAFTS

PATIENTS	AORTO-ILIAC SURGERY		AXILLARY-FEMORAL GRAFTS	
	Total No. of Patients	No. of Deaths	Total No. of Patients	No. of Deaths
Good-risk Good or moderate cardiovascular assessment, and good or moderate pulmonary assessment	44	1	7	1
Poor-risk Poor cardiovascular assessment, or poor chest assessment	10	9	10	1

Graziano, Lal, and Dobrin (1970) reported 14 males treated by axillary-femoral by-pass grafts. Of these, 11 had superficial femoral artery occlusions in addition, and there were 3 postoperative deaths. One graft clotted at 3 months and the other results were good in 7 patients, fair in 2, and poor in 1. Mannick and Nabseth (1968) reported 17 poor-risk male patients treated by this operation with 1 postoperative death, 1 primary failure, and 2 secondary failures. Urdaneta, Visudh-Arom, Delaney, and Castenada (1969) reported a patient whose bilateral axillary-femoral by-pass grafts were still patent at 35 months.

This operation offers a simple method of by-passing an aorto-iliac occlusion. It appears to be relatively free from early complications, but the late clotting rate is far too high. It might be thought that an 8- or 10-mm. graft would offer a greater chance of success. The diameter of the common femoral artery is, however, seldom greater than 6 mm. and it is thought that the continued patency of the graft is partly determined by the adequacy of the outflow tract. If the profunda femoris is able to take the full flow of the graft, secondary clotting is less likely.

Various agents have been shown to diminish coagulability, platelet stickiness, or blood viscosity, or to increase fibrinolysis. If a safe and effective drug can be found which will ensure the long-term patency of long prosthetic grafts a major drawback of this operation will have been removed.

In his case Louw (1964) used an autogenous saphenous vein-graft. An adequate length of saphenous vein, however, can be obtained only in two ways: either by removing the vein from the groin to below the knee where its calibre is often disappointingly small or by using the long saphenous veins from both sides and joining them. On the whole, autogenous veins do not recommend themselves for this purpose. However, Stipa (1971) has reported 4 cases treated with saphenous, cephalic, or basilic veins with apparent success.

NEUROLOGICAL COMPLICATIONS OF RUPTURED ABDOMINAL AORTIC ANEURYSM

BY P. M. BOLTON AND L. H. BLUMGART
UNIVERSITY DEPARTMENT OF SURGERY, WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF

SUMMARY

Two cases of neurological complications of abdominal aortic aneurysm are described, with a brief review of the other neurological complications of this condition.

NEUROLOGICAL complications are a not-infrequent manifestation of dissecting aneurysm of the aorta producing either cerebral, spinal, or, rarely, peripheral nerve lesions (Moersch and Sayre, 1950; Condon and Rose, 1969). These complications may also occasionally occur following abdominal (McAfee, 1957) or thoracic (Abrams, 1957) aortography. We report here 2 unusual neurological presentations of ruptured abdominal aortic aneurysm and add a brief review of the literature.

CASE REPORTS

Case 1.—A 63-year-old male presented to the surgical out-patients' department complaining of symptoms suggestive of a urinary-tract infection. Direct questioning revealed that he also suffered from intermittent claudication in the right calf. On examination a large abdominal aortic aneurysm was noted and both the common and external iliac arteries also felt aneurysmal. Femoral and popliteal pulses were palpable on both sides but the posterior tibial and dordalis pedis pulsations were impalpable on the right side.

The patient was admitted for assessment. An ejection systolic murmur was audible over the precordium and there was clinical and radiographic evidence of left ventricular enlargement. Neurological examination revealed no abnormality in the central or peripheral nervous systems. The blood-urea was 35 mg. per 100 ml. A microscopic examination of the urine showed innumerable pus cells with a heavy growth of coliform organisms. Intravenous pyelography showed no renal function on the left side and no definite left renal outline.

An elective operation was planned, but on the night prior to surgery the patient complained of severe lower abdominal pain of sudden onset and within 10 minutes he had developed a complete paraplegia below the level of T.V. 10. His lower limb pulses were unchanged and initially there was no abdominal tenderness or hypotension. However, rupture of the aneurysm was suspected and whilst being transferred for emergency operation he developed a tachycardia and his blood-pressure fell to 70 mm. Hg. At operation a large retroperitoneal haematoma was found and the diagnosis of aneurysmal rupture was confirmed. The aneurysm extended from 1 cm. below the origin of the right renal artery and involved both common iliac arteries. Neither the left renal artery nor the left kidney was seen or felt. After proximal and distal control had been obtained, the aneurysm was incised, the lumber vessels oversewn from within, and a bifurcated Teflon graft was sutured in place. The atherosclerotic internal iliac arteries were ligated without macroscopic effect on the colon. The time of aortic cross-clamping was 2 hours and 40 minutes.

Postoperatively the paraplegia was unchanged. The patient developed acute renal failure and haemodialysis was instituted. The abdomen became distended and bloody diarrhoea ensued, presumably due to ischaemic colitis. On the fifth postoperative day the right lower limb became cold and pulseless. His condition deteriorated progressively and he died on the seventh postoperative day. At post-mortem examination the vascular suture lines were intact. No major left renal artery was identified although there was a small atretic left renal element at the level of the pelvic brim. The right kidney was enlarged and pale. The wall of the colon showed patchy discoloration without blood in the lumen or perforation. Both femoral arteries were atheromatous but no definite premortem thrombosis was noted. The spinal cord was not examined.

Case 2.—A 68-year-old male was admitted following a fall. For a year he was known to have had an aortic aneurysm but he had been advised by his general practitioner to leave well alone. For the fortnight preceding his admission his wife had noticed him dragging his right foot on walking and he himself had noticed weakness in his right big toe. Immediately prior to admission, whilst out walking, he stumbled on his right lower limb and fell directly on to his abdomen. He had immediately developed severe abdominal pain. On admission he was extremely pale and shocked (the peripheral pulses were impalpable and the blood-pressure was unrecordable before resuscitation). A large tender swelling was palpable in the left iliac fossa and a provisional diagnosis of ruptured aortic aneurysm was made. Examination of his right lower limb revealed that it was slightly dusky. There was a foot-drop with no active dorsiflexion at the ankle and loss of extension of the hallux as well as sensory loss on the anterolateral aspect of the leg and on the dorsum of the foot. Passive movements at the ankle-joint were full. He was considered to have a right, lateral, popliteal nerve palsy. After a short period of resuscitation operation was performed. A large aneurysm of the abdominal aorta was found commencing 2 cm. below the origin of the renal arteries and involving both common iliac vessels. The aneurysm had ruptured on its left side. A bifurcated Teflon graft was sutured in place. The duration of aortic cross-clamping was 2 hours and 20 minutes.

Postoperatively the patient's condition improved. However, the right leg still showed the signs of a lateral, popliteal nerve lesion and was now ischaemic. Arteriography via the right femoral artery revealed extensive peripheral vascular disease. The ischaemia progressed and a mid-thigh amputation was performed on the ninth postoperative day with secondary suture of the skin-flaps 8 days later. He recovered well and was discharged 24 days after admission. Three months postoperatively he was walking well with a prosthesis.

DISCUSSION

Although injuries of the spinal cord or the peripheral nerves are unusual complications of abdominal aortic aneurysm, both have been recorded.

The rarity of spinal cord damage following abdominal aortic surgery is surprising as the arteria radicularis magna of Adamkiewicz is said to arise in the lumbar region in 50 per cent of cases (Adams and Van Geertruyden, 1956). This vessel is the largest of the segmental reinforcements of the anterior spinal artery. However, Adams and Van Geertruyden (1956) point out that when the arteria radicularis magna originates in the lumbar region there is also a constant large segmental contribution to the anterior spinal artery from a low thoracic spinal vessel. Presumably paraplegia can only occur if this thoracic vessel is absent or blocked as well as the lumbar arteria radicularis magna. This combination appears to be infrequent since spinal cord damage is a very rare sequel of excision of abdominal aortic aneurysm and, indeed, was not recorded in a review of 14,000 cases (DeBakey, Crawford, Cooley, Morris, Royster, and Abbott, 1964). Eight cases of spinal cord damage have been described (Hara and Lipin, 1960; Mehrez, Nabseth, Hogan, and Peterling, 1962; Coupland and Reeve, 1968; Skillman, Zervas, Weintraub, and Mayman, 1969) and a further 2 cases are mentioned in the correspondence following the communication of Skillman and others (1969). Paraplegia has also been reported in a patient with thoracic aortic aneurysm without rupture where recovery occurred following excision of the sac (Davie, 1963).

A review of the literature has failed to reveal a case where paraplegia developed as the initial sign of rupture of an abdominal aortic aneurysm. It seems likely that the paraplegia in our patient developed as a result of spinal cord ischaemia consequent upon occlusion of a major artery arising from the aneurysm and supplying the cord. This occlusion may have been related to dissection of the vessel wall or to embolism associated with the rupture.

Although interference with the abdominal component of the autonomic nervous system is a well-recognized complication of abdominal aortic surgery (May, De Weese, and Robb, 1969), autonomic lesions have not been commonly recorded in association with rupture of an abdominal aortic aneurysm. Eastcott and Gardner (1969) have, however, reported a case of autosympathectomy following extension or leakage of an aneurysm behind the vena cava.

Peripheral nerve lesions too may complicate abdominal aortic aneurysm, and femoral neuropathy following rupture of an aneurysm into the psoas sheath has been recorded (Razzuk, Linton, and Darling, 1967). Recently Kubacz (1971) has reported a case of combined femoral, obturator, and sciatic palsy in a limb associated with a ruptured abdominal aortic aneurysm. The mechanism of the femoral neuropathy in these cases was considered to be pressure produced as a result of rupture of the aneurysm into the tight fascial compartment of the psoas and iliacus muscles. The cause of the sciatic palsy was attributed to direct pressure of a common liac artery aneurysm impinging on the nerve trunks arising from L.V.4, L.V.5, S.V.1, and S.V.2.

It is interesting to speculate on the mechanism of the lateral popliteal palsy recorded in our second case. It seems unlikely that direct pressure on the nerve trunks in the pelvis can be held responsible since the medial popliteal component of the sciatic nerve was not involved. Ischaemic neuropathy is rare since nerves receive a blood-supply from several anastomosing vessels. However, the sciatic nerve is supplied by a named vessel, the arteria comitans nervi ischiadici. It is conceivable that sudden occlusion of this vessel by embolism or thrombosis might result in ischaemic damage of vulnerable nerve-fibres, particularly in a limb already the site of extensive peripheral vascular disease. Although it is possible that the lateral popliteal palsy in our second case arose from some other cause, its development in a limb with extensive peripheral vascular disease shortly before the rupture of an abdominal aortic aneurysm makes it very likely that the neurological signs were related to the arterial disease. It is tempting to suggest that the aneurysm produced the peripheral nerve lesion either via ischaemia or pressure and that the consequent foot-drop caused the fall which precipitated aneurysmal rupture.

CRYOSURGERY IN THE TREATMENT OF HEAD AND NECK NEOPLASIA

BY H. B. HOLDEN
EAR, NOSE, AND THROAT DEPARTMENT, CHARING CROSS HOSPITAL, LONDON

AND P. McKELVIE
INSTITUTE OF LARYNGOLOGY AND OTOLOGY, LONDON

SUMMARY

The clinical and cellular changes which occur after cryosurgery are described. Its advantages as a form of therapy in the treatment of neoplasia are discussed, particularly with regard to pain relief in palliation. However, the limitations of the effectiveness of cryosurgery in cancer therapy are emphasized.

The results of cryosurgery are presented in 30 cases of recurrent or persistent neoplasia, which followed more formal treatment. In 5 cases healing appeared to be complete; good palliation was achieved in 6 cases, and useful palliation in 13 cases. There was no response in 6 cases.

DURING the past 5 years the results of treatment with cryosurgery have become available, and now the advantages and disadvantages can be more critically assessed. This is especially important with regard to neoplasia in order to avoid misconceptions about a new method of therapy. Although cryotherapy is being used with some success in the treatment of other conditions of the head and neck, such as allergic rhinitis and nasal polypi, pituitary ablation, Menière's disease and epistaxis, the purpose of this communication is to report on its use in the treatment of malignant lesions of the head and neck.

Both normal and neoplastic cells may be irreversibly damaged by extreme cold. The experimental evidence to support and demonstrate this is mainly from the work of Fraser and Gill (1967) in this country, and from that of Gage, Koepf, Wehrle, and Emmings (1965), Hill (1965), von Leden and Rand (1966, 1967), and Gage (1968) in the U.S.A. In using the technique for the destruction of cells the following criteria must be met: rapid repeated freezing and thawing to a temperature of at least −20° C. with sufficient duration of freezing for a good tissue ice-ball to form. The repeated rapid freezing and thawing probably causes rupture of nuclear and cellular membranes. Also contributing to cell death are: (*a*) alterations in the lipoprotein components of the cell membranes; (*b*) *p*H changes; (*c*) toxic concentration of electrolytes; (*d*) polymerization; (*e*) denaturation of proteins (Lovelock, 1957). Added to these, and considered to be of importance, are vascular stasis and microthrombi leading to ischaemia of the tissues.

Although the above hold true for normal tissues and benign tumours there is some doubt about the absolute destructive power on some malignant tumours, as certain paramorphic malignant cells have an inherent resistance to physical trauma (e.g., mesenchymal cells appear to be more resistant to cold than epithelial cells (Fraser and Gill, 1967)).

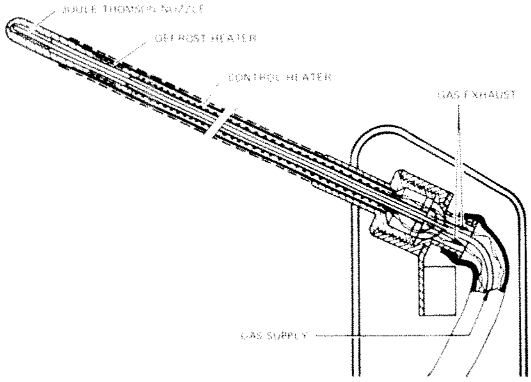

FIG. 1.—Section through a cryoprobe. The gas escaping through the narrow Joule-Thomson nozzle into the outer jacket creates the drop in temperature at the probe tip.

Other limitations of cryotherapy which must be borne in mind are: freezing is not selective—all frozen cells may die, including surrounding normal tissue; the area of destruction does not include adjacent non-frozen lymphatics and therefore treatment is only local and not regional; the vascularity of the area affects the speed and extent of freezing although temporary vasular occlusion, where possible, helps to reduce this.

However, in clinical work definite advantages of cryotherapy are apparent as an adjunct to other methods of treatment, and in certain cases it is the primary treatment of choice. Amongst the advantages of cryosurgical techniques can be listed the following features:—

1. Relative avascularity of the lesion produced with minimal or no bleeding postoperatively. This renders it very suitable for vascular tumours.

2. Cryosurgery evokes minimal tissue responses and only very slight oedema.

3. The destruction can be localized, the subsequent lesion being demarcated with some encapsulation and good healing.

4. Relative anaesthesia and relief of pain owing to the destruction of sensory nerve-endings is a particularly attractive feature when palliating for malignancy or if treating under a local anaesthetic.

5. Resistance of some tissues to freezing, such as bone, means that malignant cells invading bone can be destroyed without losing the bony architecture. Although frozen bone is devitalized malignant cells within it are destroyed.

6. There is some evidence that cryotherapy may render a tissue antigenic; since freezing may modify its antigenic structure slightly it could then behave as a foreign substance, eliciting an auto-antibody (Shulman, Yantorno, and Bronson, 1967). The antibody response appears to reach its maximum in 7–10 days, extending destruction beyond the areas initially frozen.

THE PRESENT INVESTIGATION

Cryotherapy has been used in a series of patient presenting at otorhinolaryngological department with inoperable cancers of the floor of the mouth oral cavity, pharynx (including nasopharynx), neck nasal cavity, and sinuses.

MATERIALS AND METHODS

The equipment consisted of the Amoils Cryo-unit (Amoils, 1968), modified by McKelvie and Shahee (1967), with insulated cryoprobes of varying size from 2 to 11 mm. in diameter, each with a reheatin circuit for rapid thawing and using nitrous oxide a a refrigerant. This gives rapid cooling and deal with a reasonably large volume of tissue. The working 'tip' temperature of −40° C. gives an averag 10-mm. ice-ball with a marginal temperature c −20° C. These temperatures are quite sufficient t produce the required tissue destruction. The fall i temperature is monitored by thermocouple needle around and deep to the lesion.

The majority of cases are treated under gener anaesthesia. The thermocouples are placed i position. The cryoprobe is pressed on to the lesio and freezing is commenced; it is important to plac the probe in the required position before allowing th gas to pass, as firmer adhesion is established and there i more certain rapid freezing of the tissues with les likelihood of insulated pockets. Freezing is continue until a good tissue ice-ball has formed. Ideally, th thermocouple thermometer will give an accurat indication, but this is not essential as one can soo learn to judge clinically when the tissue ice-ba has reached its maximum. The time required varie between 1 and 5 minutes, depending on the tissu vascularity and the size of the lesion. The gas flo is stopped and the reheating circuit rapidly thaws th ice. The probe can be removed in about 20 second and one can observe a crater where the probe wa placed (*Fig.* 1). As thawing continues the tissu swells again to fill the defect. The procedure i repeated in exactly the same site at least two or thre times, and then the adjacent area is treated in similar manner until one has dealt with the whol tumour (Holden, 1969).

Immediately following treatment the gross appear ance of the tissue is virtually unchanged, but durin the next 3 or 4 days necrosis occurs with superfici slough; gradually this separates to reveal clea granulations which slowly heal. If superficial bon has been treated it may become exposed and sequestrum formed, or the bare area becomes covere by granulation tissue and epithelization commenc from the edges. With normal tissues and benig lesions (particularly the vascular variety) it has bee noticed that the necrosis and sloughing are far le than with malignancies, fibrosis being the mai response. This observation supports histologic findings that peripheral fibroblastic activity occu early on the third day whilst organization in th treated area is prominent (Fraser and Gill, 1967). I these cases scarring is minimal.

Thirty cases with malignancy in the head and nec have been treated by cryotherapy, the majority aft

Table I.—DETAILS OF 30 CASES WITH MALIGNANCY IN THE HEAD AND NECK WHO WERE TREATED BY CRYOSURGERY

CASE	AGE AND SEX	TYPE AND SITE OF NEOPLASM	DURATION	OTHER TREATMENT	FOLLOW-UP AFTER CRYOTHERAPY (mth.)	RESULTS
. B.	33 M.	Recurrent transitional-cell papilloma of nasal septum	39 mth.	Wide excision with diathermy. Deep X-ray therapy	17	Some necrosis. Healed satisfactorily
. P.	55 F.	Recurrent carcinoma of maxilla	33 yr.	Maxillectomy in 1933	38	Healed satisfactorily
. W.	56 M.	Extensive carcinoma of pyriform fossa	20 mth.	Deep X-ray therapy and gold seeds to neck secondaries	7	Endoscopic cryo-application. Good pain palliation and swallowing possible until death
R. F.	80 M.	Recurrent carcinoma of tongue	6½ yr.	Deep X-ray therapy. Gold grains locally	6	Healed well. Tongue mobility improved
. B.	15 F.	Recurrent neurofibrosarcoma of pharynx and palate	9 yr.	Deep X-ray therapy and extensive excisions	5	Significant reduction in size. Improvement in voice. 4 applications
W. K.	64 M.	Persistent carcinoma of mandible and tongue	9 mth.	Deep X-ray therapy. Cytotoxic perfusion	2	Pain palliation only. 2 applications. Died
A. J. H.	63 M.	Recurrent carcinoma of floor of mouth	60 mth.	Deep X-ray therapy. Hemimandibulectomy. Cervical block dissection	24	Good remission and healing after first application. Lesser responses on 4 further applications, but pain relieved. Died
. B.	82 M.	Recurrent carcinoma of tongue	38 mth.	Partial glossectomy. Radium implant	15	2 applications. Complete healing
. M.	70 M.	Recurrent carcinoma of soft palate	40 mth.	Deep X-ray therapy	24	1 application. Complete healing
. D.	78 M.	Carcinoma of parotid into overlying skin (with secondaries in sternum)	10 yr.	Deep X-ray therapy to primary. Excision of secondary	13	Good regression of protruding part of tumour. 4 applications
. P.	49 M.	Recurrent carcinoma of larynx around tracheostome	14 mth.	Deep X-ray therapy. Laryngectomy. Cytotoxic drugs	1	Minimal healing only. Patient subsequently died
W. S.	55 M.	Recurrent subglottic carcinoma around tracheostome and in trachea	26 mth.	Laryngectomy. Deep X-ray therapy	5	Fairly good healing and permitted airway to be clear of proliferating tumour. Died of mediastinal extension. 3 applications
. H.	41 F.	Transitional-cell carcinoma of nasal septum	34 mth.	Excision and deep X-ray therapy (refused major surgery). Gold grains to cervical node	22	3 applications. Good local healing, some crusting. No local recurrence yet
. O.	49 M.	Persistent carcinoma of tongue	10 mth.	Radium implant. Hemiglossectomy	1	No palliation. Pain worse. Patient died
R. D.	47 M.	Carcinoma of mandible. Secondaries over buccal mucosa	37 mth.	Hemimandibulectomy. Cervical block dissection. Cytotoxic perfusion. Deep X-ray therapy	4	2 applications. Pain palliation for 3 months. Died
W. R.	62 M.	Recurrent carcinoma of floor of mouth	29 mth.	Deep X-ray therapy. 'Commando' operation. Methotrexate	14	Good pain palliation. Initial healing. 2 applications. Died with chest secondaries
. U.	56 F.	Recurrent carcinoma of palate	27 mth.	Deep X-ray therapy. Refused surgery	4	Some pain palliation only. Ulcer a little cleaner
. W.	61 M.	Recurrent carcinoma of tongue	17 mth.	Radium needles. Deep X-ray therapy	3	Good pain palliation. Ulcer smaller and cleaner. 2 applications
. L.	49 F.	Recurrent carcinoma of nasopharynx	10 yr.	Deep X-ray therapy. Cervical block dissection	32	Good tumour destruction and pain relief on each occasion. Conductive deafness improved
A. P.	68 F.	Carcinoma of left cheek	48 mth.	Surgery and deep X-ray therapy	14	Pain palliation only
. C.	54 M.	Carcinoma of floor of mouth	36 mth.	Laryngectomy and deep X-ray therapy previously. Perfusion of residual ulcer with methotrexate	12	Cryosurgery sole effective pain palliation
. S.	80 F.	Carcinoma of floor of mouth	38 mth.	Deep X-ray therapy	12	Arrest of growth. Partial resolution. Pain palliation

CASE	AGE AND SEX	TYPE AND SITE OF NEOPLASM	DURATION	OTHER TREATMENT	FOLLOW-UP AFTER CRYOTHERAPY (mth.)	RESULTS
A. G.	68 F.	Carcinoma of floor of mouth	18 mth.	Deep X-ray therapy	9	Pain palliation for 3 months on each 3 occasions
A. H.	54 F.	Carcinoma in neck nodes. Ulcerated persistence	36 mth.	Resection and irradiation of laryngeal primary	12	Pain palliation only. Died of pneumon after 3 years. 4 treatments; no riv palliation
S. W.	61 M.	Carcinoma of maxillectomy cavity	14 mth.	Ineffectual cytotoxic perfusion	13	Pain palliation for 1 month. 3 applic tions
H. B.	55 M.	Carcinoma in neck nodes. Shallow ulcer on presentation	38 mth.	Deep X-ray therapy	11	Pain palliated for 1 month
A. H.	66 F.	Carcinoma of floor of mouth	37 mth.	Deep X-ray therapy	12	Relief of pain. Partial temporary resol tion. 3 applications
A. P.	55 M.	Carcinoma of upper jaw	22 mth.	Deep X-ray therapy and maxillectomy. Initial relief from Epodyl infusion	11	Pain palliation brief and poor. 2 applic tions in 2 weeks
S. H.	54 M.	Carcinoma of temporal bone	26 mth.	Deep X-ray therapy	11	Pain palliation brief and poor. Died inanition after 37 months
H. W.	64 M.	Carcinoma of cheek from maxillary cavity	17 mth.	Deep X-ray therapy and resection of maxilla	11	Pain controlled for 17 months. 3 applic tions. Little resolution

other forms of treatment had failed, hence the tumours were either persistent or were recurrences after a period of time. Unless otherwise stated the tumour was treated on one occasion only. *Table I* gives brief details of these cases and summarizes the results. This table can only give a general guide to the results, as the lesions differed greatly in size, time of presentation, and type of previous treatment. However, in 5 cases the healing was apparently complete, with no recurrence at the follow-up time specified. These tended to be small lesions or recurrences which were treated early.

There was good palliation in 6 cases, with relief of pain, some healing, or return of function.

The largest number of cases (13) can be described as having useful palliation, with relief of pain and arrest of growth. Often it was found that pain relief was better than would be achieved by drugs or other means.

In 6 cases there was either minimal or no response.

Secondary bleeding was rare and when it occurred was very minor. Freezing in the vicinity of large vessels did not cause any haemorrhage or other problems. The connective tissue remains intact and the endothelium, which is presumably destroyed, soon regrows from the unaffected part of the vessel.

In the light of these findings and other published results cryotherapy must now be considered seriously as an adjunct in the treatment of neoplasia. In this respect its status is between radiotherapy and diathermy. Even if it is finally accepted only as a tool of palliation there is enough evidence to demonstrate its worth as such, particularly as it gives the patient hope and the knowledge that he is not being neglected. Cryotherapy causes no extra discomfort and as it i almost invariably a safe and simple procedure th patient's stay in hospital can be minimal.

Cryotherapy may become the treatment of choic with recurrences of malignant growths in surgicall inaccessible places, or after radiotherapy, surgery, an cytotoxic measures have failed. These includ uncontrolled tumours of the oral cavity, pharyn nasal cavity, postnasal space, and sinuses which hav resisted surgical, radiotherapeutic, or cytotoxi management. In addition, inoperable tumours i which deep bone pain is a prominent feature ma profitably be palliated by cryotherapy.

Cryosurgical techniques should improve as ne refrigerants and modes of application become available. The suggested immunological aspect will nee elucidation.

Kabikinase®
Streptokinase

Streptokinase
Kabikinase®

Surgical clearance of thromboembolism is often hazardous and troublesome. Clearance with Kabikinase can be a simpler matter, and it often yields superior results: probably because the logic of Kabikinase, highly purified streptokinase, is to potentiate the body's own *natural* ability to dissolve clots.

Kabikinase® (pure streptokinase for intravascular infusion) is manufactured by AB Kabi, Stockholm, Sweden and is available only from:

A handbook of information about thrombolyti therapy with Kabikinase will be sent on request.

VENOUS STASIS AND DEEP-VEIN THROMBOSIS[*]

By A. N. NICOLAIDES,[†] V. V. KAKKAR, E. S. FIELD, and P. FISH

DEPARTMENTS OF SURGERY AND MEDICAL PHYSICS, KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

A venographic technique for studying stasis in the deep veins of the legs of conscious patients is described. A second technique involving the clearance of radioactive material from the veins has been developed for use during operation. The results of the two methods correlate closely.

There is considerable stasis of the blood, particularly in the soleal veins, in conscious patients with the legs horizontal, and it is prolonged considerably during surgery. Using these new techniques the effectiveness of various methods said to prevent stasis has been assessed.

RECENT investigations using the ^{125}I-fibrinogen test have shown that the incidence of deep-vein thrombosis is high, not only in general surgical patients (30 per cent—Flanc, Kakkar, and Clarke, 1968; Negus, Pinto, LeQuesne, Brown, and Chapman, 1968; Kakkar, Nicolaides, Renney, Friend, and Clarke, 1970) but also in gynaecological patients (18 per cent —Friend, 1971), orthopaedic patients (50 per cent—Field, Kakkar, Nicolaides, and Renney, 1971), and urological patients (28 per cent—Nicolaides, Field, Kakkar, Yates-Bell, Taylor, and Clarke, 1972). In practically all instances the thrombosis started in the calf and particularly in the soleal veins (Nicolaides, Kakkar, Field, and Renney, 1971). Studies with the ^{25}I-fibrinogen test have also demonstrated that in urgical patients 50 per cent of the thromboses start during the operation (Flanc and others, 1968) and hat another 30 per cent occur during the subsequent 48 hours (Nicolaides, 1972). The majority of these hrombi remain localized in the calf or lyse spontaneously (Kakkar, Howe, Flanc, and Clarke, 1969); hey are harmless and do not produce emboli. Twenty per cent, however, extend proximally into and above the popliteal vein and are then liable to ragment and give rise to emboli. When thrombosis xtends as far as the pelvic veins the incidence of pulmonary embolism approaches 50 per cent (Kakkar and others, 1969).

The fact that thrombosis starts in the soleal veins at operation or soon afterwards means that the factors esponsible for intravascular coagulation produce heir maximum effect there at these particular times. mmediately after injury the various coagulation actors in an activated form have been shown to be irculating in the blood (Penick, Roberts, and Dejanor, 1965). Thrombosis has been shown to depend on the presence of such activated factors in the presence of stasis (Wessler and Yin, 1968). Thrombosis is not produced by stasis alone or by activated factors alone; it requires a combination of the two (Wessler and Yin, 1968).

It has been demonstrated already that stasis which occurs in the valve pockets and in the muscular veins of the calf in conscious and recumbent patients can be reduced by leg elevation and exercises (McLachlin, McLachlin, Jory, and Rawling, 1960). More recently several attempts have been made to prevent deep-vein thrombosis by preventing stasis in the leg veins. Many trials using the ^{125}I-fibrinogen test to detect the onset of deep-vein thrombosis in patients have been reported, but the results are inconclusive (Flanc, Kakkar, and Clarke, 1969; Browse and Negus, 1970; DeJode, Khurshid, and Walther, 1970; Rosengarten, Laird, Jeyasingh, and Martin, 1970; Hills, Pflug, Jeyasingh, and Calnan, 1971; Rosengarten and Laird, 1971; Sabri, Roberts, and Cotton, 1971).

The main aim of the present study is to determine the degree of stasis in the deep veins of the leg in conscious, recumbent patients and in those undergoing operation, and to assess the effectiveness of various methods believed to prevent stasis.

MATERIALS AND METHODS

The investigation was divided into three parts:—

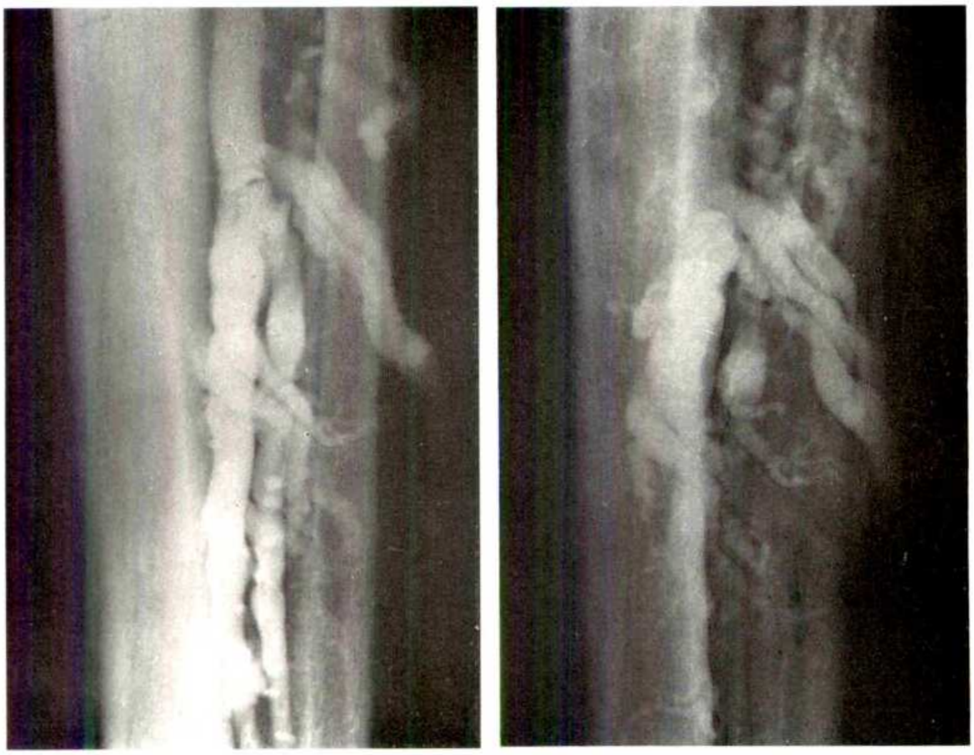
1. Clearance of Radio-opaque Material from the Tibial and Soleal Veins.—A technique of venography has been used which consistently demonstrates the soleal veins in addition to the other deep veins of the leg. This has been described in detail elsewhere (Nicolaides, Kakkar, Field, and Renney, 1971). Briefly, the patient lies horizontal on the X-ray table. A scalp-vein infusion needle is introduced into a vein on the dorsum of the foot. A 5-cm. wide pneumatic cuff is placed at the ankle to prevent any filling of the superficial leg veins and a similar cuff is placed on the mid-thigh to occlude the femoral vein. In all patients the veins of the leg are first partially emptied by a lightly applied elastocrêpe bandage. The ankle cuff is then inflated to 120 mm. Hg and the mid-thigh cuff to 200 mm. Hg. This does not occlude the arterial blood-flow because of the narrowness of the cuff. The injection of 45 per cent sodium diatrizoate (Hypaque) is commenced and the bandage is removed. The contrast medium is seen on the image intensifier to ascend in the tibial veins and to fill the soleal veins in a retrograde fashion. After injecting 30 ml. of 45 per cent sodium diatrizoate and filling the soleal and tibial veins, the injection is stopped, the mid-thigh cuff is removed, and the time taken by the contrast medium to disappear from the soleal and tibial veins is measured using a stopwatch (Nicolaides, Kakkar, and Renney, 1971).

The clearance times of the radio-opaque material from the tibial and soleal veins have been determined in 46 conscious patients who had normal veins.

---

[*] Based on three communications to the Surgical Research Society, in July, 1970, January, 1971, and January, 972, respectively.

[†] Present address: Surgical Unit, St. Mary's Hospital Medical School, London, W.2.



A B

FIG. 1.—A, The soleal and tibial veins filled with contrast medium just before releasing the mid-thigh cuff. B, One minute after the mid-thig cuff has been released. Contrast medium remains in the soleal veins.

Venography was performed in these patients in order to prove or disprove the clinical diagnosis of deep-vein thrombosis. Patients with thrombi, oedema, or cellulitis were excluded. The clearance times have been determined when the leg was horizontal (16 patients), when the leg was horizontal but with a full-length elastic stocking on (5 patients), when the leg was elevated 20° (10 patients), during active plantar flexion of the foot (5 patients), during electric stimulation of the calf muscles (5 patients), and during active plantar flexion of the foot againt resistance (5 patients) (Nicolaides, Kakkar, and Renney, 1971).

2. Simultaneous Clearance of Radio-opaque Material and ^{125}I-fibrinogen from the Soleal and Tibial Veins.—The technique described above has also been used to study the clearance of both radio-opaque material and ^{125}I-fibrinogen from the tibial and soleal veins simultaneously in 8 male volunteers with normal limbs prior to inguinal herniorrhaphy. First, the thyroid gland of these patients was blocked by the oral administration of 100 mg. of sodium iodide 24 hours prior to the test. Then 10 μc. of ^{125}I-fibrinogen mixed with 30 ml. of 45 per cent sodium diatrizoate were injected to fill the tibial and soleal veins. After releasing the mid-thigh cuff, a clearance curve of the ^{125}I-fibrinogen from the calf was obtained while the clearance of the sodium diatrizoate, as seen on the image intensifier, was timed. The clearance curve of the radioactive fibrinogen was obtained by placing the scintillation probe of a Pitman 235 isotope-localization monitor over the medial aspect of the calf at the site of the soleal vein and connecting the monitor to a pen recorder. Th scintillation probe was moved away from the le whenever the image intensifier was switched on t avoid damage to the probe from X-ray radiation. mark on the patient's skin ensured that the prob could be replaced at exactly the same position.

3. Clearance of ^{125}I-fibrinogen from th Soleal and Tibial Veins just before and durin Operation.—Thirty ml. of normal saline containin 10 μc. of ^{125}I-fibrinogen were injected into a vein o the dorsum of the foot and directed into the tibial an soleal veins using the technique described abov The mid-thigh cuff was then released and a clearanc curve obtained. This was performed just before th patients were anaesthetized and 20 minutes after th induction of anaesthesia while the operation was i progress.

The clearance times of ^{125}I-fibrinogen from th soleal and tibial veins have been determined ju before and during operation in 8 patients undergoin simple mastectomy with apparently normal limbs.

RESULTS

1. Clearance of Radio-opaque Material fro the Tibial and Soleal Veins.—This was measure in six groups of patients.

Group I: Leg Horizontal.—In 16 patients the low limb was kept horizontal and when the mid-thigh cu was released the contrast medium cleared first fro the tibial veins while it remained in the soleal vei for much longer (*Fig.* 1). The mean clearance time of contrast medium from the tibial veins was 1·1 minutes and from the soleal veins 9·6 minutes (*Fig.* 2). There was no correlation between the clearance times from the soleal veins and age (*Fig.* 3).

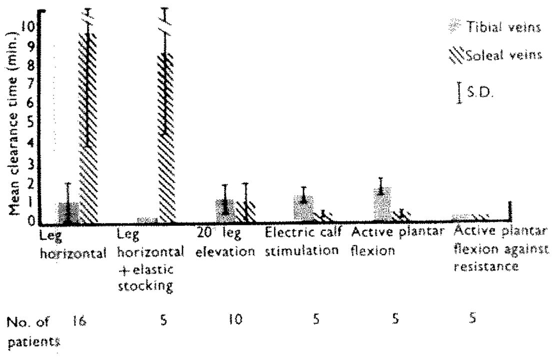


FIG. 2.—Clearance of sodium diatrizoate from the tibial and soleal veins.

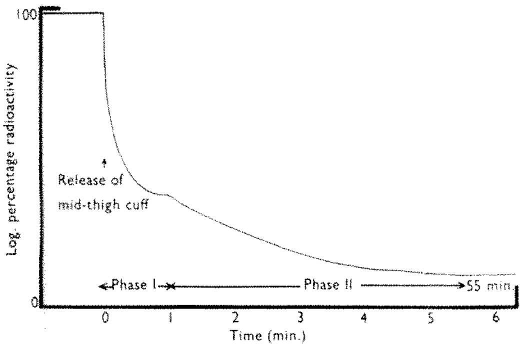

FIG. 4.—Clearance curve of ^{125}I-fibrinogen mixed with 45 per cent sodium diatrizoate from the tibial and soleal veins.

Group II: Leg Horizontal with Full-length Elastic Stocking on.—In 5 patients who were wearing full-length stockings the legs were also kept horizontal. The clearance rate from the soleal veins was similar to that in group I but the tibial veins emptied faster (*Fig.* 2).

Group III: 20° Leg Elevation.—In 10 patients whose legs were elevated 20° the tibial and soleal veins emptied simultaneously. The mean clearance time for the tibial veins was 1 minute and that for the soleal veins 1·1 minutes (*Fig.* 2).

Group IV: Active Plantar Flexion of the Foot.—Five patients were instructed to plantar flex the foot once every 4 seconds after the mid-thigh cuff was released while keeping the leg horizontal. The evidence at present indicates that the most effective rate of plantar flexion alternately to empty and refill the soleal veins is one every 4 seconds (Nicolaides, 1972). The contrast medium cleared from the soleal veins within 0·5 minute and from the tibial veins within 1·4 minutes (*Fig.* 2).

Group V: Electric Calf Stimulation.—In 5 patients the calf muscles were stimulated by electrodes to contract and produce a powerful but tolerable plantar flexion of the foot every 4 seconds after the mid-thigh cuff was removed. This rate is likely to be the most effective in preventing stasis (Nicolaides, 1972). The contrast medium cleared from the soleal veins within 0·2 minute and from the tibial veins within 1·4 minutes (*Fig.* 2).

Group VI: Plantar Flexion of the Foot against Resistance.—Five patients were asked to plantar flex the foot against resistance after the mid-thigh cuff was released. In these patients 2 plantar flexions were enough to empty both the soleal and tibial veins of contrast medium.

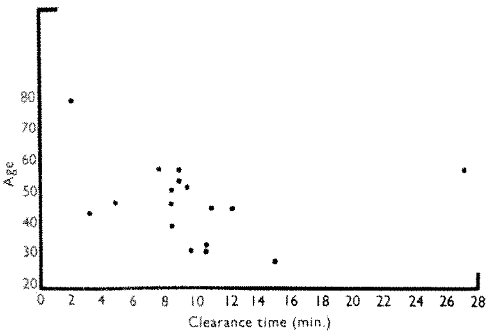

FIG. 3.—Correlation between age and clearance time from the soleal veins; $r = 0·22$, $P > 0·2$.

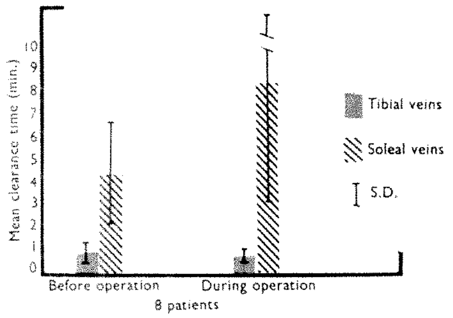

FIG. 5.—Clearance of ^{125}I-fibrinogen from the tibial and soleal veins before and during operation.

2. Simultaneous Clearance of Radio-opaque Material and ^{125}I-fibrinogen from the Tibial and Soleal Veins.—The clearance curves obtained were biphasic in all 8 patients who were investigated (*Fig.* 4). By intermittently screening and observing the clearance of sodium diatrizoate on the image intensifier it was noted that the clearance of the contrast medium from the tibial veins coincided with the end of phase I and from the soleal veins with the end of phase II (*Fig.* 4).

The mean clearance times obtained by the isotopic and radiographic method were in agreement (*Table I*). The final end-point of the isotopic method was defined as the point on the clearance curve after which the fall in radioactivity was less than 2 per cent of the initial count per minute. The final level of radioactivity was the same in both legs.

3. Clearance of ^{125}I-fibrinogen before and during Operation.—The mean clearance times of ^{125}I-fibrinogen from the tibial and soleal veins before and during operation are shown in *Table II* and *Fig.* 5. The mean clearance time of the ^{125}I-fibrinogen from the tibial veins was essentially the same before and during operation, but the mean clearance time from the soleal veins was twice as long during operation ($P < 0{\cdot}05$). In 1 patient (patient 6, *Table II*) the clearance of ^{125}I-fibrinogen from the soleal veins during operation was as long as 20 minutes.

Table I.—SIMULTANEOUS CLEARANCE OF HYPAQUE AND ^{125}I-FIBRINOGEN IN 8 PATIENTS (8 LIMBS)

PATIENT	CLEARANCE TIME OF HYPAQUE (min.)		CLEARANCE TIME OF ^{125}I-FIBRINOGEN (min.)

DISCUSSION

The present study supports the findings that deep-vein thrombosis usually commences in the soleal veins (Nicolaides, Kakkar, Field, and Renney, 1971) where there is undoubtedly the maximum degree of stasis. This is particularly so during operation and may well account for the fact that about 50 per cent of thromboses start at this time (Flanc and others, 1968) in the soleal veins (Nicolaides, Kakkar, Field, and Renney, 1971) as opposed to the tibial veins. However, it was interesting to find that there did not seem to be an increasing degree of stasis with age. This would suggest that the higher incidence of deep-vein thrombosis in the elderly may be related to factors other than stasis.

As regards the effectiveness of various methods of preventing stasis, the findings in conscious patients were interesting. Elastic stockings had a minimal effect on hastening the clearance of contrast medium from the tibial veins and this may well explain the findings that they do not prevent deep-vein thrombosis (Rosengarten and others, 1970). *Fig.* 2 demonstrates the efficacy of various other methods of preventing stasis, particularly in the soleal veins of conscious patients. Of the methods used, active plantar flexion against resistance was the most effective. Electrica stimulation of the calf and active plantar flexio were about equally effective; leg elevation to 20 was almost as effective. These findings provide guide to the value of physical methods employed b physiotherapists before and after operation to preven stasis in the deep veins of the leg.

It is particularly important to measure stasis durin operation since 50 per cent of thromboses occur a this time (Flanc and others, 1968). Radiographi techniques are inconvenient to use during operation A new technique involving the clearance of radioactive material from the deep veins of the leg has bee developed and found to be applicable withou difficulty during operation. The outstanding featur was that the duration of stasis in the soleal vein during operation was prolonged by a factor of abou 2 as compared with conscious patients. Investigations are now in progress to measure the effectivenes of various methods of preventing stasis during operation. It is not possible to give details of the results ye but there is good evidence that there are critica limits within which the stimuli are most effective i preventing stasis. It has become clear that wit electrical stimulation of calf muscles the mos important rate of stimulation alternately to empty an refill the soleal veins effectively is once every 4– seconds (Nicolaides, Kakkar, and Renney, 1971) With greater insight into the effects of these method of prophylaxis it is hoped that it will be possible t make them more effective.

ANATOMY OF THE EXTERNAL ANAL SPHINCTER

BY CHANGYUL OH AND ALLAN E. KARK
DEPARTMENT OF SURGERY, THE MOUNT SINAI SCHOOL OF MEDICINE OF THE CITY UNIVERSITY OF NEW YORK

SUMMARY

1. The anatomy of the external anal sphincter has been studied in 48 adult cadaveric and surgical specimens by anatomical dissection and histological sections in three-dimensional planes.

2. The bilaminar and trilaminar concepts of external anal sphincteric anatomy are reviewed.

3. The significant anatomical differences in the anterior portion of the external sphincter compared with the lateral and posterior portion are emphasized.

4. The different configuration of the anterior part of the external sphincter in men and women is described.

5. A new terminology is proposed, 'superficial compartment' (subcutaneous and superficial) and 'deep compartment' (deep and puborectalis), on the basis of the close anatomical relationship between each of these two pairs of muscles.

THE external sphincter is made up of a group of muscles surrounding the anal canal and is continuous above with the fibres of the puborectalis. The descriptive subdivision of the external sphincter into three separate parts, i.e., subcutaneous, superficial, and deep, was first made by Santorini (1715), and later by von Holl (1897) and Thompson (1899). This trilaminar arrangement has been widely supported (Milligan and Morgan, 1934; Levy, 1936; Eaton, 1942; Wilde, 1948; Uhlenhuth, 1953; Gorsch, 1955, 1962; Morgan and Thompson, 1956; Stelzner, 1960; Stonesifer, Murphy, and Lombardo, 1960; Wilson, 1967. It has been adopted in texts by Gabriel (1945), Grant (1952), Last (1954), Buie (1960), Bacon and Recio (1962), and in *Gray's Anatomy* (1966).

However, other investigators have failed to distinguish three parts of the external sphincter and divide it into two parts—subcutaneous (or superficial) and deep (Courtney, 1950; Goligher, Leacock, and Brossy, 1955; Fowler, 1957; Walls, 1963; Goligher, 1967; Lawson, 1969). All observers agree that the subcutaneous portion is traversed by the terminal strands of the conjoined longitudinal coat, and that the deep fibres of the external sphincter blend with the puborectal muscle.

The external sphincter is usually described as a structure which encircles the anal canal uniformly in a laminated fashion. There have been few reports of differences between the anterior and the other parts of the sphincter and of variations between the male and female. The purpose of the present report is to record a detailed descriptive anatomy of the external sphincter with particular emphasis on the anterior portion and its composition in the male and female.

MATERIALS AND METHODS

Forty-eight adult specimens were studied—21 female and 27 male. The material consisted of 8 cadaveric kidney donors, 5 abdominoperineal resections, and the rest from necropsy specimens of patients dying of conditions unrelated to the anorectum. Anatomical dissection was performed in the various planes, and the difficult and complex areas such as the transverse perinei and the perineal body were studied by an under-water technique with the aid of a loop optic magnifier (Last, 1971). Histological sections were cut in the sagittal, coronal, and horizontal (cross) planes and stained with haematoxylin and eosin, Masson's stain, and Verhoeff's stain.

FINDINGS AND DISCUSSION

The anatomy of the trilaminar arrangement of the external sphincter described by most writers can be summarized as follows.

The *subcutaneous* part situated in the perineal space inferolateral to the internal sphincter is an annular muscle which is split by half a dozen or more of the conjoined longitudinal strands. A few fibres extend anteroposteriorly and are continuous with fibres of the superficial portion of the sphincter, with or without decussation. The *superficial* portion is an elliptical band of fibres lying slightly above and lateral to the subcutaneous sphincter and separated from the subcutaneous sphincter by the most superolateral fibres of the conjoined longitudinal coat. It consists mainly of anteroposterior fibres passing from the central tendinous point of the perineum to the anococcygeal raphe which is attached to the dorsal aspect of the coccyx. The anterior fibres decussate with few, if any, circular fibres while the posterior fibres are mainly circular with posterior extensions and some degree of decussation. The *deep* portion of the sphincter, for the most part an annular muscle, blends with the lowest fibres of the puborectalis. A posterior attachment is usually missing and only a few of its fibres extend to the anococcygeal raphe. Between the upper portion of the raphe of the levator ('coccygeal muscular raphe'; Courtney, 1949) and the lower part of the anococcygeal raphe formed by the subcutaneous, superficial, and deep sphincter there lies a space behind the anal canal filled with fibrofatty tissue—the 'sub-' or 'retro-sphincteric space' of Courtney (1949). Anteriorly, some of the fibres may decussate and extend to the transverse perineal muscle, and most of the lower fibres are circular (*Fig.* 1 A).

A somewhat different arrangement has been described by Courtney (1950); the sphincter is composed of two parts—subcutaneous and deep, the deep sphincter including the superficial and deep sphincters and the puborectalis. Goligher and others (1955) also failed to demonstrate three parts of the external sphincter and described the external sphincter as one continuous sheet which is fused with the puborectalis at its upper end. However, both Courtney and Goligher and others (1955) agree that the subcutaneous portion of the sphincter is distinct from the rest of the sphincter in that it is traversed by strands of the conjoined longitudinal fibres (*Fig.* 1 A).

The continuing dispute over the subdivisions of the external sphincter is based partly on disagreement over the arrangement of the fibres of the conjoined longitudinal muscle which bind together the external sphincter muscle; individual variation is not infrequent, and the complexity of the sphincteric musculature and adjacent tissue makes it mandator to dissect in a three-dimensional plane.

Present Study.—Because of its complexity we hav found that it is essential to study each aspect (posterior lateral, and anterior) by anatomical dissection (wit or without a loop magnifier) and by serial histologica sections in a three-dimensional plane.

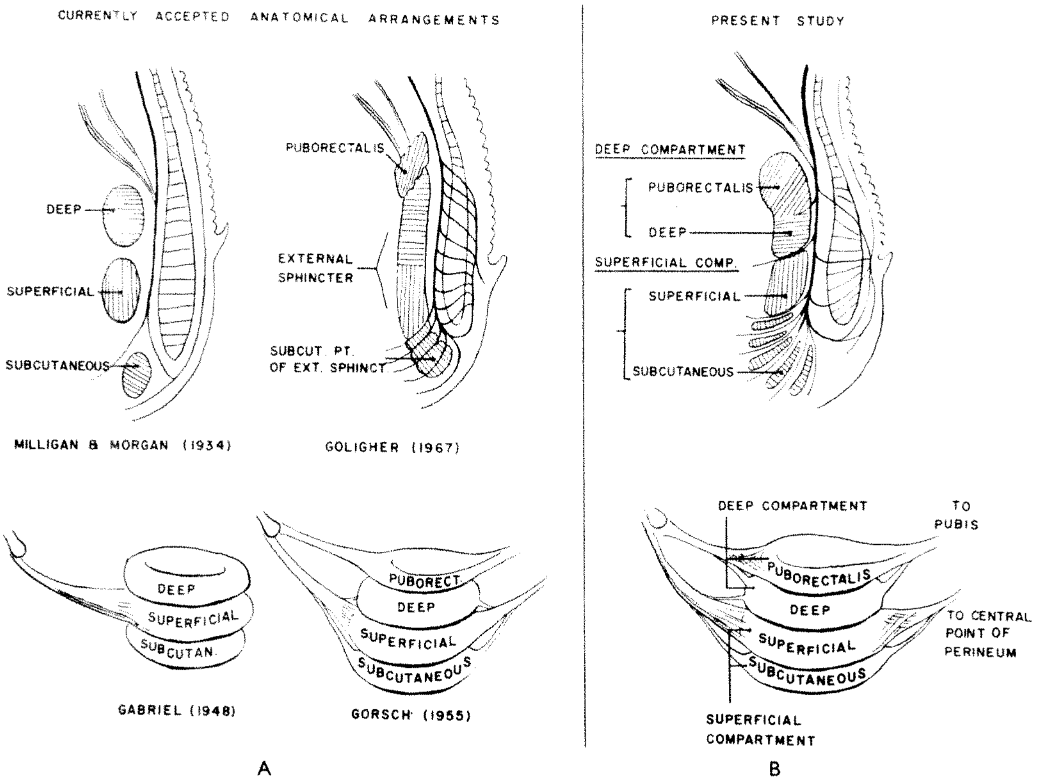

FIG. 1.—Diagram of the external anal sphincter comparing the current views (A) and the present authors' findings (B). A, Coronal sections of Milligan and Morgan (1934) and of Goligher (1967) present different views of the sphincteric arrangement—trilaminar and bilaminar patterns. The lateral views show the anteroposterior attachment of the external sphincter. Gabriel's (1948) view of the posterior attachment of the superficial sphincter differs from Gorsch's (1955) finding that all the components of the external sphincter attach anteroposteriorly. B, The deep compartment (puborectal muscle and deep sphincter) and the superficial compartment (superficial and subcutaneous sphincter) based on histological sections, and the pattern of anteroposterior attachment shown by gross dissection.

The configuration of the external sphincter show that there is a distinct difference in arrangement i the anterior aspect compared with the lateral an posterior aspects. These latter aspects also diffe in some degree from each other. Each of thes aspects will be discussed separately.

1. The structure of the posterior and latera aspects of the external sphincter conforms to th pattern described by others. However, there ar differences which need stressing.

The *lateral* portion of the external sphincte presents, on the one hand, a distinct subcutaneou component which is traversed by conjoined longitudinal fibres and, on the other hand, a deep externa sphincter which closely blends with the puborectalis Between these two muscle groups there is a stron and wide muscle sheath (superficial sphincter) close t the subcutaneous sphincter although not alway clearly distinguishable as such. This arrangement o the sphincter laterally can be clarified by histologica section rather than by anatomical dissection (*Fig.* 2 B)

Posteriorly, the subcutaneous sphincter is similarly easily recognizable with its traversing fibres of conjoined longitudinal muscle. However, the superficial and deep components are differently arranged. The superficial sphincter has the striking feature of a strong, tough, and triangular posterior extension to the back of the coccyx with some contribution by the subcutaneous sphincter. The deep sphincter, on the other hand, sends some fibres upwards and posteriorly which intermingle with the posterior

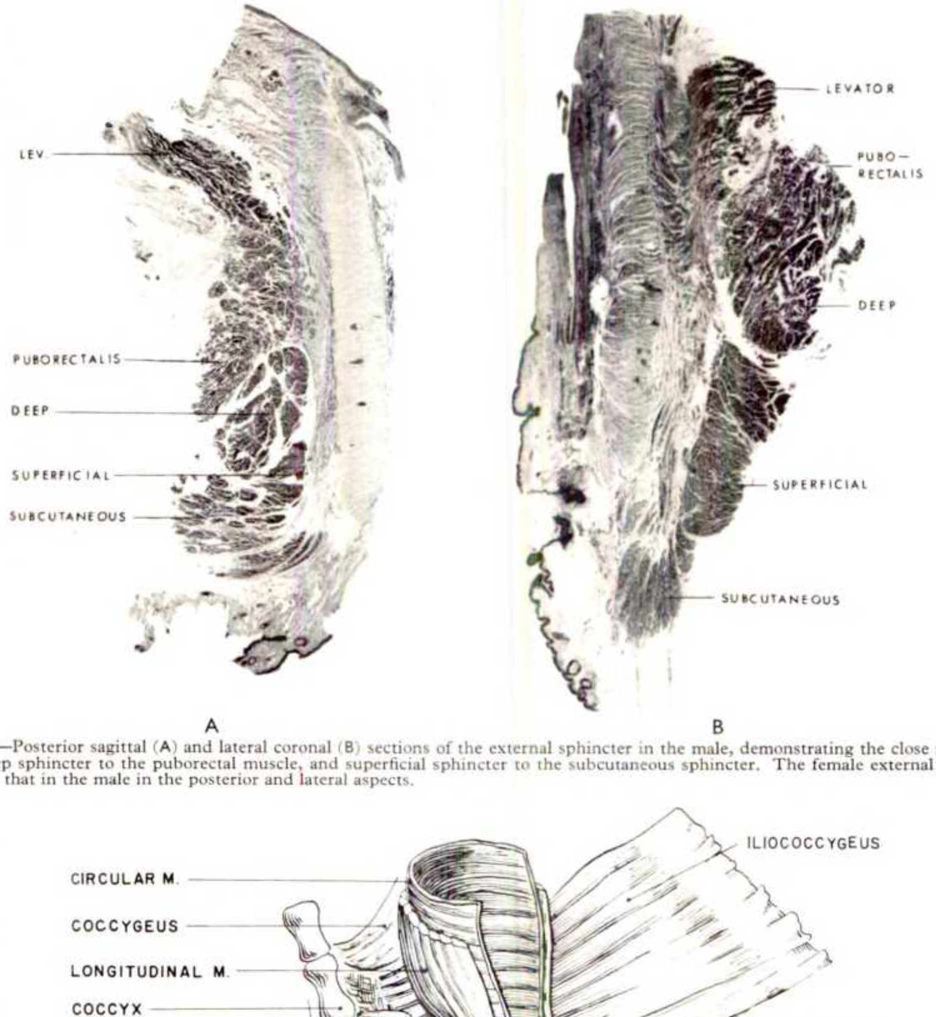

FIG. 2.—Posterior sagittal (A) and lateral coronal (B) sections of the external sphincter in the male, demonstrating the close relationship of the deep sphincter to the puborectal muscle, and superficial sphincter to the subcutaneous sphincter. The female external sphincter is similar to that in the male in the posterior and lateral aspects.

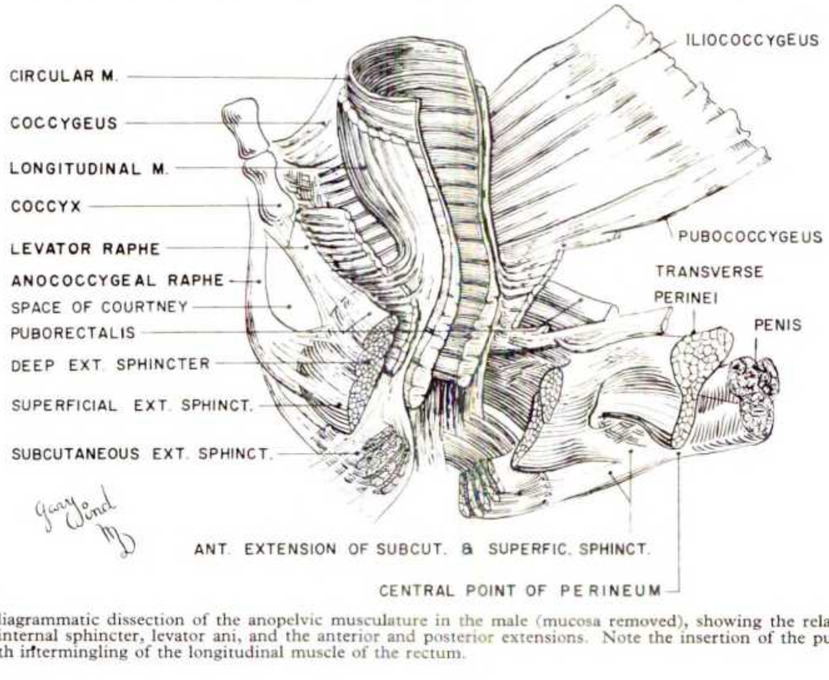

FIG. 3.—Semidiagrammatic dissection of the anopelvic musculature in the male (mucosa removed), showing the relationship between the external and internal sphincter, levator ani, and the anterior and posterior extensions. Note the insertion of the pubococcygeus into the rectal wall with intermingling of the longitudinal muscle of the rectum.

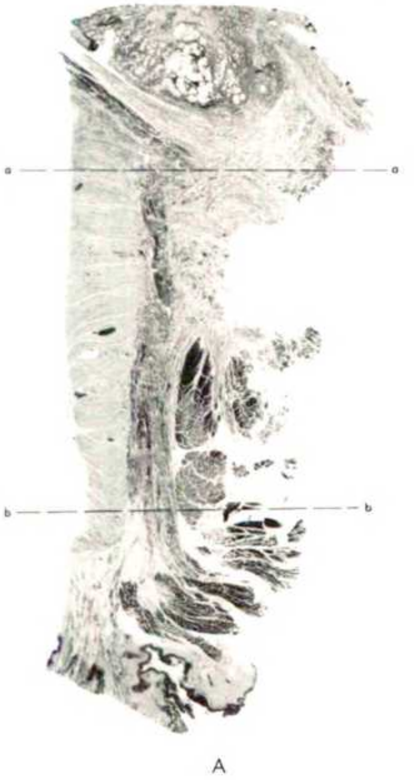

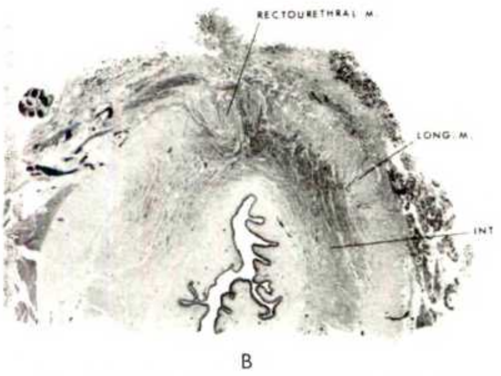

FIG. 4.—A, Anterior parasagittal section of the sphincter in the male, showing the internal sphincteric fibres projecting into the perineal body (inferior recto-urethral muscle). The conjoined longitudinal fibres envelop and bisect the deep part of the sphincter. B, Cross-section at the level of a—a in A, showing the insertion of the internal sphincter into the recto-urethral muscle.

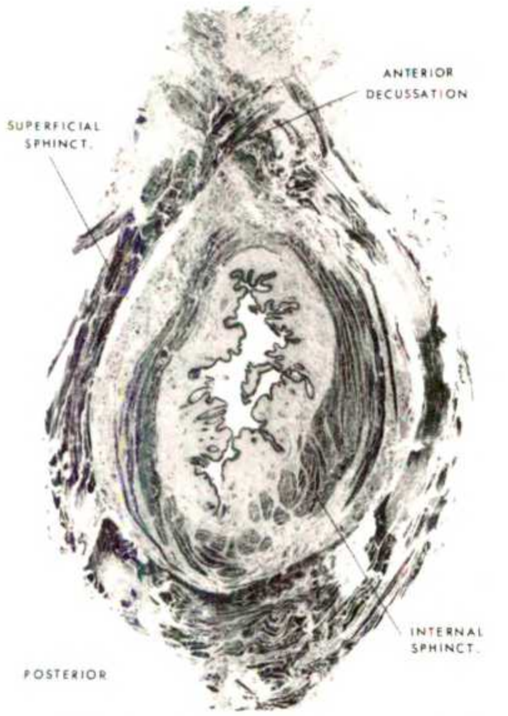

FIG. 5.—Cross-section of the superficial part of the anal sphincter in the male (at the level of b—b in *Fig.* 4 A), demonstrating the anterior decussation and its insertion into the bulbocavernosus and the central point of the perineum. No circular fibres can be seen anteriorly in the male.

puborectalis, and which then attach to the tip of the coccyx. A few fibres of the deep sphincter extend to the anococcygeal raphe. In other words, posteriorly the laminar pattern of the external sphincter can be identified by its manner of posterior extension but it is difficult to separate clearly the laminar structure by histological section (*Figs.* 2 A, 3).

Thus, a constant pattern is noted as follows:—

a. There is a close relationship between the deep sphincter and the puborectalis laterally (seen best on histological section; *Fig.* 2 B) and posteriorly (shown by their gross posterior extension to the tip of the coccyx; *Fig.* 3).

b. The subcutaneous and superficial portions of the external sphincter are also closely related by the common pattern of posterior extension to the anococcygeal raphe which inserts to the back of the coccyx, although laterally their proximity is subject to a wider variation than that of the deep sphincter and the puborectalis (*Fig.* 3).

Because there is a bilaminar arrangement in one plane whereas there is a trilaminar one in the other plane we feel that it is more accurate to describe the external anal sphincter as being composed of a *deep compartment* (deep sphincter and puborectalis) and a *superficial compartment* (subcutaneous and superficial sphincter) (*Fig.* 1 B).

2. Little attention has been paid to the marked dissimilarity of the anterior part of the external sphincter in men and women. Gorsch (1955) has noted the anterior part of the subcutaneous sphincter in women forming a prominent annular muscle lying directly below the perineal skin and bridging the interval between the diverging limbs of the superficial muscle; these limbs extend laterally, reach the pubic ramus, and fuse insensibly into the fibres of the lateral bulbocavernosus (vaginal sphincter); a few of the fibres may insert into the central tendinous point of the perineum. He did not mention any difference in the deep part of the male and female sphincters. However, on his schematic drawing of the sagittal section three distinct laminated muscles were illustrated. Fowler (1957) observed that some of the deep fibres in the female pass lateral to the perineal body to blend with the vaginal sphincter.

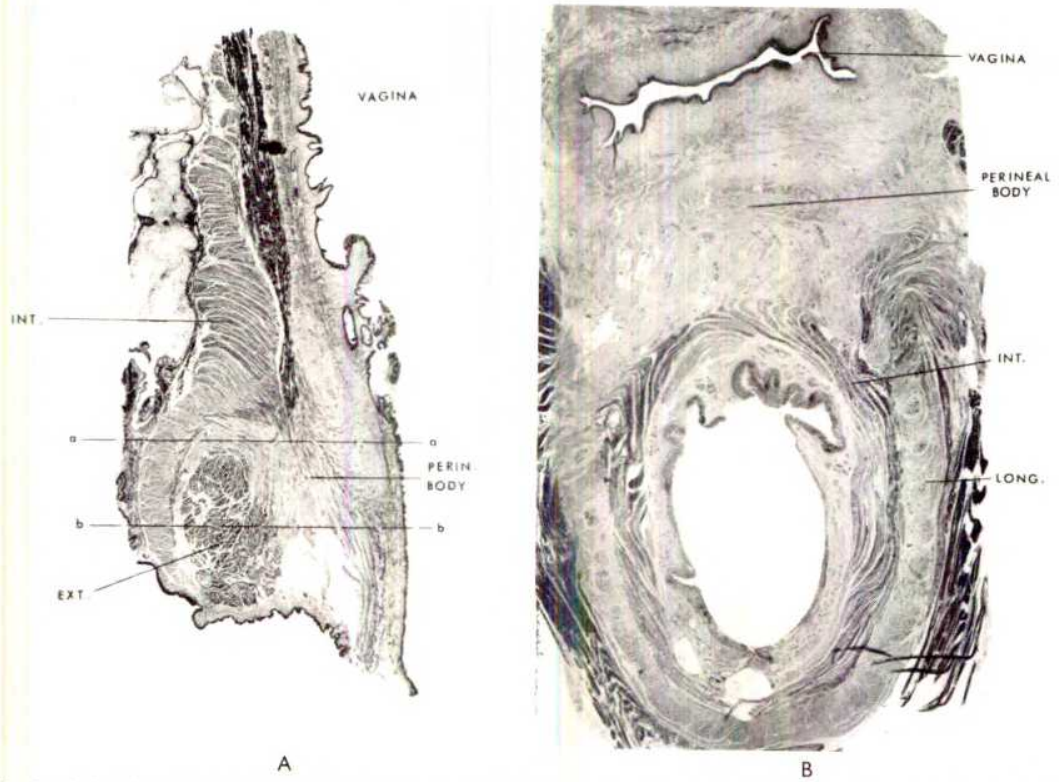

FIG. 6.—A, Anterior sagittal section of the sphincter in the female, demonstrating fibres from the internal sphincter mingling with longitudinal fibres. These fibres encapsulate the anterior muscle-bundle as a single mass. B, Cross-section of the sphincter in the female at the level of a—a in *Fig.* 4 A, showing the relationship of the projecting fibres of the internal sphincter, the longitudinal muscle, and the perineal body.

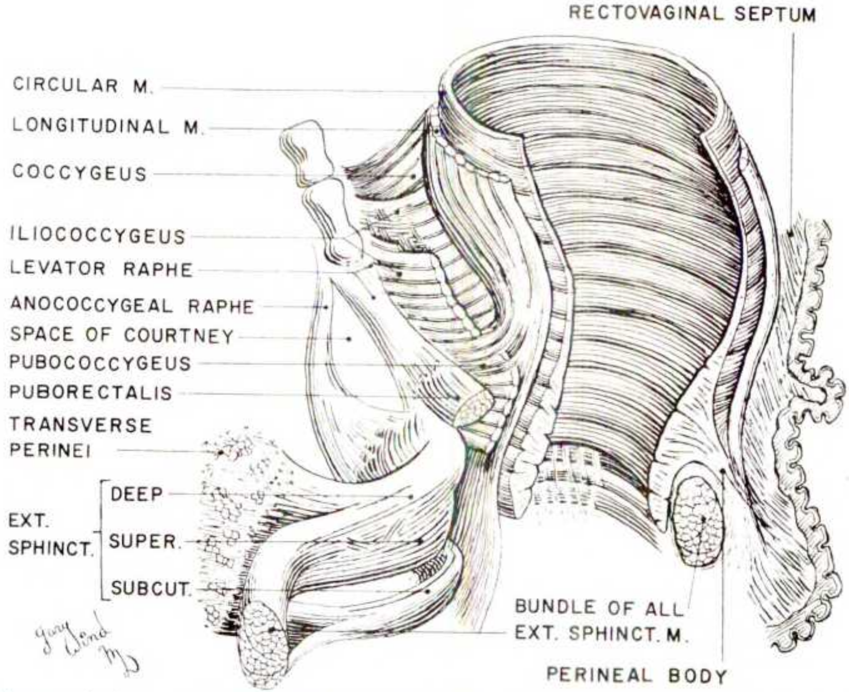

FIG. 7.—Semidigarammatic dissection of the anorectal region in the female with the external sphincter cut in the anterior mid-sagittal plane and reflected posteriorly (mucosa removed). The origin of the anterior muscle-bundle is clarified and the remaining anterolateral portions of the external sphincters are interdigitated into the transverse perinei.

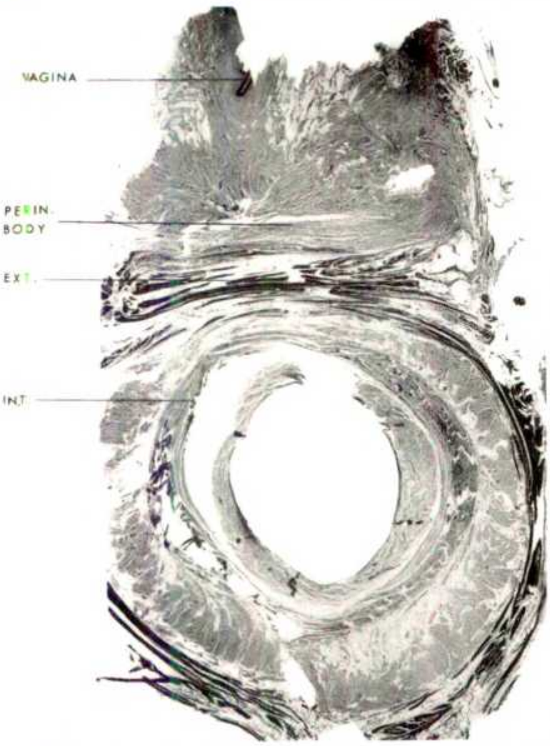

FIG. 8.—Cross-section of the sphincter in the female at the level of b—b in *Fig.* 4 A. A few decussating fibres are seen anteriorly; marked diminution of longitudinal muscle can be seen anteriorly.

The present study demonstrates that on sagittal section in the anterior midline there are specific features in each sex which differ also from those of the lateral or posterior part.

a. In the male the laminar pattern is well preserved. The lower half of the external sphincter muscles is traversed anteriorly by conjoined longitudinal fibres, and the upper half of the sphincter is enveloped (or occasionally bisected) by the conjoined longitudinal fibres in the longitudinal axis. The conjoined longitudinal fibres join with fibres of the internal sphincter which project anteriorly at the level of the perineal body (*Figs.* 4, 5). All the components of the external sphincter have anterior extensions with predominantly circular fibres, except for the superficial sphincter which has exclusively decussating fibres to the central point of the perineum, the superficial transverse perineal muscle, and the bulbocavernosus (*Fig.* 5).

The perineal body to which the external sphincter may relate is a complex structure in the male. The perineal body receives contributions from the longitudinal muscle, Denonvilliers' fascia, the transverse perineal and bulbocavernosus muscles, anteriorly projecting fibres of the internal sphincter, Colles' fascia, the urogenital diaphragm, and the recto-urethral muscle. A detailed description will be discussed elsewhere (Oh and Kark, 1972).

b. In the female the structure is very different anteriorly. On sagittal section in the anterior midline the whole sphincter appears as a single muscle-bundle which is grossly encapsulated by a mixture of longitudinal fibres and anteriorly projecting fibres of

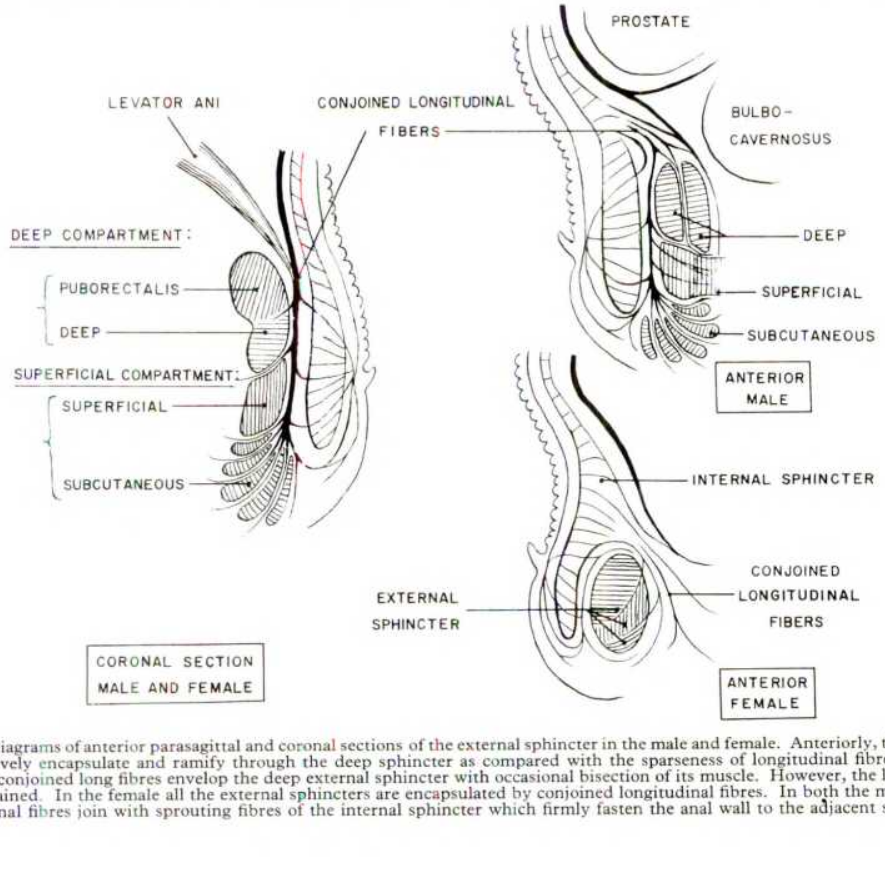

FIG. 9.—Diagrams of anterior parasagittal and coronal sections of the external sphincter in the male and female. Anteriorly, the longitudinal fibres extensively encapsulate and ramify through the deep sphincter as compared with the sparseness of longitudinal fibres laterally. In the male the conjoined long fibres envelop the deep external sphincter with occasional bisection of its muscle. However, the laminar pattern is well maintained. In the female all the external sphincters are encapsulated by conjoined longitudinal fibres. In both the male and female the longitudinal fibres join with sprouting fibres of the internal sphincter which firmly fasten the anal wall to the adjacent structures.

the internal sphincteric muscle (*Fig.* 6). In other words, on mid-sagittal section no muscular lamination can be identified anteriorly corresponding to the trilaminar sphincter of the lateral or posterior portion. However, dissection by an under-water technique and with the aid of a loop magnifier demonstrates that the origin of the fibres from each of the laminar fibres of the lateral part of the sphincter can be traced (*Fig.* 7). Only a few fibres of the lowermost part of the subcutaneous external sphincter are circular while the rest blend into the superficial external sphincter. The superficial sphincteric fibres are partly circular and may decussate and join the opposite side of the vaginal sphincter. These crossing fibres originate from the inferomedial portion of the superficial sphincter and form the antero-inferior portion of the anterior muscle-bundle. The rest of the fibres blend with the anterior median raphe and the superficial transverse perineal muscle. The deep sphincteric fibres are again partly circular in the inferomedial portion, and the superolateral portion of the sphincteric fibres fades out into the deep transverse perineal muscle and intermingles with the lower part of the puborectal muscle.

In general, all three parts of the external sphincter give circular fibres to the anterior single muscular bundle, with or without decussation (*Figs.* 8, 9). The lateral fibres of these muscles blend into the anterior median raphe or the transverse perineal muscle and puborectalis. Thus, the anterior sphincteric muscles can be distinguished from the lateral or posterior portion of the external sphincter by their appearance and in the pattern of the traversing conjoined longitudinal fibres (*Fig.* 9). These anatomical differences are probably derived from early developmental stages of evolution and integration of the anal tubercle from which the external sphincters originate (Tench, 1936; Gorsch, 1955; Wilson, 1967).

Acknowledgements.—We wish to extend thanks to Dr. G. Wind for his time and effort in preparing the anatomical illustrations; to Dr. G. Nirmul, who assisted in the dissections; and to Mrs. A. Acosta for the preparation of the histological sections.

LONG-TERM REVIEW OF FUNCTION FOLLOWING PULL-THROUGH OPERATIONS OF THE RECTUM

BY R. C. BENNETT, E. S. R. HUGHES, AND A. M. CUTHBERTSON

UNIVERSITY OF MELBOURNE AND ST. VINCENT'S HOSPITAL, AND THE ROYAL MELBOURNE HOSPITAL, MELBOURNE, AUSTRALIA

SUMMARY

1. Twenty patients previously reviewed from a functional standpoint following pull-through resection of the rectum have been reassessed 2 years or more following the initial review.

2. Fourteen of the 20 patients showed further improvement at the second examination, and half of these patients could be reclassified to indicate a significantly improved overall functional result.

3. It is clear that functional improvement may occur to a varying extent either gradually or at times rapidly even years after pull-through resection of the rectum.

IN an earlier report (Kennedy, McOmish, Bennett, Hughes, and Cuthbertson, 1970) it was suggested that functional results following pull-through operations of the rectum using the two-stage technique described by Turnbull and Cuthbertson (1961) eventually proved satisfactory in the majority of patients, though sometimes adequate function was delayed for many months. It was our belief that not infrequently a stable functional state was not reached for 12–18 months following operation, and that earlier unfavourable reports on postoperative continence (Goligher, Duthie, DeDombal, and Watts, 1965) might have been adversely influenced by the relatively short-term nature of the follow-up. To assess further the importance of time on the definitive degree of continence 20 of the original patients have been reviewed at least 2 years following the first assessment. The results of this survey confirm the original suggestion that continence frequently continues to improve for some time after operation but indicate that this period might be extended to several years in some patients. They also confirm that the majority of surviving patients will ultimately achieve quite reasonable function.

MATERIALS AND METHODS

Twenty patients were selected at random from the original 79 who were interrogated and examined by us during the previous study (Kennedy and others, 1970). They included 13 males and 7 females with ages ranging from 39 to 66 years at the time of their original operations. The first review of postoperative function had been undertaken at varying intervals ranging from 5 months to 7 years following operation, and in each case the second review was undertaken at least 2 years later. In the majority of patients this interval actually ranged between 2½ and 3 years.

The patients were very carefully interrogated and examined by an independent observer (R. C. B.) according to the pattern previously described (Kennedy and others, 1970). In particular, special note was made of whether the patient wore a pad and if so to what extent and how frequently this was soiled. The ability of the patient to recognize and distinguish between flatus and solid or liquid faeces present within the rectum was recorded. Any lack of control in the passage of flatus or faeces was noted, including minor, though perhaps embarrassing, inadvertent errors. The regularity of the bowels, the ability of the patient to remain continent during attacks of diarrhoea, and also the possible necessity for the administration of enemas were recorded. Finally, any dietetic, domestic, social, or economic restrictions as a result of functional imperfections following the operation were documented. After all these parameters of bowel function had been considered the patients were classified according to an overall assessment of bowel function, as in the previous review. The results are considered in three groups.

Group A.—This included patients with function indistinguishable from normal or virtually so. By any standards these patients would be regarded as having achieved excellent postoperative results. They were able to differentiate between faeces and flatus and made no inadvertent errors in their passage. There were not required to wear perineal pads and their underclothes were not soiled. Their bowel habit was regular and they did not require enemas. Examination revealed normal sphincteric tone and no perianal excoriation.

Group C.—This included patients with unsatisfactory bowel function. They were unable to differentiate satisfactorily between flatus and faeces and made frequent errors in their passage. They wore perineal pads which were frequently soiled. They passed motions irregularly and often required enemas. Examination revealed anal sphincters with poor muscle tone and frequently there was evidence of perianal excoriation.

Group B.—This included patients whose postoperative function lay somewhere between that of the other two groups. Although they experienced mild to moderate imperfections with varying degrees of frequency, it was considered that the postoperative function was still sufficiently good to have made the operation worth while. Those who wore pads rarely soiled them to any extent, and errors in the passage of flatus or faeces were minor rather than major in degree. Their bowels were open regularly without enemas, and examination did not reveal excoriation though it frequently did demonstrate reduced sphincteric tone.

RESULTS

The results are set out in detail in *Table I* but some particular points should be emphasized. Of the 20 patients under review, none had deteriorated and 14 showed decided improvement in bowel function since the previous review. Half of the improved patients (7) were reclassified into a higher group. Special note should perhaps be made of *Case* 1 whose classification improved from group C to group A. A more detailed account of his postoperative function on the two occasions is as follows.

Case 1.—A male, aged 53 years, was operated upon for a carcinoma of the rectum on 24 Sept., 1965.

The original review on 17 Nov., 1967 (26 months after operation), indicated a poor functional result. He had worn a pad since the time of operation and he soiled it frequently. He was unable to recognize the presence of flatus in the rectum and claimed very little control over its passage. He was able to recognize the presence of faeces in the rectum, but his bowels acted very irregularly and sometimes as often as twenty times per day, indicating an almost constant dribbling of faeces from the back passage. He noted precipitancy and when his bowels were loose claimed reasonable control for only 50 per cent of the time. He was included in group C, indicating an unsatisfactory functional result.

At the time of the second postoperative review on 27 July, 1970, which was almost 5 years after operation, he claimed that he was very much better and had almost forgotten that he had had an operation. He no longer wore a pad and did not soil his underclothes. He could recognize the presence of both flatus and faeces in the rectum and claimed good control without the occurrence of minor errors. His bowels were then somewhat constipated and rarely, if ever, worked more than once per day. Examination revealed good sphincter tone with strong voluntary contraction of the external sphincter muscles and no evidence of perianal soiling or excoriation. He was reclassified at this time into group A.

One other group C case (*Case* 14, originally reviewed 6 months after operation) was reclassified as group B. In addition, 5 group B cases were reclassified as group A. It is important to note that while 2 of these cases were originally classified less than 1 year following operation, the remaining 5 were classified more than a year and in some instances as long as 4½ years after operation. This clearly shows that functional improvement, though usually maximal in the first 1–2 years following operation, can continue for some time thereafter and even occur to a significant extent 4 or 5 years later.

DISCUSSION

In our earlier publication (Kennedy and others, 1970) we emphasized that it often took many months before a definitive or stable state of bowel function was achieved following operation. The mean time required for this to occur was 13·3 months. We stressed that the impression which is gained of function following pull-through resection of the rectum might well be coloured by the time at which the review is undertaken. At that time we felt that little improvement was likely to take place beyond 12–18 months in the postoperative period. However, the current survey clearly shows this not to be so, and although subsequent improvement does not necessarily occur in each patient, it can and frequently does so, either gradually or at times quite quickly, as late as several years following operation. Although the most significant improvement apparently occurred in *Case* 1 at about the 3-year mark, appreciable though somewhat less impressive improvement also occurred in *Cases* 3, 15, 18, and 20, all at 3 years or more following operation. It is also clear from *Case* 1 that this late improvement can be quite considerable in extent; so much so that in this instance bowel function changed from an unsatisfactory status to one barely distinguishable from normal!

One might expect this improvement to be greatest and most noticeable in those with originally poor postoperative function, but it was also apparent from our interrogation of *Cases* 7 and 11 (both of whom we had originally considered to have excellent results) that marginal, though none the less worth-while, improvement had still occurred in these patients. Subsequent consideration of their original assessment did not provide grounds for reclassifying them at a less satisfactory level at that time.

It would seem therefore that patients with poor functional results following operation can, in all honesty, be given some hope that their function might still improve even some years after operation, and that in the final analysis very few surviving patients will be dissatisfied with their result. Admittedly, for the patients whose function improves most slowly this time can be a difficult and at times embarrassing period, though they are usually ultimately rewarded by satisfactory function and the retention of a natural sphincteric mechanism.

THE FATE AND FUNCTION OF THE THYROID REMNANT

A SURGICAL AND RADIOACTIVE IODINE STUDY

H. B. YOUNG

CONSULTANT SURGEON, ROYAL AND NEW CROSS HOSPITALS, WOLVERHAMPTON

AND N. MACLEOD

FORMERLY CONSULTANT RADIOTHERAPIST, WOLVERHAMPTON GROUP OF HOSPITALS

SUMMARY

Clinical, radioactive iodine uptake, and scan studies on a series of measured thyroid remnants indicate that after thyroidectomy one lobe only actively functions in a significant number of cases and that the subthyroid state only appears in toxic cases, usually those with certain pathological, familial, or therapeutically induced changes.

Remnant size did not appear to be critical, but under-function did not occur over 8 c.c. Above this size of residuum hypothyroidism does not appear to be directly due to the operation *per se* and should not therefore be called postoperative.

A fall in the assessment parameters after 6 months in a toxic case with a remnant measuring less than 8 c.c. and one or more of the associated features mentioned above would be an indication for commencing thyroxine.

Minor degrees of lymphocytic infiltration did not correlate directly with under-function.

There was a suggestion of right-sided dominance in the remnant as in normal and diseased glands.

THE key to the euthyroid state after thyroidectomy must lie in the size and/or function of the remnant. This has, as contrasted with the gland itself, three easily measured dimensions—length, breadth, and depth—which can be expressed as c.c. Taylor and Painter (1962) used this unit after the application of a stent mould. Murley and Rigg (1968) recorded the 'cuboid' volume as ml. Our measurements of the specific gravity of thyroid tissue (mean, 1·081) show that in figures of remnant size this is almost interchangeable with the grammes used by other authors. By relating this to the weight of the excised gland a non-visual percentage removal could be ascertained.

Table I.—DISTRIBUTION OF FUNCTION IN THE SCAN

TYPE OF GLAND	NO. OF CASES	TIME AFTER OPERATION (mth.)	RIGHT SIDE		LEFT SIDE		BOTH SIDES	NO OUTLINE
			Sole	>90 per cent	Sole	>90 per cent		
Toxic	46	1	6	4	4	2	29	1
		6	7	1	5	1	30	2
Non-toxic	32	1	12	1	2	1	14	2
		6	13	0	3	1	14	1

Function was measured by the scan outline and by 24-hour ^{131}I uptake. The scan outline and volume measurements were based on counts per second after a 50-μc. dose of ^{131}I. The 50 per cent line was taken as representing thyroid tissue within the limits of the collimated tube because:—

1. In several trial remnants this line corresponded well when the trachea was 2 cm. wide (in 18 out of 20 cases) (*Fig.* 1 B).
2. This corresponded well with the edge of a phantom with the same volume as a normal thyroid, although the scan edges fused if the containers were less than 2 cm. apart. The scan outline of any phantom could not be well delineated if the volume of radioactive material was less than 1 c.c.
3. The 50 per cent line corresponded in three freshly excised specimens after a preoperative dose of ^{131}I (*Fig.* 1 A).

AIMS AND PATIENTS STUDIED

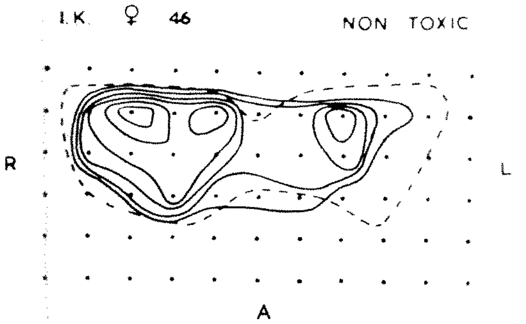
Our aims were:—

1. To measure the ^{131}I uptake and scan outline (including the lateral view) and hence the volume in each remnant about 1 month after operation when adjustment should have been made to the local effects of the operation, and to repeat these measurements in 6 months to see if any trend with regard to future function or mass of the remnant was developing.
2. To see if there was any direct relationship between the scan and remnant volumes with a view to assessing remnant size when this was not palpable in case of further trouble.
3. To see if any size was crucial to the development of the subthyroid state, which is still a matter of doubt.
4. To see if there was any evidence of right-sided dominance as in the intact gland.

The patients were operated upon between September, 1966, and September, 1969. Forty-six toxic and 32 non-toxic cases were able and interested enough to complete the assessment follow-up for periods of from 18 months to 4½ years. A further 12 (7 toxic, 5 non-toxic) did not attend at 6 months owing to pregnancy, distance, anaemia, psychological upsets, etc.

RESULTS

Table I shows the distribution of function in the scan. It was surprising to find that in more than 20 per cent of the toxic and 40 per cent of the non-toxic cases one lobe remnant only was functioning and that overall and especially in the non-toxic cases this was likely to be the right lobe (*Fig.* 1 C).



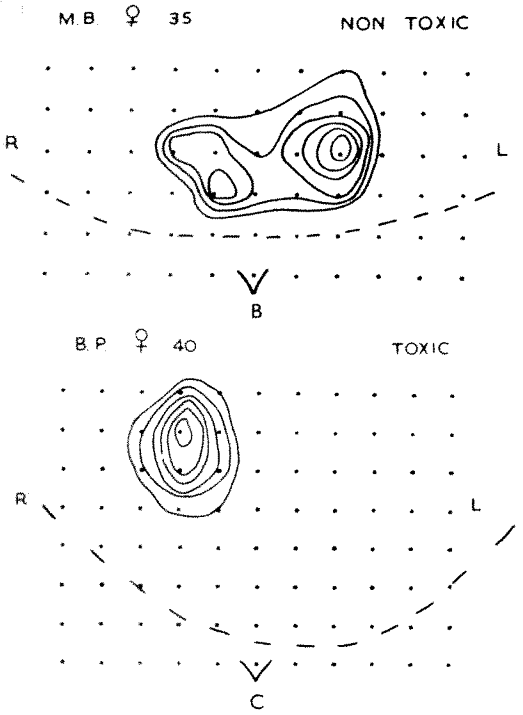


FIG. 1.—Diagrams of postoperative scans of the thyroid. A, Scan trace (50 per cent count line) (——) superimposed on the outline of the excised gland (– – –). B, A typical postoperative scan with both lobes functioning. C, A typical scan with one lobe only demonstrable.

Table II shows that no development of function was demonstrable after 6 months in the 24 remnants which did not function after operation, though in 1 toxic case a few tiny dots of function were picked up after this time. All but 1 of the cases with only one lobe functioning have remained euthyroid. *Table II* also shows that the size of the remnant that ceased to function varied from 0·125 to 8·0 c.c. in size.

Table II.—SIZE AND FATE OF NON-FUNCTIONING REMNANTS

NATURE OF CASE		SIZE OF REMNANT ON SIDE WITH ABSENT FUNCTION		APPEARANCE OF FUNCTION AT 6 MONTHS (Right and Left)
		Right	Left	
Toxic	No. Size (c.c.)	4 0·25–5·0 (average 2·2)	6 0·125–8·0 (average 4·2)	0
Non-toxic	No. Size (c.c.)	2 6·0–6·0 (average 6·0)	12 0·5–7·0 (averag 3·01)	0

All 24 cases with only one lobe functioning were euthyroid.

Table III.—RELATION BETWEEN SCAN AND REMNANT VOLUMES

NATURE OF CASE	SCAN LESS THAN REMNANT BY 1–3 TIMES (per cent)	GOOD CORRESPONDENCE ON ANTERIOR AND LATERAL SCANS (per cent)	SCAN GREATER THAN REMNANT BY 2–10 TIMES (per cent)
Toxic	10·2	38·5	51·3
Non-toxic	33·3	29·2	37·5

Table III shows that there was good correspondence between the scan and remnant volumes in nearly 40 per cent of the toxic and 30 per cent of the non-toxic cases. Where discrepancy was present, the scan was usually much larger in the toxic group than the actual stump size, perhaps owing to increased activity from continued stimulation by long-acting thyroid stimulator (LATS). Correspondence was greater in cases with only one lobe functioning, no doubt the result of lack of superimposition of one lateral lobe on the other. The lateral scan was the main variable owing to depth difficulties with the shoulder, though its actual measurement was fairly constant (0·75–1·0 c.c.). The chin occasionally caused similar difficulties with the upper part of the anterior scan.

Table IV indicates there is no relationship between the initial ^{131}I uptake and subsequent hypothyroidism, which only developed in the toxic group of cases. In the patients over 60 years of age 4 out of 5 had an initial uptake of less than 30 per cent, as did cases whose total remnant was less than 4 c.c. (*Table V*). If, however, the scan showed function on one side only and this residuum was below 0·4 c.c. the ^{131}I uptake tended to lie between 40 and 50 per cent, suggesting a contribution from the non-demonstrable remnant. *Table V* also shows that most small remnants were euthyroid.

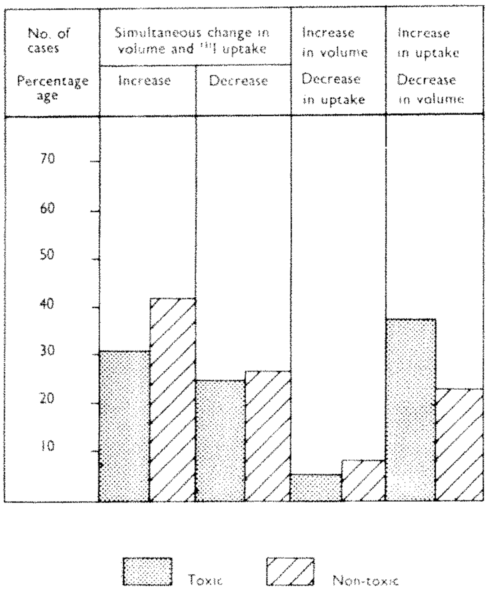

FIG. 2.—Changes in the volume of the remnant and ^{131}I uptake 6 months after the initial examination.

Table IV.—INITIAL ^{131}I UPTAKE AND SUBSEQUENT HYPOTHYROIDISM

NATURE OF CASE	NO. OF CASES	UPTAKE OF 0–30 PER CENT	UPTAKE OF 31–60 PER CENT	UPTAKE OF >60 PER CENT
Toxic	42	15	23	4
Subthyroid	8	5	3	0
Non-toxic	31	8	20	4
Subthyroid	0	0	0	0

No clear correlation could be found between the percentage of gland removed and the initial ^{131}I uptake, though high values tended to be found after 80 per cent removal while low values (under 30 per cent) occurred in two-thirds of those after 95 per cent removal. Of 2 cases with over 99 per cent removal, 1 non-toxic case had an uptake of 26 per cent while the other, a toxic gland, had no demonstrable function.

The histogram (*Fig.* 2) shows the several patterns of change after 6 months. Commonly there was a parallel increase or decrease in both parameters, but in 30–40 per cent the function increased though the volume decreased. The detailed figures from which this histogram was drawn show that one-half will show an increase of ^{131}I uptake (up to 600 per cent), one-quarter will show no change, and a smaller number a decrease. The volume most commonly remains the same or decreases, but there were wide individual variations.

Table V.—INITIAL ^{131}I UPTAKE IN PATIENTS WITH SMALL FUNCTIONING REMNANTS

NATURE OF CASE		SIZE OF REMNANT			AVERAGE INITIAL ^{131}I UPTAKE (per cent)
		1–2 c.c.	2–3 c.c.	3–4 c.c.	
Toxic	*a*	1	3	3	26
	b	1	2	0	41
Non-toxic	*a*	1	2	2	18
	b	1	0	1	49

a, Both lobes functioning; total thyroid tissue, 4 c.c.

b, One lobe functioning; lobal thyroid tissue on functioning side, 4 c.c.

The optimum size of remnant can be assessed by study of the fate of the average remnant, that of the small remnant, the histopathology present, and the clinical features associated with under-function of the residuum. In toxic cases the average size of the remnant was 6·5 c.c. (range 0·5–24·0 c.c.) and the average percentage removed, 84 (range, 71–96 per cent), with a 17·4 per cent incidence of subthyroidism and no recurrence.

In non-toxic cases the figures were 7·9 c.c. (range 2·0–18·5 c.c.), 85 per cent removal (range 42–99 per cent), and no case of hypothyroidism.

Small remnants (below 4·0 c.c.) were left in 8 toxic cases, with 1 subthyroid state, and in 5 non-toxic cases, with no under-function. In 5 cases in which the scan showed function on one side only the remnant was less than 4.0 c.c. and all were euthyroid.

In all the cases developing myxoedema the remnant was 8·0 c.c. or less, but certain other common factors were present. These are detailed in *Table VI*. All the cases were toxic; all had lost volume or even scan outline after 6 months; in most the function after this time had diminished even if originally adequate; in all these cases the pathological changes were degenerate (foci of calcification, lymphocytic infiltration, thyroiditis, or excess colloid). Usually other factors were present—a family history of goitre, severe or refractory disease, sensitivity to anti-thyroid drugs, or an odd psychology requiring continuous medication which was potentially goitrogenic.

No correlation was found in relation to age, moderate variations in toxicity, previous adiposity, menopause or diabetes, or blood group.

The time interval to the appearance of subthyroidism varied from 3 months to 3 years.

Some degree of lymphocytic infiltration was, however, not always ominous, and 10 toxic and 6 non-toxic cases (mean remnant size of 6·5 c.c. for toxic and 9·5 c.c. for non-toxic) were noted as showing minor degrees of lymphocytic infiltration without developing hypothyroidism at 3 years. In all except 1 either the ^{131}I uptake or volume had gone up markedly (over 40 per cent) at 6 months or both had gone up at this time. The exception was a woman of 57 years in whom the ^{131}I uptake fell from 26 to

* All the cases were toxic.

16 per cent and in whom both scans were too low to plot. However, at 3 years she was clinically well and had a normal serum-cholesterol.

In a similar way the occurrence of one of the other adverse factors alone did not always presage underfunction. There were 3 cases who had had previous courses of drug treatment (remnant sizes 9·0, 7·0, and 4·75 c.c.—the last with some lymphocytic infiltration) and 3 with a family history of goitre (remnant sizes 6·0, 4·75, and 5·5 c.c.) who remained euthyroid. In 4 of these 6 cases both the ^{131}I uptake and the volume had gone up, but in 2 (remnant sizes 4·75 and 5·5 c.c.) they were down. These 2 patients will require careful observation or, better perhaps, prophylactic thyroxine.

These results indicate the following conclusions:—

1. It should be possible to predict many of those cases who would be likely to develop hypothyroidism after thyroidectomy if a ^{131}I uptake and scan outline were carried out 1 month after operation and 6 months later in any toxic case with degenerative histology, a family history, previous prolonged drug or irradiation therapy, or continued tablet taking; a falling uptake and volume would be a strong indication for prophylactic thyroxine administration.
2. Taking the 50 per cent count line there was a good correlation between the scan size and that of the remnant in 30–40 per cent of the cases, and more in the toxic group. In the others the ratio varied widely, the scan usually being the greater. This is not accurate enough to 'measure' the size of a 'non-palpable recurrence'.
3. A remnant size of just over 8 c.c. is likely to provide maximum protection against surgically induced myxoedema, with minimal recurrence of thyrotoxicosis, even in the presence of a single predisposing factor.
4. In remnants made similarly on each side often only one showed function on the scan and this was more likely to be the right side in the ratio of 3 : 1, suggesting that the remnant retains the dominance noted in normal scans.

DISCUSSION

It was surprising to find that in 24 cases (33·3 per cent)—mostly non-toxic glands—the postoperative scan showed function on one side only, though there was an apparently similarly treated and equally large and vascular remnant on the other side. The average size of the 'disappearing' stump was 4·1 c.c., though our studies indicated that 1 c.c. of active thyroid tissue should have been confidently demonstrable and separable from another of similar size 2 cm. apart.

Artagaveytia, De Grossi, Gotta, and Pecorini (1965), Thomson (1966), and Wiener and Roos (1968) have drawn attention to the fact that the normal scan is often asymmetrical, favouring the right side, and that most disease processes occur more frequently in the right lobe, while hemi-atrophy appears most often in the left lobe. Wiener and Roos (1968) state that the richer vascularization of the right lobe has been proposed as an explanation. We have often noted that the right inferior thyroid artery appeared larger than the left and that if there was any difficulty in finding an inferior thyroid artery it was usually the left one owing to its small size. The vascular insult of operation would thus be likely to affect the left remnant more severely. Such vascular factors would contri bute to the difficulties relating scan to actual volum measurements and would affect the less robustl bloody, non-toxic stump more than the toxic rem nant, accounting for the larger proportion of scan which were smaller than the remnants in this grou of cases.

The loss of function in a lobe did not lead to hypc thyroidism even when the remaining active remnar size was 4 c.c. or less. All were euthyroid except case with a 3-c.c. residuum which had had previou ^{131}I treatment and subsequently had become euthyroic

Our experience would suggest that in the nor degenerative, non-treated, non-familial gland a thy roid remnant of 4 c.c. would be unlikely to cause i effects or to allow recurrence.

However, the degree of lymphocytic or other de generation can only be clear after examining th postoperative histology and, as in our series, tox cases with such changes and a remnant of less tha 8 c.c. had an incidence of hypothyroidism of abou 18 per cent and it would seem wise to cover th possibility by leaving a remnant of more than th size.

Thus, leaving a residuum of just over 8 c.c. (i our cases tending to be 3 cm. long by 1·3 cm. wic by 1 cm. deep on each side) would probably be satisfactory standard remnant. Taylor (1966) recon mended this same size using a configuration of 4 2 × 0·5 cm. on each side. Taylor and Painter (196 found that in their cases of thyrotoxicosis who we euthyroid after operation the volume of the remna was 8 c.c. This corresponds with the lower end Murley and Rigg's (1968) measured thyroid remna range (6–15 ml.).

According to British experience, therefore, 8 c. would seem to be the optimum remnant. The use such an optimum remnant would not, howeve abolish completely hypothyroidism occurring aft operation, as this is well known to occur spo taneously in toxic and non-toxic goitres and certain minimum incidence of hypothyroidism wou be inevitable in any sizeable series from the progressi pathological changes involved.

Green (1950) found the correlation between th development of hypothyroidism and lymphocyt infiltration to be close and we found it to be sign ficant in those cases who became subthyroid.

Nevertheless, there was another group of 16 cas (10 toxic, 6 non-toxic) with a mean remnant size 6·5 c.c. and 9·5 c.c. respectively, in whom son degree of lymphocytic infiltration was noted, but myxoedema developed during up to 3 years of obse vation. In all the cases the ^{131}I uptake or volun had gone up markedly, viz. over 40 per cent, or bo had gone up significantly, with 1 exception.

In the main in both toxic and non-toxic cases fun tion tends to increase with the passage of time, b in 35 per cent it will diminish and it is in this grou especially if toxic and associated with one of th other factors outlined, that under-function will occ

Adequate remnant size covering degenerative hist logy will not alone prevent hypothyroidism and sm size alone will seldom cause it. Our own smalle remnant (500 mg.) gave a 55 per cent uptake at months. Szilagyi, Barrett, and Preuse (1955) fou the incidence of hypothyroidism was only significa below 150 mg., but the safety of operation was difficult to ensure below 800–1000 mg. Marchetta, Krause, and Sako (1963) noted that after 'total' thyroidectomy for carcinoma the postoperative scintigram after a few months showed a radioactive iodine uptake of 20–25 per cent.

Thus neither knowledge of the technique used by different authors, nor remnant size, nor operative histology, contains the whole secret of the development of hypothyroidism. In our series it only occurred in the toxic gland and in other series only significantly in the toxic gland.

Some other factor in addition, found for practical purposes only in the toxic group, must be necessary to produce this liability to myxoedema. Such a factor might be the continuation of the auto-immune process which caused the disease. While LATS is one of the few immunoglobulins to stimulate cells it might well later destroy or exhaust the gland. It appears to cause the type of thyrotoxicosis associated with focal thyroiditis (Mason, 1967) and with a tendency towards under-function without antibody formation—Category I of Hargreaves and Garner (1968). Anderson (1964) thought that this picture was in part due to a delayed hypersensitivity process. A genetic component in its aetiology is indicated by the high incidence of myxoedema and Hashimoto's disease in the relatives of those suffering from thyrotoxicosis. Spontaneous myxoedema can also develop.

There are thus many factors, other than operation, capable of producing hypothyroidism after operation. It is probable that if the remnant is above 8 c.c. hypothyroidism is not due to the operation *per se* and should not be labelled postoperative, as it is due to the nature of the disease or other iatrogenic intervention. Indeed, thyroidectomy can not only control thyrotoxicosis but even alter and improve the toxic histological appearances of the gland remnant, especially after the first year (Curran, Eckhert, and Wilson, 1958).

Recovery from any transient hypothyroidism following operation is generally thought to have taken place within 6 months. Therefore, whatever the individual cause in these high probability cases outlined above, the tendency towards under-function should be assessed by postoperative scan outline and ^{131}I uptake measurements after 1 and 6 months. If both are down or the ^{131}I uptake is markedly down thyroxine should be given to anticipate the appearance of myxoedema.

Neither a single postoperative ^{131}I uptake nor an assessment of the percentage uptake per c.c. of residual tissue gave any worth-while guide to subsequent thyroid status. However, a weight-gain of 6·35 kg. above that lost in the preoperative toxic phase in the presence of careful dietary habits might be considered a useful clinical hint of incipient hypothyroidism.

Acknowledgements.—We should like to thank in particular Mr. C. W. Mullet, physicist, the Royal Hospital, for his helpful advice; Miss P. A. Carrington, of the Radioactive Isotope Department, for her meticulous care and interest with the scans and uptake measurements; and Mr. R. Paton, of the Photographic Department, for the illustrations.

EVALUATION OF BREAST TUMOUR SEX CHROMATIN (BARR BODY) AS AN INDEX OF SURVIVAL AND RESPONSE TO PITUITARY ABLATION

BY MICHAEL PERRY*
DEPARTMENT OF SURGERY, ROYAL POSTGRADUATE MEDICAL SCHOOL, LONDON

SUMMARY

In a retrospective study of 36 patients with advanced breast cancer relationships were found between the tumour Barr body count and the response to pituitary ablation and the length of survival. High tumour Barr body counts were associated with long survival after treatment, and low counts with short survival $(P<0{\cdot}001)$. High counts were also associated with a good response to pituitary ablation, and low counts with a poor response $(P<0{\cdot}01)$. The tumour Barr body count gave possibly better prediction than urinary steroid measurement.

A BARR body is defined (*Fig.* 1) as a female cellular sex chromatin marker, 1 μ in diameter and located against the inner surface of the nuclear membrane envelope (Barr and Bertram, 1949). Any living nucleated cell may be used in the examination for sex chromatin, but in practice cells with clear nuclei obtained from easily accessible sites are used.

---

* Present address: Surgical Professorial Unit, St. Bartholomew's Hospital, London, E.C.1.

Barr bodies may be identified in about 50 per cent of normal female cells. This is also the case for most tumours, in that the tumour Barr body count is equivalent to the normal count for that patient (Sohval and Gaines, 1955; Tavares, 1955). However, Kimel (1957) found that breast cancer was an exception to this rule. He studied 100 cells in a tumour and counted the number containing Barr bodies. In his study of 91 mammary cancers Kimel found that 66 per cent of the tumours had counts of less than 40 and that 53 per cent had counts of less than 30. In normal tissues, however, the lowest sex chromatin count observed was 40. Only 34 per cent of the tumours studied had counts in the normal range of 40 or more.

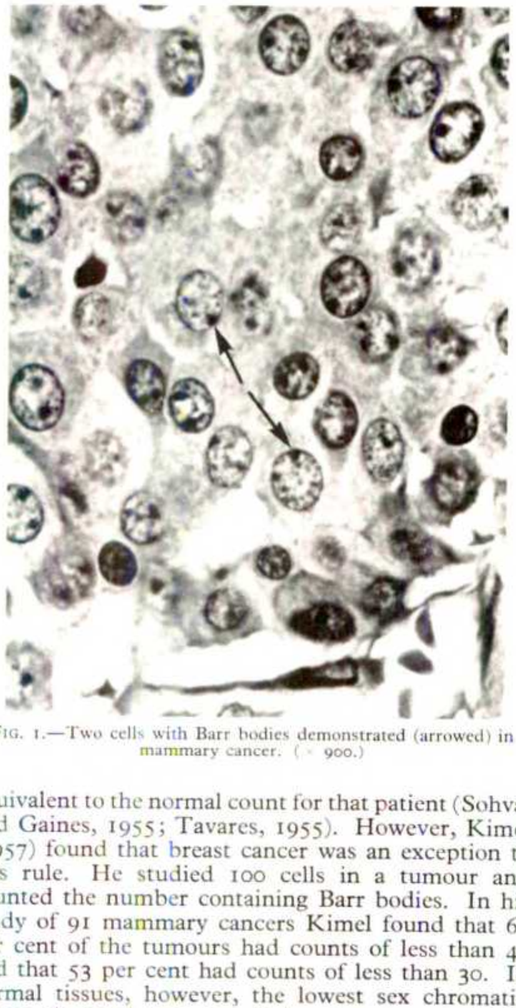

FIG. 1.—Two cells with Barr bodies demonstrated (arrowed) in mammary cancer. (× 900.)

Bohle, Burger, Fischbach, and Schooli-Tubingen (1965) summarized 10 reports from the German literature on studies of sex chromatin in cases of breast cancer. They concluded that low tumour sex chromatin counts were associated with lowered responsiveness to hormones and that these tumours were more malignant than those with high counts. Shirley (1967) confirmed these findings. In a retrospective study from the Massachusetts General Hospital he found that hormonal therapy was most likely to be successful in patients with normal sex chromatin in their tumours. In addition he found that the response to hormonal therapy was extremely poor in women under the age of 50 years with high sex chromatin counts and in older women with lo counts. These results do not confirm the hypothes that the sex chromatin complement of the tumo indicates oestrogen dependence. No comparison h been published of the value of the tumour Ba body with that of the urinary steroid estim tion in predicting survival or response to trea ment.

PATIENTS AND METHODS

Thirty-six mammary cancers were studied, select at random from routine surgical slides stained wi haematoxylin and eosin. Most of the sections we taken from drill biopsy specimens and thus we unsuitable for accurate interpretation of tiss differentiation. Approximately 100 cells were counte on each slide and the number of cells containing Ba bodies was expressed as a percentage of the tot number of cells counted. Slides were only include in the study if the sections were evenly stained an the cells clearly defined.

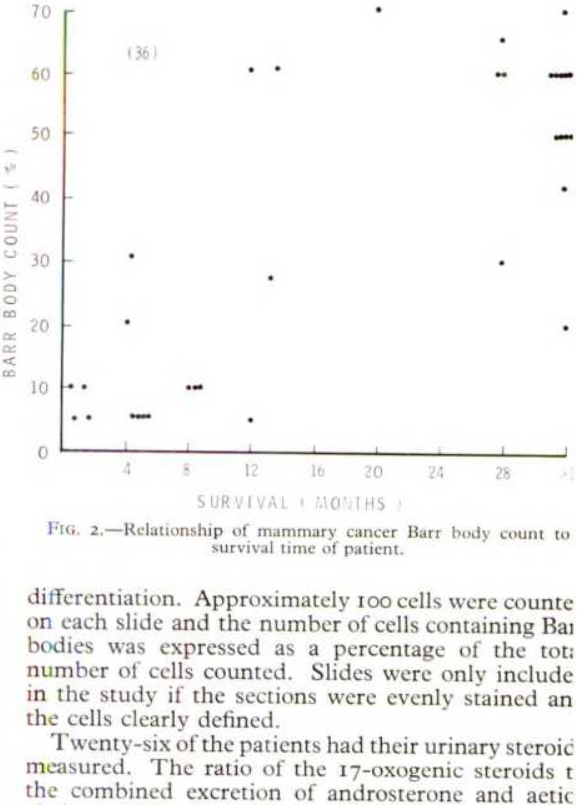

FIG. 2.—Relationship of mammary cancer Barr body count to survival time of patient.

Twenty-six of the patients had their urinary steroi measured. The ratio of the 17-oxogenic steroids t the combined excretion of androsterone and aetic cholone (11-deoxy-17-oxosteroids) has been foun to be a good index of response to endocrine therap (Fotherby, Sellwood, and Burn, 1970). A value of for the ratio provided a fair degree of discriminatio between those who responded and those who did no the proportion of responders being three times greate in those with a low ratio than in those with a hig one.

RESULTS

Relationship of Mammary Cancer Barr Bod Count to Survival Time of Patient.—In *Fig.* there appear to be two populations: one with lo counts and a short survival, and the other with hig counts and a longer survival. Many of the patient shown as having survived more than 30 months are in fact, still alive. All the patients in *Fig.* 2 an subsequent figures had advanced disease and were treated by endocrine therapy.

Comparison of Barr Body Count and Steroid Ratio in Relation to Response to Pituitary Ablation (*Fig.* 3).—The high tumour Barr body count was associated with a good response to pituitary ablation whereas the low count was not ($P < 0{\cdot}01$). Similarly, patients with low steroid ratios were found to respond to pituitary ablation significantly better than patients with higher ones ($P < 0{\cdot}05$).

Comparison of Barr Body Count and Steroid Ratio in Relation to Survival Time (*Fig.* 4).—Patients who survived up to 12 months after treatment have been compared with those who survived

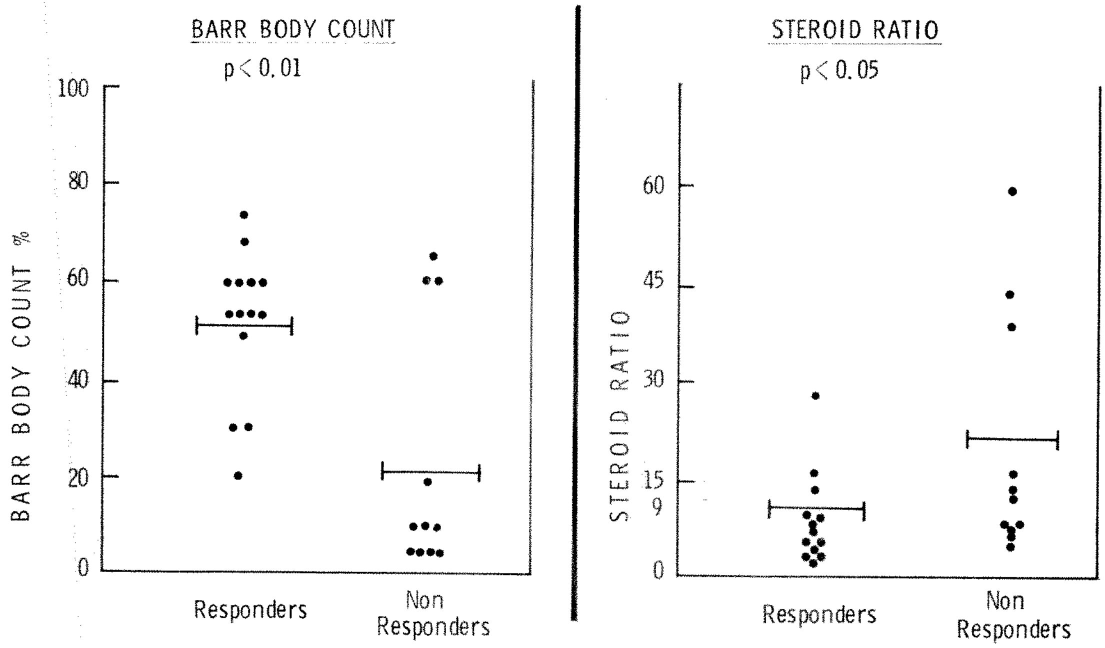

FIG. 3.—Comparison of Barr body count and steroid ratio in relation to response to pituitary ablation.

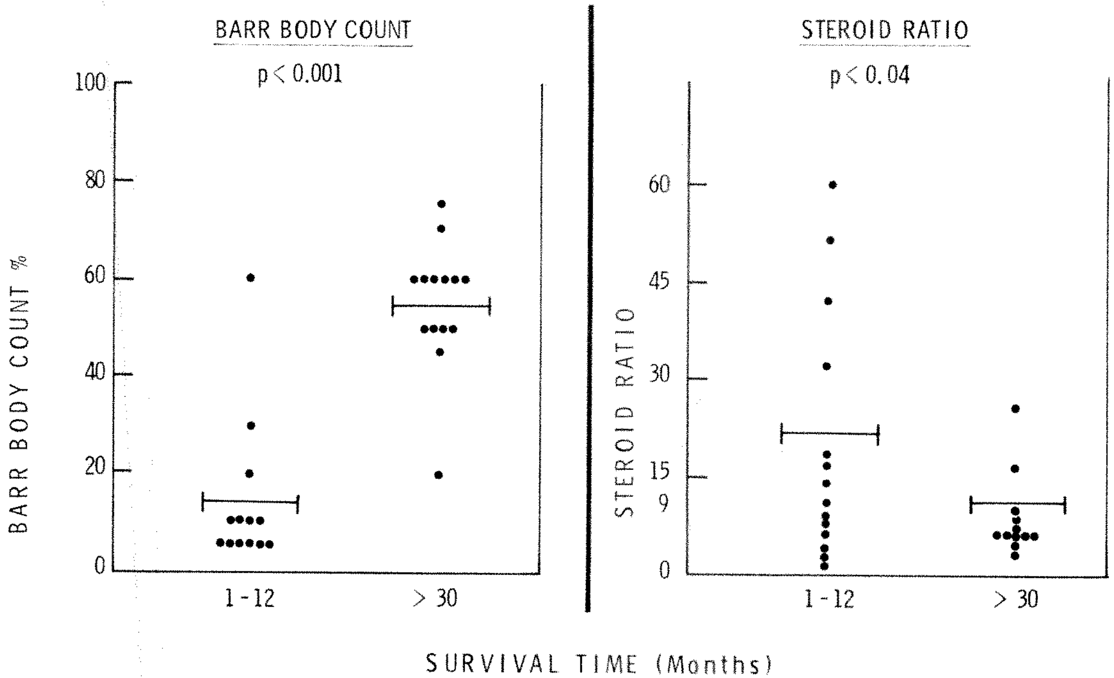

FIG. 4.—Comparison of Barr body count and steroid ratio in relation to survival time.

more than 30 months in respect of the Barr body count and of the steroid ratio. The mean Barr body count was higher ($P < 0.001$) and the mean ratio lower ($P < 0.04$) in those who survived the longer time.

Relationship between Barr Body Count and Steroid Ratio in Patients who underwent Pituitary Ablation.—Twenty-two of the patients who underwent pituitary ablation had both the tumour Barr body count and the urinary steroid ratio measured. Simple inspection of the data suggested that a level of 40 per cent for the Barr body count (like that of 9 for the steroid ratio) provided a fairly good discrimination between those who responded and those who did not. The relative values of these two factors in relation to response are shown in *Fig.* 5 and *Table I*. Although the numbers are small, the data suggest that the steroid ratio and the Barr body count together may provide a better prognostic index of the response to therapy than either alone.

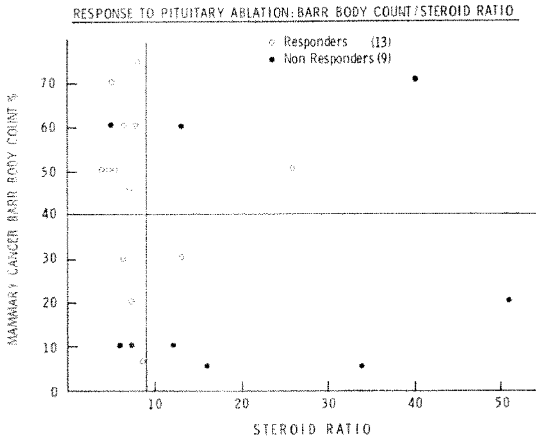

FIG. 5.—Relationship between Barr body count and steroid ratio in patients who underwent pituitary ablation.

Table I.—RELATION OF BARR BODY COUNT AND STEROID RATIO TO RESPONSE TO PITUITARY ABLATION (*see also Fig.* 5)

	RATIO OF RESPONDERS TO NON-RESPONDERS	PERCENTAGE
Steroid ratio alone		
<9	11 : 14	79
>9	2 : 8	25
Barr body count alone		
>40	9 : 12	75
<40	4 : 10	40
Steroid ratio and Barr body count		
<9 and >40	8 : 9	89
>9 and <40	1 : 5	20

DISCUSSION

This study suggests that the simple method of counting the numbers of cells containing Barr bodies in the mammary cancer is significantly related to both the length of survival of the patient and her response to pituitary ablation and that it may therefore be of prognostic value.

The tumour Barr body count has been criticized on the grounds that it is merely a reflection of the degree of differentiation of the tumour, normal counts being associated with well-differentiated tumours and low ones with poorly differentiated tumours. In the present study the pathologist was able to assess the degree of differentiation in only 14 of the 36 patients. All 14 patients had advanced disease of the breast and were not treated by mastectomy, the tumour material being taken by drill biopsy. However, it is interesting to note that in 9 out of the 14 specimens the count correlated well with the degree of differentiation of the tumour but that in 5 it did not. Conclusions cannot be drawn from such small numbers.

There is disagreement in the literature about the relationship of the tumour Barr body count and the degree of dissemination of the cancer. Kimel (1957) presented evidence that tumours with high counts were more likely to metastasize than those with low counts, whereas Bohle and others (1965) found that lower counts were associated with a shorter survival time—a finding in agreement with our results.

The comparison of the tumour Barr body count with the urinary steroid ratio is an interesting one. Both estimations agree with regard to prediction of survival and the response to pituitary ablation, but it may be that the tumour Barr body count provides better discrimination. When the two estimations are compared in *Figs.* 3 and 4 with respect to response to treatment and survival, the Barr body count shows a greater difference between the means and a higher level of statistical significance in both groups.

A good correlation might be expected between the tumour Barr body count and the urinary steroid ratio in view of their similar predictions concerning response to pituitary ablation and to survival of the patient. However, this is not the case (*Fig.* 5). It may be, as suggested already, that the two estimations together provide a better discriminant than either alone, but the attraction of the Barr body count is that it is simple and can be used in any hospital.

Acknowledgements.—I am indebted to Mr. J. Ian Burn and Professor R. B. Welbourn for permission to study patients under their care and for their help in the preparation of this paper. I am grateful to Mr. Cedric Richmond for technical help and to Miss Diane Lippiatt for secretarial assistance.

AMPUTATION NEUROMA OF THE GREAT AURICULAR NERVE AFTER PAROTIDECTOMY

By MICHAEL HOBSLEY

DEPARTMENT OF SURGICAL STUDIES, THE MIDDLESEX HOSPITAL, LONDON

SUMMARY

Division of the great auricular nerve during the operation of parotidectomy sometimes results in an amputation neuroma. The condition can be diagnosed on clinical grounds, thus obviating the need for further surgical exploration.

THE finding of a subcutaneous nodule in or near he scar after parotidectomy for neoplastic disease naturally raises the strong possibility that the lump represents an implantation recurrence of the growth. The present article describes 2 patients in whom such nodule was found to be benign, namely, an amputation neuroma of the great auricular nerve, and another 2 in whom the same diagnosis seemed probable. Criteria are suggested by which the clinical diagnosis of this condition may be made.

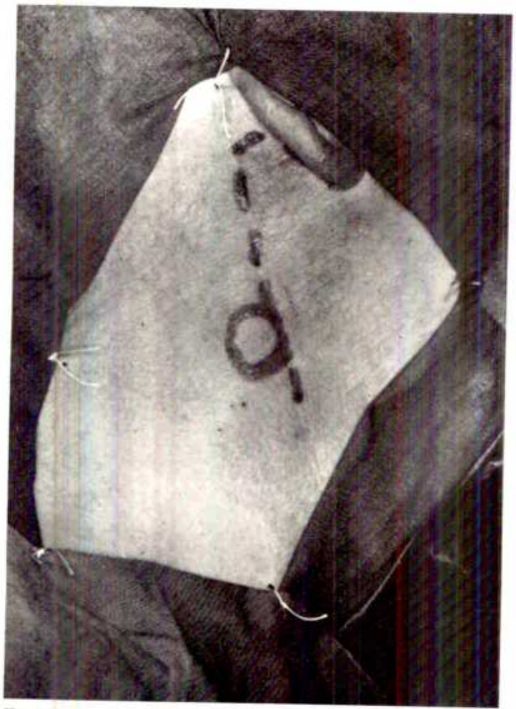

FIG. 1.—*Case* 1. The circular outline of the subcutaneous nodule has been marked and the position of the old parotidectomy scar indicated as a dotted line.

CASE REPORTS

Case 1.—E. H., a male aged 54 years, presented in 1964 with a 10-year history of a lump in the right parotid region. A total parotidectomy for a lesion in the deep part of the gland was performed on 20 March, 1964, with conservation of the facial nerve. The histological diagnosis was pleomorphic adenoma. The patient made a satisfactory recovery.

Follow-up was uneventful till 24 Nov., 1970, when the patient reported some discomfort in the lower third of the scar, radiating upwards and forwards into the face on movements of the neck. On examination there was a tender nodule in the region indicated in *Fig.* 1. Digital pressure on this nodule resulted in radiation of pain as the patient had described. On 12 March, 1971, the lump was excised with a wide margin of surrounding tissue; the proximal part of the great auricular nerve was found to run straight into the nodule, and 3 cm. of the nerve were excised with the nodule (*Fig.* 2). The histology of the excised mass (*Fig.* 3) was that of a typical amputation neuroma.

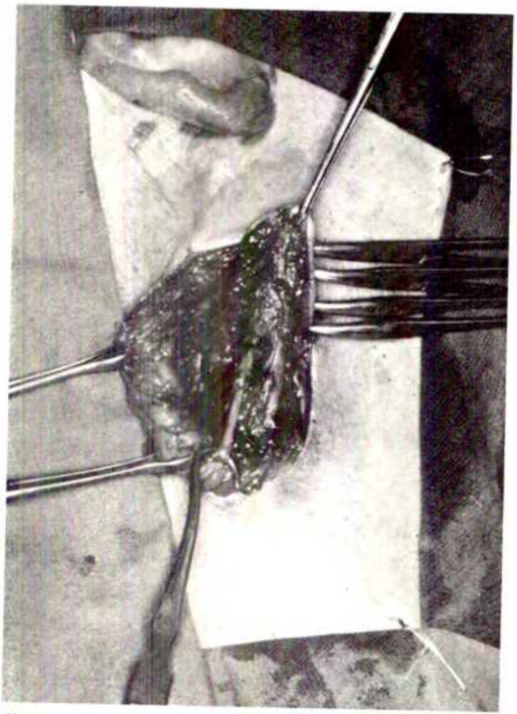

FIG. 2.—*Case* 1. The nodule is being explored. The stump of the great auricular nerve is stretched over the hook at the anterior border of the sternomastoid muscle and runs upwards and slightly forwards into the nodule. The latter was excised with a margin of normal subcutaneous tissue and the neighbouring part of the scar.

Case 2.—E. S., a female aged 42 years, presented in 1968 with a swelling in the right parotid region which had been slowly growing since she was a child. She was under treatment elsewhere for various symptoms and signs thought to be due to disseminated sclerosis. At operation on 8 Nov., 1968, a superficial parotidectomy was performed, with preservation of the facial nerve. Apart from a mild temporary paresis of the branches of the facial nerve to the right eye and lower lip recovery was uneventful. The histological diagnosis was pleomorphic adenoma. The facial weakness disappeared between 2 and 8 months later.

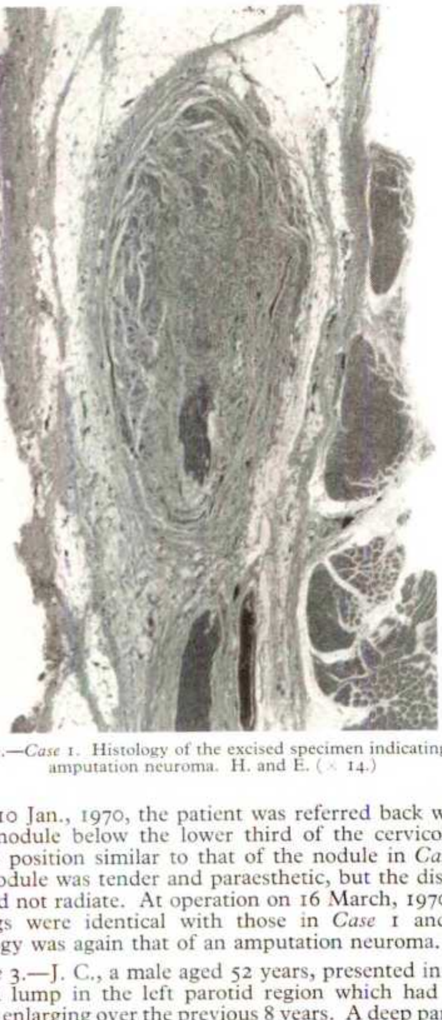

FIG. 3.—*Case* 1. Histology of the excised specimen indicating an amputation neuroma. H. and E. (× 14.)

On 10 Jan., 1970, the patient was referred back with a small nodule below the lower third of the cervicofacial scar (a position similar to that of the nodule in *Case* 1). The nodule was tender and paraesthetic, but the discomfort did not radiate. At operation on 16 March, 1970, the findings were identical with those in *Case* 1 and the histology was again that of an amputation neuroma.

Case 3.—J. C., a male aged 52 years, presented in 1968 with a lump in the left parotid region which had been slowly enlarging over the previous 8 years. A deep parotidectomy, i.e., removal of that part of the gland deep to the facial nerve with preservation of the nerve and the superficial part of the gland, was performed on 31 July, 1964. Recovery was uneventful. The histology of the excised gland showed a pleomorphic adenoma, with some areas suggesting a low-grade muco-epidermoid carcinoma.

On 9 May, 1967, mild gustatory sweating was noticed by the patient, and on 27 June a lump was noted in the subcutaneous tissue over the upper third of the anterior border of the sternomastoid. The lump was tender and the paraesthesiae produced by pressure radiated forwards and upwards into the face. No treatment was undertaken, and there has been no change in the size (1 cm. diameter) or tenderness of the lump during subsequent follow-up. The patient was last seen on 4 May, 1971.

Case 4.—T. D., a male aged 33 years, presented in 1968 with an 11-year history of recurrent right parotid swelling related at first to meals. Sialography showed a clinically dilated main parotid duct with a series of strictures and therefore parotidectomy was advised. Superficial parotidectomy was performed on 20 April, 1969, with conservation of the facial nerve. Recovery was uneventful. The histology of the excised gland showed non-specific chronic parotitis. Follow-up revealed no abnormality until 19 Jan., 1971, when a tender nodule was felt in a similar site as in the other 3 patients. There was no change in the findings on 4 May, 1971.

DISCUSSION

The great auricular nerve is usually one of the first landmarks to be encountered when the anterior border of the sternomastoid is defined during the operation of parotidectomy. It is standard practice that the nerve, which is usually present as two parallel branches, is divided at the muscle border. The theoretical possibility that the proximal cut end of the nerve might form an amputation neuroma was confirmed by the histological findings in *Cases* 1 and 2 The features of tenderness and paraesthesiae on pressure are similar to the clinical characteristics of amputation neuromata elsewhere and have been used to diagnose *Cases* 3 and 4 without recourse to excision biopsy.

A conservative policy seemed fully justifiable in *Case* 4 because the original operation was done for a non-neoplastic condition and in *Case* 3 such a policy has been vindicated by the lack of change in the nodule for 4 years.

It seems likely that the condition of amputation neuroma of the great auricular nerve is quite common. Knowledge of this possible diagnosis may save the patient and the surgeon needless worry, and in particularly characteristic cases may even obviate an unnecessary operation.

Recently it has been stated that the branches of th nerve running posteriorly (but not those anteriorly can be preserved in many parotidectomies (Patey 1969), and with this technique a palpable neurom has so far not been recognized (Patey, 1971).

Acknowledgement.—I am grateful to Mr. D. H Patey, who has seen several other examples of thi condition, for bringing it to my attention.

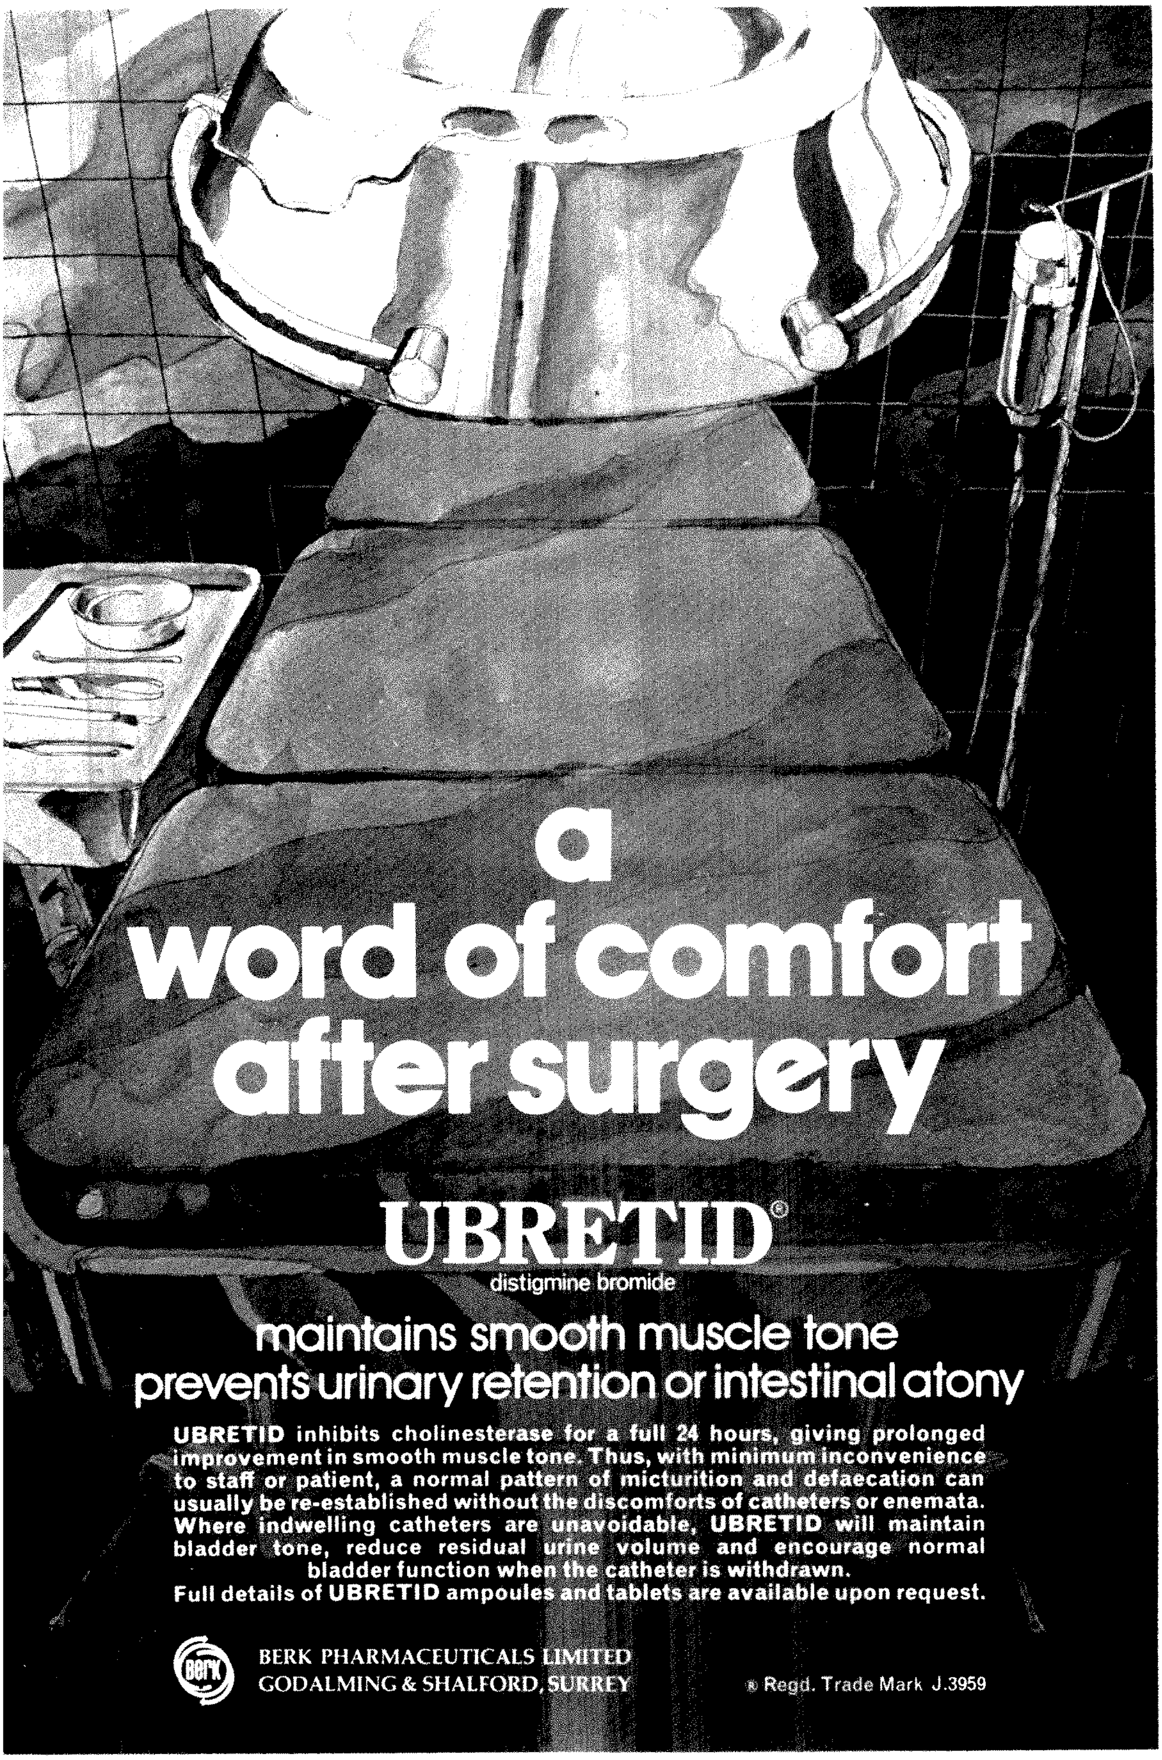
ADDENDUM

Since this article was written the author has seen more examples of the condition. The first patient, man of 31 years, had undergone elsewhere a super ficial parotidectomy for a pleomorphic adenoma i 1962, and on three occasions subsequently a nodul of similar tumour had been excised from the scar. fourth lump appeared in 1971 and had the feature of a neuroma as emphasized above, but because o the complicated history it was excised and the diag nosis of neuroma confirmed. In the other 2 patients a woman of 37 years whose parotidectomy for a pleo morphic adenoma had been performed 2 years prev ously, and a woman of 72 years whose parotidectom for an acinic-cell tumour had been performed 5 year previously, a clinical diagnosis of neuroma has bee made confidently and no excision performed.



UBRETID®

distigmine bromide

maintains smooth muscle tone
prevents urinary retention or intestinal atony

UBRETID inhibits cholinesterase for a full 24 hours, giving prolonged improvement in smooth muscle tone. Thus, with minimum inconvenience to staff or patient, a normal pattern of micturition and defaecation can usually be re-established without the discomforts of catheters or enemata. Where indwelling catheters are unavoidable, **UBRETID** will maintain bladder tone, reduce residual urine volume and encourage normal bladder function when the catheter is withdrawn.

Full details of **UBRETID** ampoules and tablets are available upon request.

SHORT NOTES OF RARE OR OBSCURE CASES

ANTEROPOSITION OF THE PORTAL VEIN AND SPONTANEOUS PASSAGE OF GALL-STONES

CASE REPORT AND EMBRYOLOGICAL HYPOTHESIS

BY WILFRID BROOK AND MICHAEL GARDNER
TORBAY HOSPITAL, TORQUAY

SUMMARY

A case of a woman who passed seven gall-stones 'per vias naturales' is presented. At subsequent operation for painful jaundice the portal vein was found to lie in front of the common bile-duct, although in its lower part it was retroduodenal.

A new embryological hypothesis to explain the preductal portal vein is presented.

THE spontaneous passage of gall-stones from the gall-bladder 'per vias naturales' has been regarded as an unusual happening, but in fact it is probably quite common and explains the rapid recovery observed in many cases of obstructive jaundice.

The case described here is 1 of the 20 cases which have been seen in the Torbay area during the past 8 years where the natural passage of stones has been proved (Gardner, Holden, and Monks, 1966). The second point worthy of record in this patient was the abnormal situation of the portal vein, which lay in a surgically hazardous position anterior to the common bile-duct.

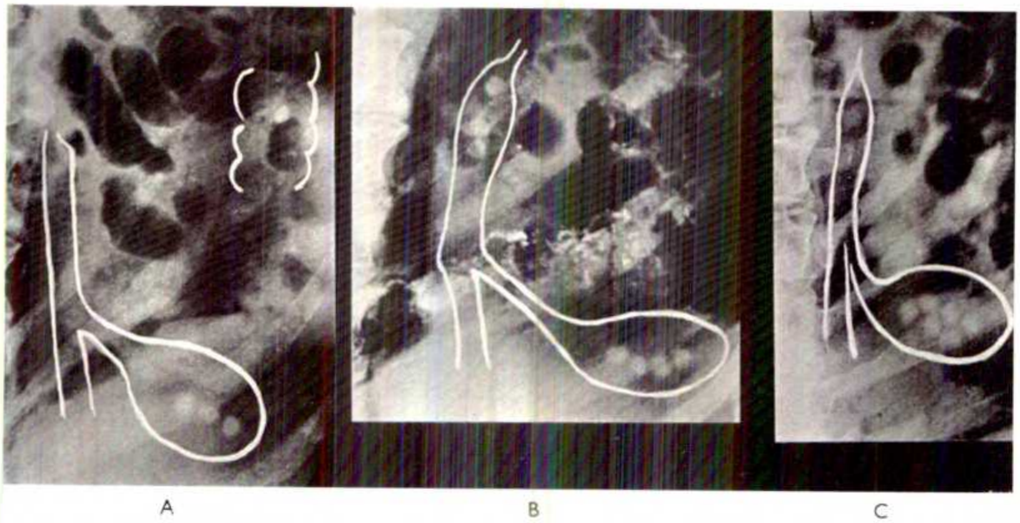

FIG. 1.—Serial straight radiographs showing the passage of seven radio-opaque gall-stones. For the sake of clarity the gall-bladder and main ducts have been outlined. A, Six stones are present in the gall-bladder and one in the common bile-duct (25 Jan., 1966). B, Four stones are present in the gall-bladder and three in the common duct (31 March, 1966). C, Three stones are present in the gall-bladder and one in the colon (9 April, 1966). A further radiograph on 15 April showed one stone in the common bile-duct, but none in the gall-bladder. At repeat examination 8 days later all the stones had disappeared.

CASE REPORT

L. B., a widow aged 84 years, had suffered attacks of biliary colic for 22 years following an attack of erysipelas complicated by pulmonary embolism, but jaundice had only been noticed during the past year. An especially severe attack necessitated her urgent hospital admission in January, 1966. Straight radiographs of the abdomen at this time showed seven radio-opaque stones (*Fig.* 1). A deep venous thrombosis in her leg dictated conservative treatment and during the next 4 months straight radiographs taken after further attacks of pain demonstrated the serial passage of all the stones (*Fig.* 1). Her symptoms then improved. Repeated cholecystograms during the subsequent 19 months failed to outline the gall-bladder, but 3 years later some return of function was demonstrated after a triple dose of contrast medium. However, she suffered recurrent attacks of painful jaundice and surgery became mandatory. At operation five black stones, 3 mm. in diameter, were found in an inflamed and partly disintegrated gall-bladder.

An attempt was made to locate the common bile-duct in the free edge of the lesser omentum in the usual way. Aspiration with a fine needle of the dark-coloured vessel that lay in the normal position of this duct produced only venous blood. In view of this the duct was explored by the transduodenal route. It soon became clear that the portal vein after emerging from behind the upper border of the duodenum came to lie anterior to the common bile-duct in its passage to the liver.

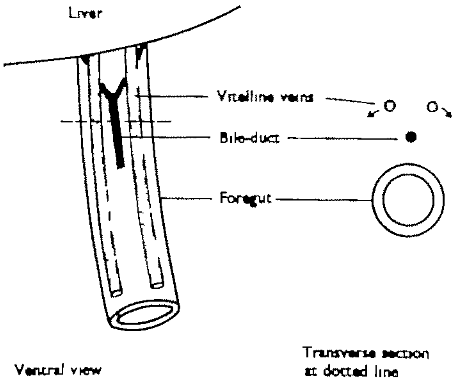

FIG. 2.—Vitelline veins in front of the foregut.

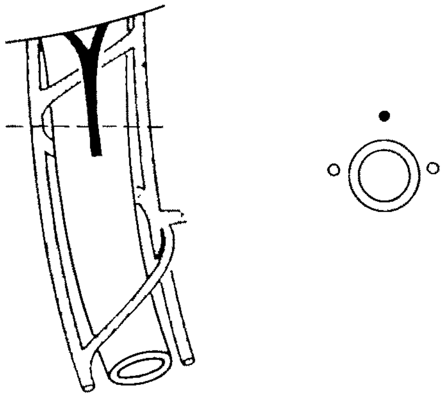

FIG. 3.—Cross-channels around the foregut. (*Modified from Last*, 1966.)

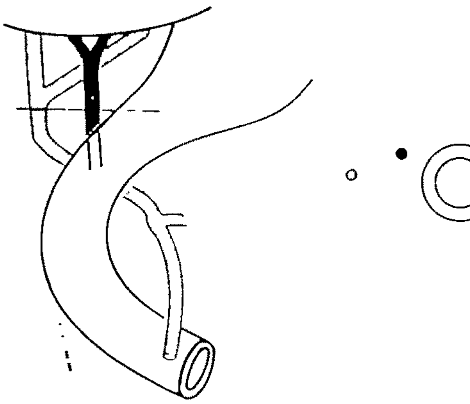

FIG. 4.—Development of the portal vein. (*Modified from Last*, 1966.)

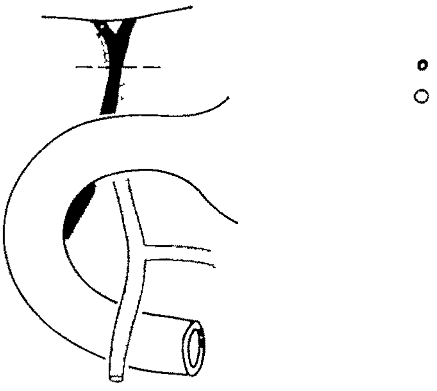

FIG. 5.—Final stage. (*Modified from Last*, 1966.)

Sphincterotomy of the ampulla of Vater was performed, and in view of the patient's past history of thrombo-embolism the inferior vena cava was narrowed by a silicone rubber clip to stop the upward passage of lethal-sized emboli to the lungs (Gardner, 1970).

Convalescence was uneventful apart from a further venous thrombosis in one leg and the patient has remained well during the past 2 years.

DISCUSSION

There is no reason in this case to postulate a connexion between the very rare condition of precholedochal portal vein and the relatively common phenomenon of spontaneous passage of gall-stones.

We have been able to find only 1 other recorded case where the portal vein passed up behind the duodenum and then continued upwards in front of the common bile-duct. This abnormality was discovered in a middle-aged woman during an operation for gall-stones (Greatrex, 1965). Other instances of anteroposition of the portal vein in the lesser omentum have been recorded, but in all of these the vein was anterior to the pancreas and duodenum in the lower part of its course. Indeed, in some instances this position had led to duodenal obstruction and to the discovery of the anomaly (Kakkar and Tompkin, 1968). A bleeding duodenal ulcer has been reported in association with an anteroposition of the portal vein (Bernard, Perry, and Walker, 1959) as have other developmental anomalies both local and distant, such as malrotation of the gut, biliary atresia (Renner and Child, 1963), cardiovascular defects, situs inversus, annular pancreas, and duodenal mucosal diaphragm (Boles and Smith, 1961).

Congenital Abnormalities of the Portal Vein.—In contrast to other veins anomalies of the portal vein are very rare, and they have been classified as follows (McGregor, 1963):—

1. The portal vein may empty directly into the inferior vena cava.
2. The vein, its formative vessels, and tributaries may lie anterior to the pancreas and duodenum.
3. The pulmonary veins may join the portal vein.
4. Congenital strictures of the vein may occur.

Embryology of the Portal Vein.—The normal ortal vein develops from the two vitelline veins and he anastomoses between them around the embryonal luodenum. Originally the paired vitelline veins eturn blood from the yolk sac to the heart. They un upwards, at first ventral (*Fig.* 2), and then later ne on each side of the gut (Davies and Davies, 962), the right and left veins communicating with ach other by cross-channels (*Fig.* 3). Parts of this enous system disappear and the portal vein develops rom the persistent caudal part of the left vitelline ein and the cranial segment of the right vitelline ein joined together by a persisting cross-channel hat passes behind the part of the foregut that ultimately becomes the first part of the duodenum. The S'-shaped vein so formed straightens out and with he rotation of the duodenum finally becomes the ortal vein (*Figs.* 4, 5).

To explain the abnormal retroduodenal-preductal osition of the portal vein Greatrex (1965) postulated he persistence of the cranial part of the left vitelline ein and the right caudal vitelline vein with development of a cross-anastomosis in an abnormally anterior lane (*Fig.* 6), as in his patient the portal vein crossed rom right to left in front of the common bile-duct. We suggest as an alternative explanation that the cranial segment of the right vitelline vein may fail to move from its original position in front of the gut to its normal embryonic position alongside it (*Fig.* 7).

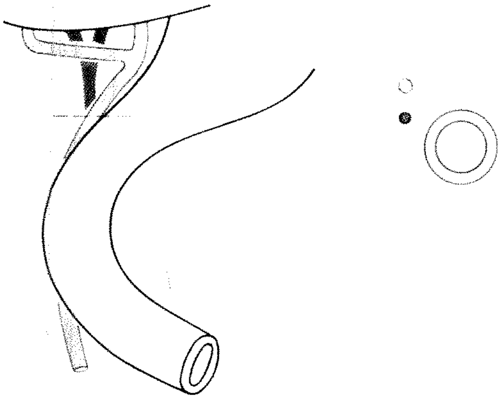

FIG. 6.—Greatrex's (1965) explanation of the development of a preductal portal vein.

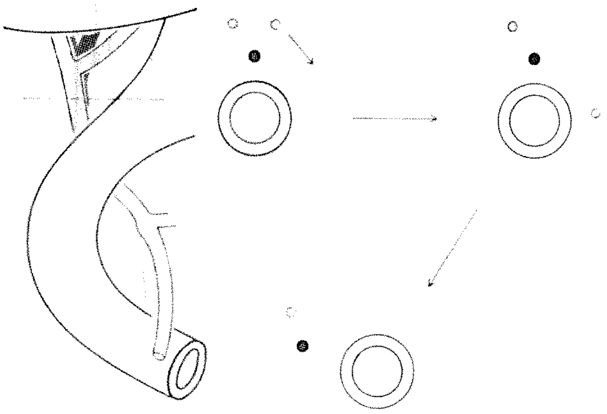

FIG. 7.—Development of a preductal portal vein. It is postulated that the cephalic portion of the right vitelline vein has remained in its original anterior plane.

Acknowledgement.—We are indebted to Dr. Gerald Crawford of the Department of Anatomy, Oxford University, for his help with our embryological problem.

MESENTERIC NEUROFIBROMATOSIS IN CHILDHOOD

BY S. CYWES AND MARGARET J. MAYELL*

RED CROSS WAR MEMORIAL CHILDREN'S HOSPITAL, CAPE TOWN, SOUTH AFRICA

SUMMARY

A child is reported in whom severe malabsorptive ymptoms were present from a short time after birth ogether with increasing pseudo-obstructive episodes. Total neurofibromatous involvement of the small-owel mesentery was found at laparotomy at the age of 4½ years. The child survived a further 2¼ years. The relevant literature is discussed.

NEUROFIBROMATOSIS is a not-infrequent genetically determined disorder, the first clinical signs of which usually appear during late childhood or adolescence. As a mode of presentation malabsorption is rare at any age. The following case, for whom there appears

to be no parallel in the literature, showed the features of malabsorption and pseudo-obstruction from the first weeks of life, developed café-au-lait spots at 4½ years, and died from the effects of gastro-intestinal functional impairment 2 years later.

CASE REPORT

H. E., aged 1¾ years, was admitted to the Red Cross War Memorial Children's Hospital, Cape Town, in October, 1963, with a 7-day history of vomiting, diarrhoea, and abdominal distension. Further inquiry revealed, however, that although the recent episode was of 7 days' duration, with abdominal distension as a new feature, the patient had in fact been having episodes of vomiting with the passage of bulky, loose, offensive stools since birth, each episode lasting 5–7 days and recurring every 2 weeks. Initially the child had been fed on a powdered milk formula; since weaning her diet seemed perhaps to have been of a rather poor quality. She had been born on 15 Dec., 1961, by spontaneous vertex delivery to a healthy 36-year-old mother; the birth weight was 3 kg. There were 3 older siblings, 1 of whom had congenital heart disease.

Examination revealed a pale, undernourished, apathetic child, weighing 8·85 kg., with oedematous hands and feet, a generalized skin rash, and a very distended, tympanitic abdomen with visible loops of bowel.

Investigations showed a haemoglobin of 7·25 g. per cent, a reticulocyte count of 2·8 per cent (rising to 12 per cent during treatment), a reversed serum albumin/globulin ratio, a positive culture of *Salmonella* in the stool, and a megacolon on barium-enema examination. The megacolon was not thought typical of Hirschsprung's disease. Other investigations included a chest radiograph, blood-urea, cholesterol, calcium, phosphate, and alkaline

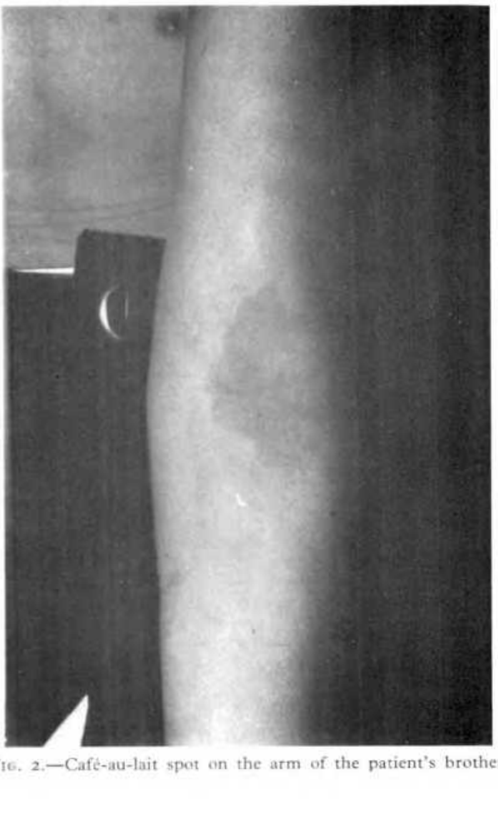

FIG. 2.—Café-au-lait spot on the arm of the patient's brother.

phosphatase estimations, and a sweat test. These showed no abnormality.

Treatment of the iron-deficiency anaemia and the *Salmonella* enteritis was given and the child improved to some extent. After 8 weeks her weight had risen to 10 kg. and she was discharged home on a toddler diet. She was still having several vomits and loose stools daily.

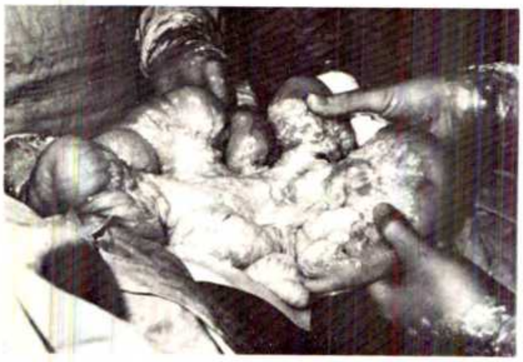

FIG. 3.—Operative findings in the small-bowel mesentery.

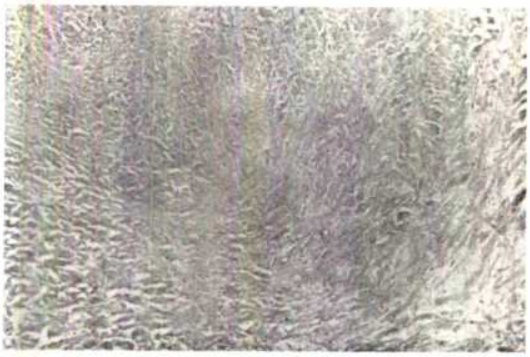

FIG. 4.—Histology of the biopsy specimen showing features of neurofibromatosis.

Her next admission, in August, 1965, was again for the nvestigation of recurrent episodes of vomiting and abdominal distension; diarrhoea had become less of a problem. She had been admitted twice to another hospital with the same symptoms earlier in 1965 but investigation had failed to reveal any obvious causative pathology. The episodes of vomiting and abdominal distension now lasted for 2–7 days and recurred every 4 weeks. Examination showed a similar picture to that on the previous admission —the child was grossly underweight at 11·8 kg., having gained only 1·8 kg. in the preceding 20 months, her abdomen was greatly distended, masses were palpable, and the liver was enlarged by two fingers' breadth. Rectal examination was thought suggestive of Hirschsprung's disease. A full investigation, including a rectal biopsy, failed to reveal any abnormality consistent with her clinical features. Symptomatic treatment, including a controlled diet, aperients, and rectal wash-outs, was carried out with some improvement.

Her symptoms continued unabated and in June, 1966, at the age of 4½ years, she was again transferred from another hospital where she had undergone further intensive investigation. On this occasion a family history of tuberculosis was obtained and both the patient and 2 of her siblings were found to have café-au-lait skin lesions *Figs.* 1, 2). Her weight had fallen to 11·47 kg. and her abdomen was tender and distended with palpable masses and free fluid present. Chest and abdominal radiographs showed features compatible with a diagnosis of tuberculosis, the Heaf test was positive, and the erythrocyte sedimentation rate was elevated.

Laparotomy on 4 July, 1966, showed, however, not tuberculosis but diffuse tumour infiltration of the whole depth of the mesentery of the entire small bowel from the posterior abdominal wall, where it measured 15 cm. in breadth, to the mesenteric border of the bowel (*Fig.* 3). There was no obvious abnormality of the bowel itself. Biopsy showed the tumour infiltration to be typical of neurofibromatosis (*Fig.* 4). Further surgery was not feasible.

The child made a good postoperative recovery and was discharged home. During the succeeding 2¼ years she became increasingly weak and ill as a result of recurring anaemia, hypoproteinaemia, and chest infections (*Fig.* 5); supportive therapy included blood and plasma transfusion, the use of intravenous fat and amino-acid solutions, and antibiotics. In addition she was admitted on six occasions with the features of acute intestinal obstruction, e.g., vomiting, abdominal pain, distension, hyperactive bowel sounds, and visible peristalsis. Although treated on each occasion by intravenous fluids, nasogastric aspiration, and low-bowel wash-outs these acute episodes usually seemed to settle spontaneously rather than as a result of therapy and the bowel would start to function again. A 24-hour stool-fat estimation during a functional period was 27·7 g. The child's condition deteriorated progressively, however, and she eventually died at home in October, 1968, at the age of 6¾ years.

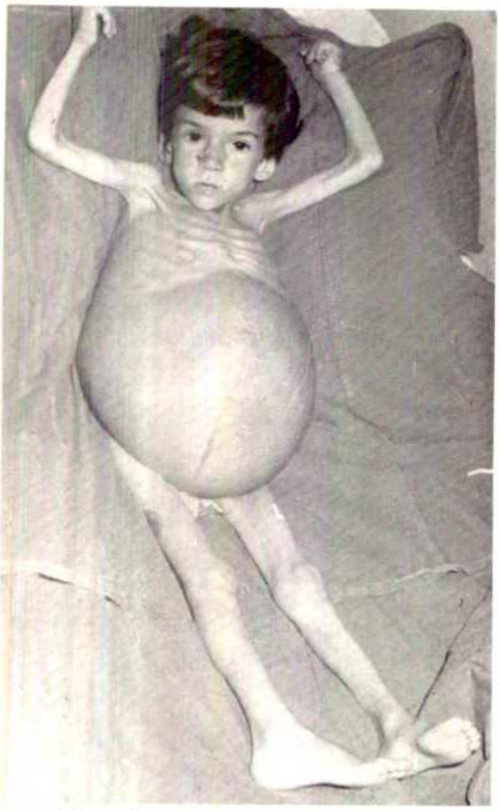

FIG. 5.—The patient, aged 6½ years, during the last hospital admission.

DISCUSSION

Neurofibromatosis, commonly named after von Recklinghausen who described it in its generalized form in 1882, is a hamartomatous disorder characterized principally by nerve-sheath tissue overgrowth but also by malformations of other tissues and secondary functional effects. It is genetically determined, the gene being an autosomal dominant with a variable degree of expression; this results in great variation in the clinical picture seen, from the full generalized syndrome through incomplete to monosymptomatic forms.

A family history is not obtained in all cases because (1) the relatives may only develop the clinical signs late in life, (2) the disorder in the relatives may be very mild and remain clinically unrecognized, and (3) a proportion of cases are the result of spontaneous gene mutation. The histogenesis is hard to understand and has been the subject of much debate. The hamartomatous nerve-sheath overgrowth contains both ectodermal (Schwann cell) and mesodermal (endo- and perineurial fibroblasts) derivatives in varying proportions. One possibility is that the endoneurial and perineurial fibroblasts are of Schwann-cell origin since Schwann cells have been shown to produce collagen in tissue culture and in neurolemmal tumours. The other possibility is that nerve sheaths may develop from a common blastema formed of both ecto- and mesodermal components, the ultimate cell differentiation being determined more by the proximity to the growing axon than by the cell of origin (Willis, 1962).

Reviews of the condition as it presents in childhood are few. Fienman and Yakovac (1970) report 46 cases collected over a 22-year period at the Children's Hospital of Philadelphia. They found a family history in 21 cases and clinical signs at birth in 20. The most common presenting sign was café-au-lait spots, or enlarging superficial tumours, or both. During the follow-up period serious central neural lesions occurred in 12 children, 19 cases had musculoskeletal pathology, and 4 had significant vascular pathology. In no case in this series did gastro-intestinal pathology feature at any stage.

A search of the literature for cases similar to the present one, with major gastro-intestinal involvement presenting in childhood, reveals 4 relevant publications. That of Chalkley and Bruce (1942) reports the case of an 8-year-old girl who presented with malnutrition and an abdominal mass. She was found to have neurofibromatous involvement of the mesentery of the terminal 80 cm. of ileum and of the whole colon to the sigmoid loop. She underwent excision with a good early result. There was no family history and the presence or absence of skin lesions is not recorded. Lane and Hooper (1964) report a fit, well-nourished, 8-year-old boy with café-au-lait pigmentation, who was found to have an abdominal mass at routine examination for another purpose. This proved to be neurofibromatous involvement of the mesentery supplying 35 cm. of ileum. Excision gave a good result. Contzen (1952) reported a 12-year-old girl who presented with a 4-year history of recurrent abdominal pain, an abdominal mass, café-au-lait spots, and other evidence of generalized neurofibromatosis. Laparotomy revealed neurofibromatous involvement of the ascending an transverse mesocolon which was amenable to excision The child subsequently died as a result of sarcomatou change in a cervical neurofibroma. The fourth case that of Ternberg and Winters (1965), is of interes because symptomatically it most closely resembles th present case although the mesentery was not primaril involved. The child, a boy, presented at 4½ years wit considerable emaciation, constipation, and café-au-lai pigmentation. A barium enema showed a megacolo but, on rectal biopsy, ganglion cells were present. Th patient's symptoms were severe and a Swenso procedure was carried out. His symptoms continue unchanged and at the age of 7½ years a further biops still showed ganglia to be present but also demonstrated replacement of the myenteric plexuses b neurofibromatous infiltration. A further excision o colon back to apparently normal bowel was done bu neurofibromatous tissue remained.

Two adults are reported with localized neurofibromatosis of the mesentery (Dudley, 1930; Barton an Inglis, 1931), and 1 case is recorded with simila involvement of the greater omentum (Thomas an Jelliffe, 1953). Two of these 3 patients had precedin café-au-lait pigmentation. The presenting symptom were, respectively, subacute obstruction due t kinking of the adjacent bowel, gastro-intestina haemorrhage, and an abdominal mass. Cases o mesenteric involvement secondary to a neurofibrom of the bowel wall are more numerous and no relevant to this discussion.

The case reported here differs from the case recorded in the literature in that the mesenteri involvement was very much more extensive an therefore quite unamenable to surgical resection. I seems possible, in the light of the case of Ternber and Winters (1965), that our patient may also hav had involvement of the myenteric plexuses of th colon.

Cytotoxic agents were not exhibited in this cas although both nitrogen mustard and cyclophosphamide have been tried in generalized neurofibromatosis (Hayes, Spurr, Felts, and Miller, 1961 Gulati, 1966).

CHRONIC SCHISTOSOMAL APPENDICITIS

BY J. C. VOIGT* AND M. M. GREGORY
ROYAL FREE HOSPITAL, LONDON

SUMMARY

A case of schistosomiasis of the vermiform appendix in an immigrant patient is presented.

CASE REPORT

THE patient was a 29-year-old Nigerian woman who had been in England for 5 years. She had 1 child aged 3½ years, and the menstrual cycle was normal. On presentation at the Royal Free Hospital she complained of right-sided abdominal pain which had persisted for 1 year. There were no urinary or alimentary symptoms. On examination the only abnormality was an indefinite tender cystic swelling, possibly the caecum, felt in the right iliac fossa and also through the right vaginal fornix.

Investigations included the following: haemoglobin, 13·2 g. per 100 ml.; sickle test, positive (trait); white cell count, 6000 per c.mm., with 1260 eosinophils. A chest radiograph was normal. An intravenous pyelogram suggested slight medial displacement of the pelvic portion of the right ureter but showed no other abnormality.

The right-sided abdominal pain was of sufficient severity to interfere with the patient's daily activities, and she was admitted in due course for laparotomy. This was done through a right paramedian incision on 30 April, 1971. The liver and gall-bladder were seen and felt to be normal. The kidneys, spleen, stomach, duodenum, and pelvic organs also appeared normal. The caecum was not unusual, but the vermiform appendix had a yellowish colour and was tethered by several old inflammatory adhesions. Appendicectomy was carried out, and the postoperative progress was satisfactory.

Histological examination showed chronic inflammation and fibrosis of the appendix with many schistosome ova, some of which were calcified (*Figs.* 1, 2).

In the postoperative period further repeated urine and stool specimens were examined, but no ova or parasites were found and no blood was present. Liver-function tests were normal. Two weeks after operation a liver biopsy was obtained and the only abnormality was the presence of scanty, fine, dark-pigment granules of a schistosomal type lying in the portal tract phagocytes; no ova were seen and there was no fibrosis. Six days later *Schistosoma haematobium* ova were found in an unstained rectal biopsy. It was proposed to complete investigations with a cystoscopic examination, but the patient was now well and declined further investigation.

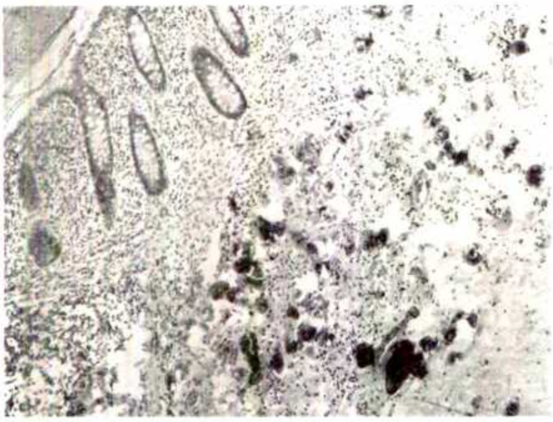

FIG. 1.—Section of the wall of the appendix showing many schistosome ova in the fibrotic and inflamed submucosa. H. and E. (× 40.)

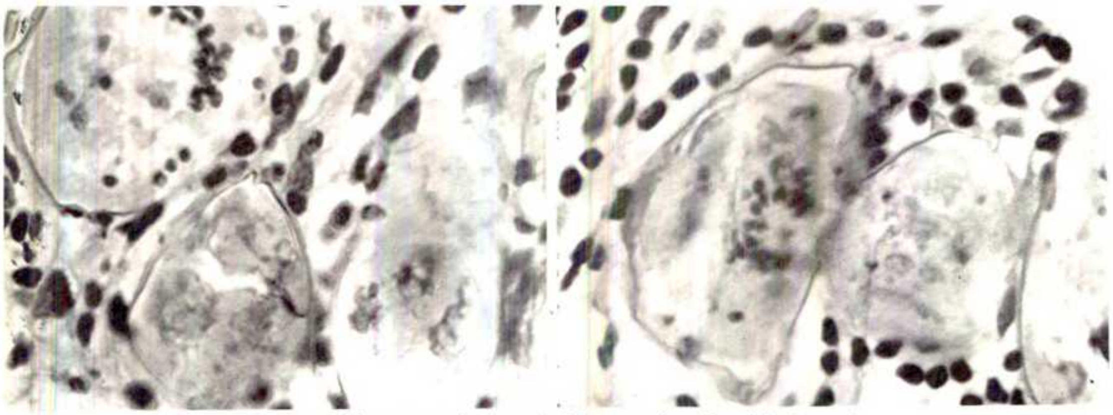

FIG. 2.—Schistosome ova in the wall of the appendix. H. and E. (× 550.)

DISCUSSION

Diagnosis in this case would not have been achieved without the histological examination of the appendix. The mild eosinophilia suggested a parasitic infection, but repeated stool and urine examinations were negative. Several rectal biopsies were needed before an ovum was found.

---

* Present address: Hillingdon Hospital, Uxbridge, Middlesex.

Bowesman (1960) estimated that in West Africa about 20 per cent of cases of chronic appendicitis are due to schistosomiasis. These patients invariably have low-grade chronic discomfort, but the appendix is seldom acutely inflamed. A yellowish tingeing of the appendix owing to schistosomal pigment is sometimes seen at operation. No cases of post-appendicectomy faecal fistula have been noted in these patients.

Talib (1967) mentioned that recurrent appendicitis due to *S. haematobium* infection is common in Iraq. Ibrahim, El-Mazni, and Bahnassy (1968) described the disease in Egypt and stressed the frequency of mixed *S. mansoni* and *S. haematobium* involvement of the appendix, colon, and rectum. Mynors (1957) reported *S. mansoni* involvement of the distal small bowel in the Sudan, resembling a regional ileitis.

Gelfand (1967) made caustic potash digests of autopsy material in southern central Africa and counted the number of ova. In a series of 72 autopsies on subjects affected by bilharziasis 45 (62·5 per cent) appendices showed the presence of ova. All contained ova of *S. haematobium*, but, in addition, ova of *S. mansoni* were present in 6.

In conclusion, schistosomal infection of the vermiform appendix may be an incidental finding in endemic areas. It may, however, cause recurrent or chronic appendicitis and this possibility must be remembered in patients who have come from parts of the world where the schistosome is found.

Acknowledgements.—We are indebted to Dr P. J. Scheuer for the histology of the liver biopsy, to Dr. P. D. Marsden for the rectal biopsy, and to Dr I. A. D. Bouchier for permission to report this patient. We also thank Mr. C. Gilson for the photographs.

FOREIGN-BODY PERFORATION OF A JEJUNAL DIVERTICULUM

By MALCOLM FIDLER

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

Perforation of a jejunal diverticulum is usually the result of inflammation. A second example of a much rarer cause of perforation due to a foreign body is described together with a brief review of the literature.

The presence of jejunal diverticula is an infrequent radiological and operative finding, and such diverticula are present in only 0·2 per cent of autopsies (Browne and McHardy, 1940; Altemeier, Bryant, and Wulsin, 1963). Perforation is not rare but, to date, only 1 case of perforation by a foreign body has been reported (Navarre and Schmidt, 1958). A further case of foreign-body perforation is reported here, together with a review of the complications of jejunal diverticulosis and a discussion of the difficulties of diagnosis and treatment.

CASE REPORT

Mr. V. T., aged 64 years, was admitted as an emergency to University College Hospital, London, in November, 1969, with a 5-hour history of severe epigastric pain. The pain had begun suddenly and had been constant in nature, causing him to roll about. After about 15 minutes the pain had remitted, but had returned 30 minutes later and had remained constant since. The patient complained of nausea but had not vomited. There was no previous history of significant abdominal pain or indigestion. He had eaten fish on the previous day.

Examination.—The patient looked generally ill. He had false teeth and his tongue was dry; his temperature was 36·7° C. and his pulse was regular at 84 per minute Palpation of the abdomen revealed generalized tenderness rebound tenderness, and muscular rigidity, the signs being most marked in the epigastrium. A small, reducible right inguinal hernia and a small epigastric hernia were present. Rectal examination was normal.

Straight abdominal radiographs showed a little free gas under the left dome of the diaphragm and a few distended coils of jejunum.

A provisional diagnosis of perforated peptic ulcer was made and, following resuscitation, laparotomy was undertaken.

Operation.—The abdomen was opened through a right paramedian incision. There was copious free faeco-purulent fluid in the peritoneal cavity. As there was no obvious source of the fluid, the duodenum, stomach, large bowel, and appendix were examined and found to be normal Attention was then turned to the small intestine. The jejunum from 15 to 40 cm. distal to the duodenojejunal flexure was the site of numerous small diverticula on the mesenteric border. One of these, which was 2 cm. in diameter and larger than the others, had been perforated at its apex by a 2-cm.-long fish bone. As the patient's condition was satisfactory and only a short (25 cm.) length of bowel was involved with diverticula, it was decided to resect the whole affected segment to prevent future complications from any residual diverticula. Intestinal continuity was restored by an end-to-end anastomosis. The patient made a satisfactory recovery from the operation.

DISCUSSION

The first description of a false diverticulum of the intestine is usually attributed to Sömmering in 1794 (Fischer, 1900), and in 1807 Sir Astley Cooper included illustrations of jejunal diverticula in his monograph on hernia. In 1881 Osler described a patient with 55 diverticula of the jejunum demonstrated at autopsy. The first published account of an operation on jejunal diverticula was by Gordinier and Sampson (1906), who described a case where inflammation of a diverticulum in the lower jejunum or upper ileum had caused intestinal obstruction. Since then there have been several reports of jejunal diverticula and their complications which, according to Herrington (1962), occur in less than 10 per cent of cases. The complications have been summarized by MacGregor and Hamilton (1970) and the most important are, in order of frequency, malabsorption, haemorrhage, perforation (inflammatory or traumatic), diverticulitis without perforation, obstruction, volvulus, pneumoperitoneum, ectopic pancreatic tissue, and malignant disease.

Perforation of a jejunal diverticulum is most commonly the result of diverticulitis (Thorek and Manzonilla, 1954). Three cases of perforation following closed injury to the abdomen have been reported by Herrington (1962), and 1 case of perforation by a 3-cm.-long piece of bone in a patient who had had difficulty in chewing steak with his new false teeth (Navarre and Schmidt, 1958).

Probably the most important factor in arriving at a correct preoperative diagnosis is to bear the likelihood of this condition in mind, even though the previous history may not provide any indication as to the existence of these diverticula. In many cases, as in the patient reported here, the diagnosis will be thought to be perforated peptic ulcer and the true state of affairs will only be discovered at laparotomy. Even when the abdomen is open the diagnosis may not be obvious, and if a generalized peritonitis is found and the more common causes have been excluded the possibility of perforation of a jejunal diverticulum should be considered. That it may be difficult to demonstrate is shown by the fact that in some reported cases the diagnosis was only made at autopsy following an unproductive laparotomy. Welsh (1966) has described a technique of demonstrating diverticula, involving the distension of short lengths of the jejunum by 'milking' the bowel contents along.

Following the discovery of a perforated jejunal diverticulum, the treatment will differ according to circumstances and this may be summarized as follows:

1. Resect all the involved segment if the patient's age and condition permit this and not too much intestine is involved.
2. If much intestine is involved, resect the perforated segment and emphasize, for future reference, in the notes and to the patient that more diverticula remain. The procedure may be limited to excision only of the perforated diverticulum.
3. Invaginate the diverticulum.
4. Suture the perforation and cover with an omental patch in the old and very ill.

Acknowledgement.—I should like to thank Mr. David Bailey for his help and advice in the preparation of this article and for allowing me to publish details of the patient who was under his care.

NICKEL SENSITIVITY TO SURGICAL SKIN CLIPS

BY LAURENCE F. TINCKLER
FORMERLY PROFESSOR OF SURGERY, UNIVERSITY OF SINGAPORE

SUMMARY

1. A case of hitherto unrecorded skin sensitivity to surgical skin clips is reported.
2. A sensitivity test revealed that the sensitivity was to the nickel constituent of the copper/nickel alloy of which surgical clips are manufactured.
3. It is suggested that when the use of skin clips is anticipated inquiry should be made of the patient as to the previous experience of sensitivity to metal articles of attire and the use of skin clips consequently avoided if the reply is affirmative.

As there is no record of nickel sensitivity to surgical skin clips having previously been reported it is felt that the following case history will be of interest.

CASE REPORT

The patient, a male aged 57 years, presented with chronic intractable duodenal ulceration for which vagotomy and pyloroplasty was carried out in June, 1970. The midline upper abdominal incision was closed with metal skin clips.

The patient's postoperative recovery was complicated by pulmonary atelectasis superimposed upon his chronic bronchitis. On the eighth postoperative day a skin rash appeared surrounding the abdominal wound and which spread to involve a wider area of the abdominal wall, the elbow flexures, the area behind the knees, and the buttocks (*Figs.* 1, 2). The rash was initially erythematous, later becoming exudative with crusting and scaling. The patient was treated with Betnovate ointment and as the skin reaction was considered to be due to sensitivity to the skin clips—the rash first appearing in relation to the clips—these were promptly removed. Subsequently the rash in all the areas progressively faded and disappeared some 2 weeks after its initial appearance.

On detailed inquiry of the patient's past history it was revealed that some years previously he had noted a skin sensitivity to wrist watches, buckles, and collar studs. He had consequently discontinued wearing these articles.

A sensitivity patch test was carried out on the skin of the patient's back by fixing a sixpence in position with adhesive strapping. Within 48 hours the reaction shown in *Fig*. 3 resulted, evidently as a response to the nickel in the coin. A similar reaction was noted in relation to a skin clip applied to adjacent skin at the same time. Nickel sensitivity was further confirmed by a formal skin test using nickel sulphide (*Fig*. 4).

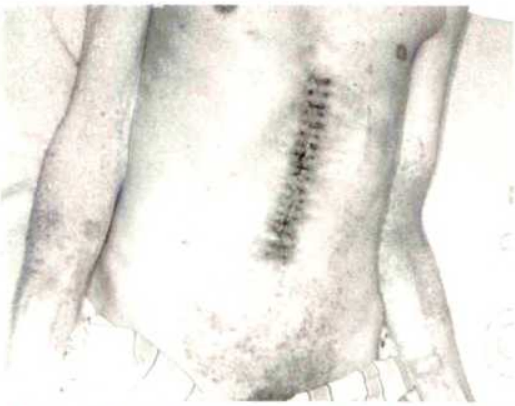

FIG. 1.—Skin-sensitivity reaction in relation to the site of the metal surgical skin clips and the metastatic rash on the abdominal wall and flexure aspect of the arms.

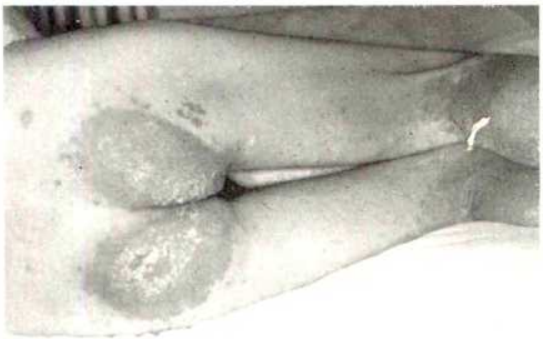

FIG. 2.—Metastatic skin sensitivity rash involving the buttocks and the flexure aspect of the legs.

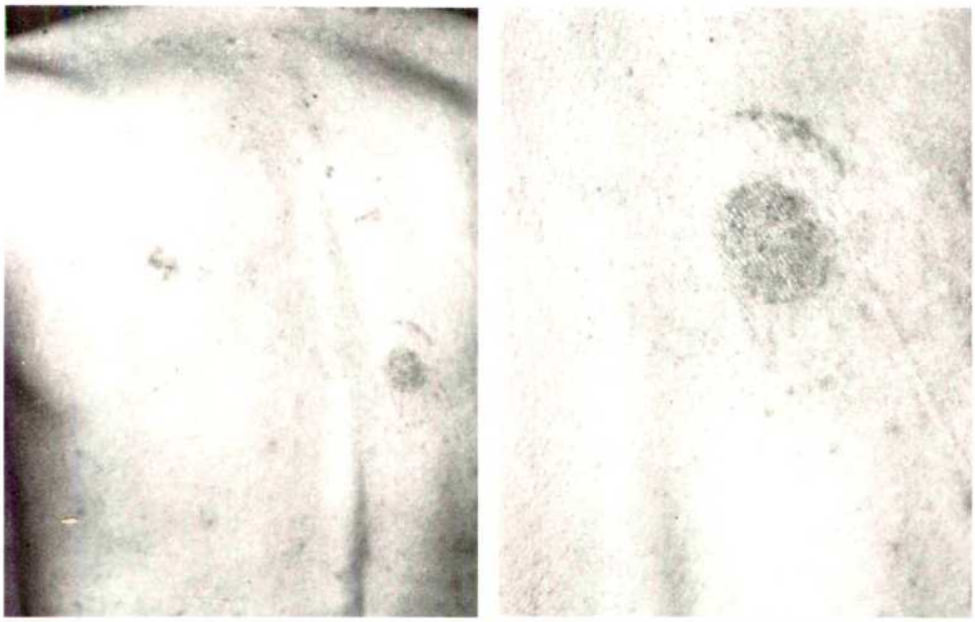

FIG. 3.—Skin reaction to a sixpence and a metal skin clip applied to the skin as a sensitivity test.

DISCUSSION

Nickel sensitivity is five to eight times more common in women than in men, and in the United Kingdom nickel is the single most common cause o contact dermatitis in women.

In 80–90 per cent of women with nickel sensitivity suspected dermatitis is the first manifestation women usually being sensitized by objects worn close to the skin such as suspenders, brassière fasteners ear-ring clips, necklace fasteners, and wrist watche and straps. Men, on the other hand, are more likely to develop nickel sensitivity by occupational exposure.

Secondary eruptions of the skin in areas other than those in direct contact with the nickel-containing articles are a characteristic feature of nickel dermatitis and occur in 80–90 per cent of patients. These secondary eruptions commonly start shortly after o at the same time as the primary eruption and in rare cases even precede it. Spread to other parts of th body may be caused by traces of nickel on th finger-tips but another possibility is that it is an autoimmune response. The elbow flexors and flexor surfaces of the arms and legs are the most common sites of the secondary eruptions (Rook, Wilkinson, and Ebling, 1968).

In men nickel dermatitis is predominantly of an occupational origin but some people are sensitized by the buckles of wrist watches, spectacle frames, collar studs, cuff links, and zip fasteners, as evidently was the present patient.

In the case reported here direct questioning of the patient revealed that many years previously he had abandoned wearing a wrist watch and the use of collar studs because he was aware that these articles provoked a rash involving the adjacent skin.

Although nickel sensitivity to surgical skin clips must be an uncommon occurrence, when a surgeon uses skin clips routinely for wound closure it is probably a wise precaution to ask the patient preoperatively about any previous experience of skin eruptions when in contact with metal objects. This question can be included in the inquiries routinely made into previous sensitivity to such agents as penicillin. If the patient gives a positive answer the use of skin clips should be avoided, closing the skin instead with suture material.

The rapidity of onset and the extent of the secondary eruption in the present case were probably related to the fact that the skin clips punctured the skin, thus increasing the opportunity for nickel to be absorbed and for a sensitivity reaction to develop.

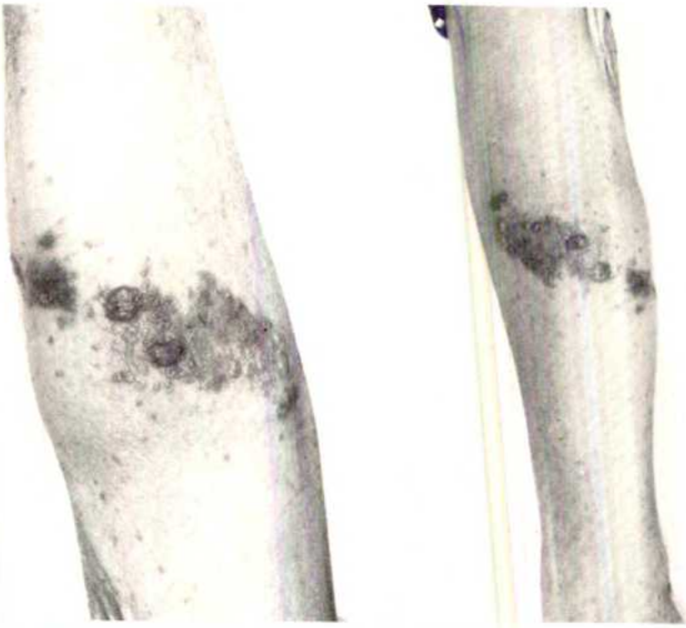

FIG. 4.—Result of a formal nickel sensitivity skin test carried out with the application of nickel sulphide.

An inquiry to the manufacturers of the surgical skin clips revealed that the clips are composed of cupronickel in the proportions of 80 per cent copper to 10 per cent nickel, the remainder being zinc with traces of lead as an impurity, and that the manufacturers were unaware of the possibility of sensitivity to their clips.

This case raises the question whether metal sensitivity to the staples used in stapling machines for intestinal anastomosis is a potential hazard. Staples should not perhaps be used indiscriminately but only after questioning the patient to eliminate the possibility of metal sensitivity.

REVIEWS AND NOTICES OF BOOKS

Lumbar Disc Disease. Edited by Blaine S. Nashold, jun., M.D., Durham, N.C., and Zdenek Hrubec, Sc.D., Washington, D.C. 10 × 7 in. Pp. 139 + xiii. Illustrated. 1971. London: Henry Kimpton. £7·45.

This monograph gives the results of a 20-year clinical follow-up study from seventeen Veterans Administration Hospitals in the United States of America. The follow-up was the result of teamwork in which many orthopaedic surgeons, neurosurgeons, and radiologists took part.

Although the report raises more questions than it answers it does reveal certain facts.

Myelography is a safe procedure with few side-effects and the dye is not always absorbed as judged by the fact that it was still visable in some cases after 20 years. Radiographs may reveal degenerative changes in the disks although no clinical evidence may be found.

Pain was immediately relieved in a significant percentage of the patients by operation. It was noted that patients with intractable sciatica plus motor symptoms appear to be treated best by operation, but surgery may not relieve motor signs.

A large number of tables are included in this book, giving a detailed list of residual signs and symptoms. Goniometer readings of the spine movements are also included.

This investigation brings out the fact that we as yet know little about the final results of disk lesions in the lumbar region.

Ellison's Atlas of Surgery of the Stomach and Duodenum. By Larry C. Carey, M.D., Pittsburgh, Pennsylvania, and Robert H. Albertin, M.A., Milwaukee, Wisconsin. 12 × 9½ in. Pp. 165 + xii, with 349 illustrations. 1971. London: Henry Kimpton. £11.

This large atlas depicting various operative procedures on the stomach and duodenum will be of real value to all students and postgraduates who wish to have an accurate impression of these various techniques.

The wash illustrations show the various stages of the different operations. The drawings are excellent and very clear. This is by far the best illustrated atlas of the surgery of the stomach and duodenum that has so far been published.

Operations for splenectomy, distal pancreatectomy, and liver biopsy are also included.

An Introduction to Clinical Research. By W. P. Small, V.R.D., Ch.M., F.R.C.P.E., F.R.C.S.E., Edinburgh, and Urban Krause, M.D., Uppsala, Sweden. 8½ × 5½ in. Pp. 125 + ix, with 46 illustrations. 1972. Edinburgh: Churchill Livingstone. £1·50.

This is a useful and practical paperback which should be read by all clinicians who are interested in the long-term follow-up of their cases. It will appeal particularly to surgeons who wish to know the results of different forms of treatment.

It is interesting to compare and contrast the methods adopted in Edinburgh and Uppsala in Sweden. The problems of financing long-term follow-up are discusse at length.

It is pleasing to see reproduced part of one of Lor Lister's ward books from the Royal Infirmary Edinburgh in which the final result of treatment recorded.

Surgery Annual 1971. Edited by Philip Coope M.D., Florida, and Lloyd M. Nyhus, M.D Chicago. 9¼ × 6¼ in. Pp. 444 + xiv. Illustrated. 197 London: The Butterworth Group. £7.

This book with its numerous contributors, mainly fro American medical centres, deals with important surgic topics. Such subjects as post-traumatic pulmonar insufficiency and progress in clinical organ transplantatio are discussed in great detail. Burn therapy is considere and it is surprising to read that in a large series of bur Curling's ulcer occurred in 11·7 per cent.

Other subjects, such as urodynamics and urete surgery, spasms of the oesophagus, primary brea cancer, the ischaemic limb, and cardiac pacing, are dea with in an interesting and practical manner.

At the end of each chapter there is a representative li of references culled from the international medic literature. Senior graduates who are working for high surgical degrees or diplomas will find this book a gre help in their studies.

This is a book for the library of the modern surgeon.

Questions and Answers in Orthopaedics. Secon edition. By Floyd G. Goodman, B.S., M.D., Michiga and George R. Schoedinger, III, B.S., M.D., S Louis. 9¼ × 6¼ in. Pp. 264 + vii. 1971. Londo Henry Kimpton. £5 60.

The fact that a second edition was necessary proves th value and popularity of this book, which contains 159 review questions covering the whole field of orthopaedic including pathology, physical medicine, and rehabilitatio The answers and references are given at the end of th book.

This book will be very useful to students and hospit residents as it acts as a quick revision of the whole fiel of orthopaedics.

Non-specific Mesenteric Lymphadenitis. By V Tuchel, Bucharest. 9¼ × 7 in. Pp. 139 + viii, with 4 illustrations. 1972. Basel: S. Kargar. £7·05.

This monograph on non-specific mesenteric lympha denitis, or lymphadenopathy as we term it in this country gives a very comprehensive survey of this condition. I contains the author's personal experience, the results o many years of study, in addition to a rich bibliography Every facet of this clinical condition is discussed a length and clinical cases are recorded.

The physiology and physiopathology of the conditio are considered at length. Terminal ileitis and Crohn' disease are contrasted with this condition.

Surgery is indicated if abscess formation or obstructio of the bowel occurs. The author has published numerou papers in Romania, France, Germany, Belgium, and Switzerland.

This is a useful reference work on non-specific mesenteric lymphadenitis.

Instructional Course Lectures, Vol. XX. THE AMERICAN ACADEMY OF ORTHOPAEDIC SURGEONS. 11 × 8¼ in. Pp. 244 + x. Illustrated. 1971. London: Henry Kimpton. £9.

THIS volume XX of *Instructional Course Lectures* represents selective lectures given at the Annual Meeting of the American Academy of Orthopaedic Surgeons held in Chicago in January, 1970. It contains articles on the orthopaedic management of haemophilia, deformities due to cerebral palsy, the painful shoulder, osteotomies of the hip, and osteo-arthritis of the knee and its early arrest.

These various articles are stimulating and instructive and reveal the trend of American orthopaedic surgery and the treatment of some interesting conditions.

Physics applied to Anaesthesia. Second edition. By D. W. HILL, M.Sc., Ph.D., F.Inst., F.I.E.E. 8½ × 5½ in. Pp. 304 + xvii. Illustrated. 1972. London: The Butterworth Group. £4·60.

THE second edition of this important book appears 4 years after the first and it has been thoroughly revised and brought up to date. It is an important contribution to anaesthetic literature and it will be a valuable addition to the library of all anaesthetists. All those junior anaesthetists, and they are many, who are working for the F.F.A. R.C.S. will find this book invaluable.

New illustrations have been added, and there are extensive references for the reader who wishes to explore a particular topic.

Pathology of Tumours of the Oral Tissues. Second edition. By R. B. LUCAS, M.D., M.R.C.P., F.R.C. Path., Professor of Oral Pathology, University of London. 9¼ × 7¼ in. Pp. 386 + x. Illustrated. 1972. Edinburgh: Churchill Livingstone. £7.

PATHOLOGY is an important branch of medicine and it is of interest to all clinicians.

Tumours of the oral tissues are of interest, not only to dental surgeons, but also to all surgeons who operate on the mouth and adjoining tissues.

The numerous illustrations throughout this book are superb and could not be bettered; the photomicrographs are outstanding. An excellent short account of the normal histology and development of the oral tissues has been included.

A first-rate reference volume on the pathology of tumours of the oral tissues.

Postoperative Cardiac Intensive Care. Second edition. By M. V. BRAIMBRIDGE, M.A., M.B., B.Chir. (Cantab.), F.R.C.S. (Eng.), Consultant, St. Thomas's Hospital, London. 9¼ × 6¼ in. Pp. 176 + x. Illustrated. 1972. Oxford: Blackwell Scientific Publications. £2·50.

THE second edition of this very practical book has been very extensively revised and brought up to date.

The emphasis is on an accurate assessment of the haemodynamic situation so that appropriate measures can be taken to prevent cardiac deterioration.

The various chapters deal with water, electrolyte, and energy requirements, the management of a low cardiac output, respiratory failure, cerebral damage, renal failure, hepatic damage, and infection, and the diagnosis and management of the complications affecting each of these systems are considered in detail.

The chapter dealing with cardiac arrest is excellent and the clear pictures depicting the treatment of this condition are admirable.

This is a book that should be in every intensive care unit for the use of resident medical officers, students, and nurses.

Surgical Disorders of the Peripheral Nerves. By SIR HERBERT SEDDON, C.M.G., F.R.C.S., London. 9¾ × 7¼ in. Pp. 332 + xi. Illustrated. 1972. Edinburgh: Churchill Livingstone. £8.

THIS is one of the most important works that has been published since the end of the Second World War. Injuries of nerves are common in wartime, but they are also common in road accidents today. It is the clinical experience of wartime nerve injuries that is being used to deal with civil injuries.

Sir Herbert Seddon has long been dedicated to the treatment of peripheral nerve injuries and it is pleasing to find that he has dedicated his work to the memory of Hugh Cairns and George Riddoch, with whom he worked during the Second World War.

This book is a classic and will remain one for a very long time to come, for the author presents his subject in a masterly way.

The structure of a peripheral nerve is discussed in detail and illustrated with excellent photomicrographs, including some electron photomicrographs. The degeneration and regeneration of an injured nerve are considered in a practical and lucid way. The clinical picture and methods of examination are portrayed in a very clear fashion. The operative treatment is discussed at great length and the factors influencing indications for operation are stressed to the full.

The results of repair of nerves are given. There is a full list of references and an author and subject index.

A great feature of this work is the excellence of the illustrations. The line drawings, the clinical photographs, the X-ray pictures, and the photomicrographs are all of a very high order.

This is a book of which the medical profession of Great Britain may well be proud.

A great credit to British surgery.

Management of Arterial Occlusive Disease. Edited by W. ANDREW DALE, M.D., Nashville. 8¾ × 5¾ in. Pp. 506 + xiii. Illustrated. 1972. London: Lloyd-Luke (Medical Books) Ltd. £11·70.

THIS book is the outcome of the National Conference on Management of Arterial Occlusive Disease which was held at Nashville, Tennessee, in November, 1970.

The many contributors from various centres and clinics from all over America have covered the subject of arterial occlusive disease in a very comprehensive manner. It may be said that during the past three decades much progress has been made in the treatment of this condition.

The twenty-eight chapters contained in this book deal with the effect of diet and exercise on arterial disease, angiography in arteriosclerosis, vein-grafts, bovine arterial grafts, thrombo-endarterectomy, transluminal angioplasty, and sympathectomy.

The illustrations throughout the book are good, especially the arteriograms. Transluminal dilatation of an atheromatous core seems to give better results than one would expect.

Dr. Dale, who has devoted the greater part of his surgical career to the study of vascular disease, must be pleased with the production of this book. It is a useful reference volume dealing with an all-too-common disease.

Fundamental Physics of Radiology. Second edition. By W. J. MEREDITH, O.B.E., D.Sc., F.Inst.P., and J. B. MASSEY, B.Sc., F.Inst.P., Manchester. 9½ × 6½ in. Pp. 666 + viii, with 460 illustrations. 1972. Bristol: John Wright & Sons Ltd. £6·25.

THE second edition of this very practical and useful book on the fundamental physics of radiology has been very thoroughly revised, and the chapter on radioactive isotopes and the section on radiation protection have been enlarged.

Although this book has been written for students who are preparing for the various examinations of the Society of Radiographers and Radiotherapists, it will be useful to all those who wish to know more about the physics of isotopes, radium, and cobalt.

Physics continue to play an important part in the clinical medicine and surgery of today and all branches of medicine will find this book a very useful reference volume.

Every medical school library should have this book on its shelves.

A Manual of Respiratory Failure. Tracheostomy, Endotracheal Intubation and Mechanical Ventilation. By ELI RUSH CREWS, M.D., and LEOPOLDO LAPUERTA, M.D., Texas. 9¼ × 6 in. Pp. 198 + xiii. Illustrated. 1972. Springfield, Ill.: Charles C. Thomas. $11.75.

THIS is a practical and useful manual, for it describes and discusses the many and varied causes of respiratory failure and then proceeds to give the necessary treatment. With the ever-increasing multiple accidents on the roads of Great Britain and America the necessity for emergency tracheostomy and endotracheal intubation is increasing daily.

It is true that tracheostomy has been used for centuries for laryngeal obstruction. At the turn of the century it was used in the treatment of laryngeal diphtheria, a disease rarely seen today. Tracheostomy is a life-saving procedure in certain cases of brain injury and upper-airway obstruction but its use is now being replaced by endotracheal intubation.

The authors of this book have described the physiopathology of respiratory failure in an excellent fashion and have given the treatment which is required.

Numerous illustrations and tables are used to clarify and enhance the text. Special attention is given to respiratory nursing care and respiratory care units.

A book which students and nurses will find of real value.

Examination of the Hand. By GEORGE L. LUCAS, M.D., Madison, Wisconsin. 9 × 6 in. Pp. 232 + xiv. Illustrated. 1972. Springfield, Ill.: Charles C. Thomas. $14.

ALTHOUGH there are many books devoted to the surgery of the hand, there is still room for this one which is devoted to the examination of the hand and the diagnosis of various conditions which may affect this part of the upper extremity. The hand is frequently injured in the ever-increasing number of road-traffic accidents. Treatment of an injured hand begins with an accurate diagnosis.

This book is divided into three convenient sections: acute injury, evaluation of reconstructive problems, and disability evaluation.

The section on disability evaluation is concerned largely with a description of the measurement and methods of arriving at a permanent partial disability estimate. Several tables relating to amputation and disability formulae are included at the end of the book.

The illustrations throughout the book, especially the line drawings, are excellent. This is a book for students, house-officers, and casualty residents.

Surgeon to Soldiers. By EDWARD D. CHURCHILL, M.D., Boston. 9 × 6 in. Pp. 490 + xiii. 1972. Oxford: Blackwell Scientific Publications. £6.

THIS interesting and informative book is culled from the diary and records of a very distinguished surgical consultant who served on many fronts during the Second World War. Although this book is packed with surgical information concerning every aspect of modern warfare, Professor Churchill has a lucid style of writing and his book has the warmth of a novel.

The book is divided into five parts. Part 1 deals with medical mobilization and all that this entails. Wound shock and blood transfusion are considered at length. Thermal burns and new sulpha drugs are discussed. Part 2 is devoted to North Africa, the various hospitals, prisoners of war, and war wounds, and there is an important chapter on prostitution and venereal disease. Part 3 is concerned with the Sicilian campaign. Part 4 describes the war in Italy and the treatment of gas gangrene and mustard-gas casualties. Part 5 deals with the last phase of the war, and the invasion of Southern France is described and various congresses of army surgeons are detailed.

The author discusses some of the medical controversies and the drama behind them that polarized many physicians into separate factions and, at times, posed a threat to the best possible care for the wounded.

Professor Churchill makes liberal use of case histories, official medical reports, and the experience of other combat surgeons, which add a further dimension to this informal, first-hand account of surgery and surgeons in just about every type of hospital in an overseas theatre, from surgical field tents to rear echelon installations.

There can be no doubt whatever that this volume is a major contribution to medical military literature. This book will make a strong appeal to all surgeons the world over.

Der Vena Cava-Katheter. By C. BURRI, Ulm, and D. GASSER, Basel. 9 × 6 in. Pp. 126, with 29 illustrations. 1971. Berlin: Springer Verlag. DM.42.

THIS book is an excellent review of 3241 patients treated in nine different centres in Germany, Austria, and Switzerland during a 1-year period with caval catheters used either for infusion or for the measurement of central venous pressure. The different sites of insertion of the catheter are discussed, and jugular and subclavian catheters are preferred, while femoral catheters are condemned because of their high complication rate. Venepuncture is preferred to the cut-down technique. The various complications encountered are discussed in detail and as a result of large experience the authors draw logical and sensible conclusions. The detailed summary is given in English, and this little book should be consulted by anyone using caval catheters in the management of the seriously ill patient. The printing and paper are excellent, but for what it is the book is expensive at about £5.

1971 Year Book of Surgery. Edited by SEYMOUR I. SCHWARTZ, M.D., Rochester. 9 × 6 in. Pp. 516. Illustrated. 1972. London: Lloyd-Luke (Medical Books) Ltd. £6·55.

MOST surgeons will agree that the *Year Book of Surgery* is a 'must' for their library, for this book enables them to keep up to date with all that is new in surgery in every part of the world.

Today it is hard to believe that it was at the turn of the century that the *Year Book of Surgery* first appeared and has continued ever since.

As one would expect, the present volume covers a mass of different subjects, including fluids and electrolytes, shock, trauma, burns, wound healing, transplantation, tumour immunology, the liver, congenital heart disease, and the peripheral arteries.

The illustrations throughout the book have been well chosen and are well produced. Experimental surgery receives full coverage.

This is a desk book for the surgeon of today; it can be read at odd times between seeing patients.

Sectional Anatomy and Tomography of the Head. By GUY D. POTTER, M.D., New York. 11 × 7½ in. Pp. 334 + xi. Illustrated. 1972. London: William Heinemann Medical Books Ltd. £13·50.

THIS is a useful and practical atlas comprising 145 radiographs of anatomical sections 1 mm. thick of the human head. A line drawing of each section is shown so that the reader can pick out easily the various relations of the different structures of the head. These sections were made in the coronal, lateral, axial, and oblique directions.

When all the sections are added together one has a detailed three-dimensional concept of the anatomical formation of the structures of the head and their relationships to one another.

This atlas will be of real value to the radiologist who can compare his radiographs with those in this volume. Any abnormality in the body structure can be seen.

Anatomists will find this atlas useful in teaching students the outline of the skull at various levels, and nasal surgeons will find this volume invaluable as a reference work.

The author is to be congratulated on a great piece of work.

Modern Trends in Diseases of the Ear, Nose and Throat—2. Edited by P. MAXWELL ELLIS, M.S., F.R.C.S., London. 8½ × 5½ in. Pp. 401 + ix. Illustrated. 1972. London: The Butterworth Group. £8.

THIS book is badly published and is certainly not in line with the Butterworths tradition. The review copy contains no title page, only 1 page of the list of contents, and an incomplete preface. Pages 16 and 17 are blank. For a book costing £8 net these omissions show grave lack of supervision as far as the publishers are concerned.

The subject-matter contained in this book is of real interest to all those who are concerned with the treatment of diseases of the ear, nose, and throat. Some of the contributions are outstanding, namely, laryngeal paralysis, cancer of the larynx, and the surgery of the salivary glands.

The illustrations throughout the book are good and well produced.

Progress in Surgery, Volume 10. Edited by M. ALLGÖWER, Basel, S. E. BERGENTZ, Malmo, R. Y. CALNE, Cambridge, and U. F. GRUBER, Basel. 9½ × 7 in. Pp. 132, with 55 illustrations. 1972. Basel: S. Karger. £6·05.

THIS book is volume 10 of a popular series which was begun in 1961.

In this present volume there are some outstanding articles. J. C. Goligher and his colleagues at the Department of Surgery at Leeds contribute an interesting article on Crohn's disease, with special reference to surgical management. This article reviews new information of importance concerning this complicated field. Peter Lord of London reveals his originality in his articles on the treatment of hydrocele and haemorrhoids.

Another article of interest is that by Morgan and Fleisch in which these authors explain the remarkable progress which has been made during the past years regarding calcium and phosphate metabolism, an area of interest even for those not directly involved in bone surgery.

This is a book that all practical surgeons will wish to possess.

Surgery of the Oesophagus. The Coventry Conference. Edited by R. ABBEY SMITH, Ch.M., F.R.C.S., F.R.C.S. (Edin.), and R. E. SMITH, M.A., M.B., B.Ch., F.R.C.P., Coventry. 8½ × 5½ in. Pp. 240 + xvii. Illustrated. 1972. London: The Butterworth Group. £6.

THIS volume contains the proceedings of the conference held at the Postgraduate Medical Centre, Coventry, in July, 1971. After reading this book, which covers every aspect of the surgery of the oesophagus, the reader must be convinced that the conference was a great success. Not only are the proceedings of real interest and importance, but the discussions which followed reveal a great interest in this type of surgery.

Up to the beginning of the Second World War carcinoma of the oesophagus was for the most part treated by palliative gastrostomy, although Grey Turner struggled on with his 'pull-through' operation.

Today resection of the oesophagus is an everyday procedure and this very practical book records how replacement of the oesophagus may be achieved both in the infant and in the adult.

The consultants at Coventry are to be congratulated in producing such an interesting volume.

Handbuch der Kinderheilkunde, Volume VIII, Part 2. Edited by H. OPITZ, and F. SCHMID, Heidelberg. 10½ × 7½ in. Pp. 770 + xvii. Illustrated. 1972. Berlin: Springer Verlag. DM.236.

THIS volume on tumours in childhood is the last one in a series on paediatrics. The authors of the various chapters are paediatricians from West and East Germany and the total omission of a paediatric surgeon or a radiotherapist from the list of authors is remarkable. The volume covers all conceivable tumours in childhood including benign lesions such as haemangiomas and lymphangiomas as well as neurofibromatosis. The book contains a vast amount of statistical information collected from the world literature but, on the other hand, it is of little help to the clinician in relation to diagnosis, and it is certainly of no use to the surgeon or radiotherapist wanting advice about the treatment and management of a particular patient.

However, this volume is a superb summary of the world literature on malignant disease in children even if the summary appears to be totally uncritical. All the chapters have extensive lists of references and undoubtedly this book will be a great help to anybody wishing to publish a paper on any aspect of malignant disease in childhood. This volume should therefore find its place in the libraries of units dealing either with children or with malignant disease but it is expensive at £30 and it is unlikely to be of practical help to the practising paediatrician or paediatric surgeon.

Testicular Tumours. Edited by DOUGLAS E. JOHNSON, M.D., Texas. 10 × 7 in. Pp. 296. Illustrated. 1972. London: Henry Kimpton. £9.

THIS monograph written by a team of urologists, pathologists, and radiotherapists from various medical centres in the United States of America presents a comprehensive survey of the whole problem of cancer of the testicle.

Few medical practitioners realize that cancer of the testicle ranks second only to reticulo-endothelial neoplasms as a cause of death from cancer in young men. Although primary tumours of the testicle are common, secondary or metastatic tumours are rare.

In this book the surgical management of testicular tumours is discussed at length, and the part played by radiation therapy and chemotherapy is well presented.

The actual operation of radical orchidectomy with high ligation of the spermatic cord at the internal abdominal ring is described and illustrated.

Throughout the book the numerous illustrations are of a high order and are quite a feature of the book.

An excellent reference volume on an important subject.

Radiology of the Skull and Brain, Volumes 1 and 2. Edited by T. H. NEWTON, M.D., San Francisco, and D. GORDON POTTS, M.D., New York. 11 × 8¼ in. Pp. 869 + xxiv. Illustrated. 1971. London: Henry Kimpton. £35·35.

THESE two large books with numerous illustrations constitute the most up-to-date and comprehensive work on the radiology of the skull and brain. The numerous contributors, all masters in their own particular field, come from various centres in America, Canada, Great Britain, and Italy.

Volume 1 is divided into four parts. Part 1 deals with the technical aspects of skull roentgenography, which includes film analysis and tomography of the skull. Part II is concerned with skull maturation, the foetal skull, and the changes in the skull during childhood. In Part III the size and shape of the skull vault are discussed in some detail. The thickness of the skull is considered as well as the cranial sutures and the fontanelles. Part IV deals with the skull base, and the basal foramina and canals and the sella turcica are dealt with in detail. This is really a radiographic atlas as the vast majority of the illustrations are skiagrams. These pictures—often ten to a page—are excellent and well produced.

Volume 2 is also divided into four parts which are a continuation of Volume 1. Part V is concerned with the orbit, including the optic canal and superior orbital fissure. Orbital calcification also comes under review. Part VI deals with the congenital abnormalities of the skull. This is an excellent account and is illustrated with a profusion of first-class clinical photographs. Part VII presents a series of metabolic diseases involving the skull, while Part VIII is devoted to other diseases of the skull including acromegaly and Paget's disease.

This is a most comprehensive reference work and it should be found in every medical library.

An excellent production.

Frontobasale Verletzungen. By C. PROBST. 9 × 6 in. Pp. 285. Illustrated. 1971. Bern: Verlag Hans Huber. DM.56.

THIS is a monograph on injuries to the anterior cranial fossa. The book reports in detail the author's experience of 28 patients and this is compared with the large published series available. Active and early surgical intervention is advocated and the various methods of dealing with cerebrospinal rhinorrhoea are described. Both synthetic materials and cartilage grafts are used to close defects in the base of the skull.

Some experimental work on sheep relating to surgical techniques is also described.

The most impressive part of the book is the list of references, totalling almost 700. This volume should be of interest and use to neurosurgeons who have to deal with trauma. It is, however, very expensive.

Neoplasms of the Gastrointestinal Tract. By WILLIAM C. LOWE, M.D., M.Sc., New Jersey. 10 × 7 in. Pp. 347, with 64 illustrations. 1972. London: Henry Kimpton. £9.

THIS book although written for students will prove of interest and value to surgeons, gastro-enterologists, and nurses.

The vast amount of clinical material which has been portrayed in this volume came from the Veterans Administration Hospital in New Jersey.

The long-term follow-up of cases of gastro-intestinal cancer produces some interesting figures. Cancer of the stomach still remains a killer, but cases in which complete gastrectomy is performed have the best prognosis. Cancer of the colon because of its early obstructive symptoms and consequent resection has a high percentage of cures.

In this book a very extensive survey of gastro-intestinal cancer is presented and the pathology, prognosis, and treatment are discussed in detail.

A useful contribution to our knowledge of cancer of the alimentary canal.

Prosthetic Replacement of the Aortic Valve. By LESTER R. SAUVAGE, M.D., Washington, ROBERT F. VIGGERS, M.S., Washington, KNUTE BERGER, M.D., Washington, STEPHEN B. ROBEL, M.S., Washington, PHILIP N. SAWYER, M.D., New York, and STEPHEN J. WOOD, M.D., Washington. 9 × 6 in. Pp. 217 + xiv. Illustrated. 1972. Springfield, Ill.: Charles C. Thomas. $18.

SINCE the termination of the Second World War surgery of the heart has progressed by leaps and bounds and the latest achievement is the replacement of the human heart valves by various and ingenious prostheses. In this monograph which is truly comprehensive the emphasis is on the replacement of the aortic valve. The book begins with an account of the structural mechanics of the aortic valve and then the hydraulics of the valve are considered. The healing of the encapsulable parts of the aortic valve prosthesis is discussed at some length.

Aortic valve design resolves itself into the application of principles of healing and hydraulics to the specific geometry of the aortic root. While many factors remain to be clarified, the basis for continued progress has been established. It may well be that within a few years the aortic valve prosthesis will be sufficiently safe to be implanted early in the course of the patient's illness before significant structural damage has occurred to the myocardium or to the lungs.

This is a book that all cardiologists and heart surgeons should read, for it is full of useful clinical information.

Emergency Room Care. Second edition. Edited by CHARLES ECKERT, M.D., New York. 9 × 6 in. Pp. 423 + xv. Illustrated. 1971. Edinburgh: Churchill Livingstone. £4·50.

THE second edition of this useful students' book has twenty-six contributors, all of whom are affiliated with the Albany Medical College of Union University, Albany. They cover this important subject in a very practical and comprehensive way.

Today when intensive-care units are common to most hospitals both at home and abroad this book will be found invaluable to both students and nurses. The price of the book is quite moderate.

G·DAY

those first vital 24 hours in serious bacterial infections

- when effective therapy must be initiated to prevent rapid deterioration in the patient's condition
- when the causative organism is unknown or uncertain
- when there is no time for trial and error

GENTICIN INJECTABLE

gives more bactericidal cover than any other antibiotic

Genticin Injectable is available in 2 ml multidose vials. Each 2 ml contains 80 mg gentamicin as gentamicin sulphate.

Further details are available on request from:
Genticin Technical Service,
Slough 23971
Nicholas Laboratories Limited
British Schering Limited
Slough Buckinghamshire

Bier / Braun / Kümmell

Chirurgische Operationslehre

8th edition. Editors: Prof. Dr. h.c. E. DERRA, Düsseldorf, Prof. Dr. P. HUBER, Innsbruck, and Prof. Dr. W. SCHMITT, Rostock. 6 *volumes. Approx.* 5000 *pages. Leather binding. Approx.* **900M**

Volume 1: **Allgemeine Operationslehre.** 1969. *XIX*, 556 *pages, with* 484 *illustrations.* 4⁰. *Leather binding.* **90M**

Volume 3/1: **Operationen am Hals und Brustkorb.** 1971. *XIX*, 624 *pages, with* 630 *illustrations.* 4⁰. *Leather binding.* **90M**

At the beginning of the year 1973 come out:

Volume 4/1: **Operationen am Bauch.** 1972. *Approx.* 650 *pages, with about* 500 *illustrations.* 4⁰. *Leather binding. Approx.* **100M**

The purchaser of one volume will be obliged to buy the complete work.

The new BIER/BRAUN/KÜMMELL continues to be the indispensable reference book which should be included in every hospital library and on the bookcase of every surgeon. The experienced specialist will want to consult it, the younger surgeon for whom it will open up a whole new world of modern surgery will learn from it. The 8th edition of the "Manual of Clinical Surgery" will remain the reliable guide and adviser it has always been during its more than 50 years of existence.

CHURCHILL
LIVINGSTONE

MANUAL OF SURGICAL THERAPEUTICS

Edited by R. E. CONDON and L. M. NYHUS

1970 *390 pages* *48 illustrations*

Spiral bound **£3·25**

The authors provide comprehensive information on the diagnosis and treatment of shock, trauma, and cardiac disorders. Preoperative and postoperative care are covered in detail. Surgical infections, bacteriology, and complications are discussed with complete sections on drug usage, side effects, and administration.

RENAL TRANSPLANTATION

JEAN HAMBURGER, JEAN CROSNIER,
JEAN DORMONT, and JEAN-FRANÇOIS BACH

1972 *346 pages* *49 illustrations* **£7·00**

The team of surgeons responsible for the first kidney transplant in 1952 have written this new book to share their experience of 20 years' work in the field with surgeons, immunologists and nephrologists. The authors contend that transplantation is not practicable without a full appreciation of all the problems, ranging from the immunology laboratory to the operating theatre. In considering both theory and practice, they have made a major contribution to one of the most exciting scientific adventures in human experience.

THE ALCOHOLIC PATIENT IN SURGERY

ALBERT B. LOWENFELS

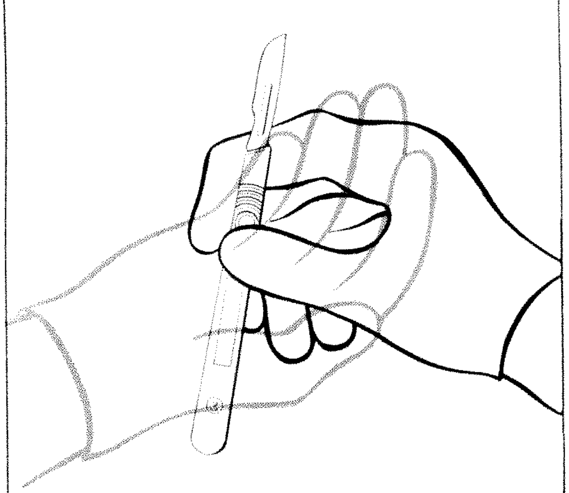
1972 *280 pages* *81 illustrations* **£6·00**

The observations contained in this book result from 20 years' experience at hospitals in which a unique opportunity existed for the study of the alcoholic patient.

All surgeons who treat alcoholic patients recognize that they pose a continuing challenge in both a diagnostic and therapeutic sense.

CHURCHILL LIVINGSTONE

15–17 Teviot Place, Edinburgh



Another surgeon is about to use one of the world's finest surgical blades.... ...this happens thousands of times every day!

It happens because the blades are by Swann-Morton, the people who meet the highest requirements in surgical knives.
We need say very little about our superiority. The world's surgeons have proved it for us!

Swann-Morton

SWANN-MORTON LIMITED
PENN WORKS, OWLERTON GREEN
SHEFFIELD S6 2BJ. ENGLAND.

. . . . there's no reason why anyone hould be able to tell. There's no eason why a patient with a colostomy and hose around him should be embarrassed y odours and tell-tale noises.

Celevac (a special grade of methylcellu-ose) enables the patient to control his owel action—absorbs, and holds in oose chemical bondage, both H_2O and $_2$S. Your patient can live with is colostomy—and others can live ith your patient.

Give him Celevac—and a copy of our booklet "The Home Management of a Colostomy"—and he will be doubly grateful.

John Wright ***JUST PUBLISHED***

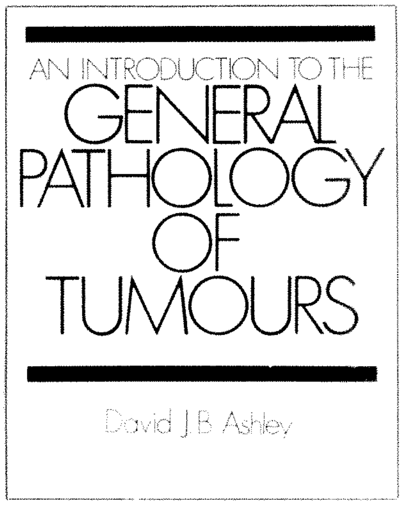
The Principles of Transurethral Resection and Haemostasis

By J. P. Mitchell, T.D., M.S., F.R.C.S., F.R.C.S.E., *Lecturer in Urology, University of Bristol; Consultant Urological Surgeon, United Bristol Hospitals; Consultant Urologist, Southmead General Hospital.*

This book is based on an essay for which the author was awarded the *Jacksonian Prize*, the oldest and most cherished prize of the Royal College of Surgeons of England.

Transurethral resection is essentially a practical subject in surgery, involving the basic principles of surgical technique, with success depending largely on clinical acumen in diagnosis. Not only urologists and trainee urologists but all surgeons can learn much from this book.

276 pages 124 illustrations **£6·00**



By D. J. B. Ashley, T.D., M.D., F.R.C.P.PATH., *Consultant Pathologist, Morriston Hospital, Swansea.*

This book is offered as a contribution to the application of general medical and scientific principles to the understanding of neoplastic disease in the human. It is directed to the clinician, both undergraduate and postgraduate, who is concerned with the care and management of patients suffering from neoplastic disease and who wants a résumé of current knowledge in this field.

120 pages 16 illustrations Paper Covers **£2·00**

ABO Haemolytic Disease of the Newborn

By E. R. Gold, M.D., *Research Fellow, Department of Child Health, University of Bristol*; and N. R. Butler, M.D., F.R.C.P., D.C.H., *Professor of Child Health, University of Bristol.*

This monograph studies in detail ABO haemolytic disease of the newborn, and will be of interest to blood-group serologists, obstetricians, and paediatricians.

216 pages 11 illustrations **£4·00**

EDITORIAL NOTICES

Editorial Communications should be addressed to the *Editorial Secretary, British Journal of Surger c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editori Committee: they are accepted with the understanding that they are contributed to this Journal only, a that articles and their illustrations become the property of the Journal unless the authors state, befo publication, that they reserve the right to themselves. Each article should be accompanied by an adequa summary, suitable for publication. Authors are asked to ensure that original illustrations are securely pack and adequately protected.

Reprints can be supplied at a reduced price if authors indicate their requirements at the time that proc are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimu number.

No. of Pages	Number Required							
	50	100	150	200	250	300	400	500
2	£2·10	£2·80	£3·20	£3·80	£4·30	£4·80	£5·90	£6·90
4	2·70	3·90	4·60	5·40	6·16	6·90	8·40	9·90
6/8	4·50	5·80	7·10	8·30	9·60	10·80	13 40	15·90
10/12	7·20	9·80	11·70	13·70	15·70	17·70	21·80	25·40
14/16	8·70	11·10	13·50	15·90	18·30	20·70	25·50	30·30
18/20	11·40	15·10	18·20	21·30	24·50	27·70	33·90	39·00
Covers	1·50	2·10	2·70	3·30	3·90	4·50	5·70	6 90

An additional charge will be made for reprints containing coloured illustrations, depending upon t amount of extra work involved.

Business Communications should be addressed to *John Wright & Sons Ltd., British Journal of Surger Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

Binding.—Handsome Cloth Cases may be obtained for binding Vol. 57. Case 70p post free; Case a binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be ma to the Publishers, who will also undertake the binding if desired.

Back Numbers.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

Advertisements.—All communications should be addressed to *H. S. Janes & Partners Ltd., St. Marti House, 159 Clapham High Street, London, S.W.4.*

INSTRUCTIONS TO AUTHORS

Preparation of MS.—Papers should be submitted in typescript and the author should retain a carb copy. Double spacing should be used throughout, except for quotations.

Tables and Illustrations.—Tables should be numbered in roman numerals and set out on shee separate from the text. Illustrations, too, should be kept separate from the text and should be number consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legen should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy phot graphs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounte should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. Wh *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparenci where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be ask to make a contribution towards the cost.

References.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list authors quoted is put at the end of the article in alphabetical order. Each reference in the list should gi in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volu (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has writt more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, t place of publication should be stated and the publisher's name. The names of collaborating authors should given in full on the first occasion, but in later citations the words "and others" should follow the first nan Abbreviations for journals should be those adopted in the "World List of Scientific Periodicals" (196

Only in papers in which many and frequent references have to be made should the items be numbere the numbers may then be inserted in the text without interrupting it with a list of names.

CRYOSURGERY

THEATRE and out-patient applications of cryosurgery are rapidly increasing with the greater awareness of the potentialities presented by this new technique.

Spembly's association with equipment developments are long standing and a comprehensive range of instruments are manufactured and tested under special clean room conditions at our modern premises in Andover.

Our ophthalmic cryosurgical systems are in evidence throughout the world; over 6000 have now been supplied, and attention is now focusing on tissue destruction techniques in Gynaecology, ENT and Oral Surgery, Dermatology and Urology.

Interesting experimental procedures are being developed in Proctology and Orthopaedics and there has been a resurgence of interest in Neurological procedures. We are also actively involved in Renal cooling systems.

Anatomical, procedural and heat exchange problems necessitate the use of various systems, but our TCC10 system currently provides the best all round general purpose facility. The new TCC40 system is the first completely non-electric high power freezing system to be produced and will undoubtedly have a major role in the future treatment of neoplasms and highly vascular structures.

The first British symposium on Cryosurgery takes place in London on October 27th and, following the first European Congress in Vienna earlier this year, indicates the prominence attached to this new form of treatment.

Further information on the symposium, organised by the Society for Low Temperature Biology, is obtainable from the meetings secretary, Mr. C. J. Green, Room 4X012, Clinical Research Centre, Watford Road, Harrow, Middx, and we will be participating in the exhibition associated with this meeting.

Equipment will also be displayed at the Royal College of Surgeons on the occasion of the Autumn meeting of the British Association of Oral Surgeons (October 6th and 7th) and in Newcastle at the N.A.T.N. Congress (October 11th–13th).

Product data sheets, reprints and advice on current procedures are always available from our staff in Andover and our Regional Engineers.

Ask your secretary to telephone our Cryo Medical Division at Andover 65741 or write for further information to:–

atraugrip jaw instruments

The unique design of the Atraugrip Jaw Forceps ensures that the finest tissue can be grasped firmly without being crushed. Complete occlusion of blood vessels is afforded without danger of perforation or damage to intimal linings and the forceps will not slip even under high intra-vascular pressures.

These special holding properties are only made possible by extremely accurate machining of the jaws to provide interlocating rows of very fine teeth forming parallel, shallow, wedge-shaped troughs in which the tissue is delicately but securely grasped.

Originally designed for cardiovascular surgery the Atraugrip feature is now being extended to include certain forceps used in other techniques.

The current range of Atraugrip Forceps for cardiovascular, intestinal, thoracic and paediatric surgery are illustrated in our latest booklet, copies of which are available on request.

no fear
no infection
no pain

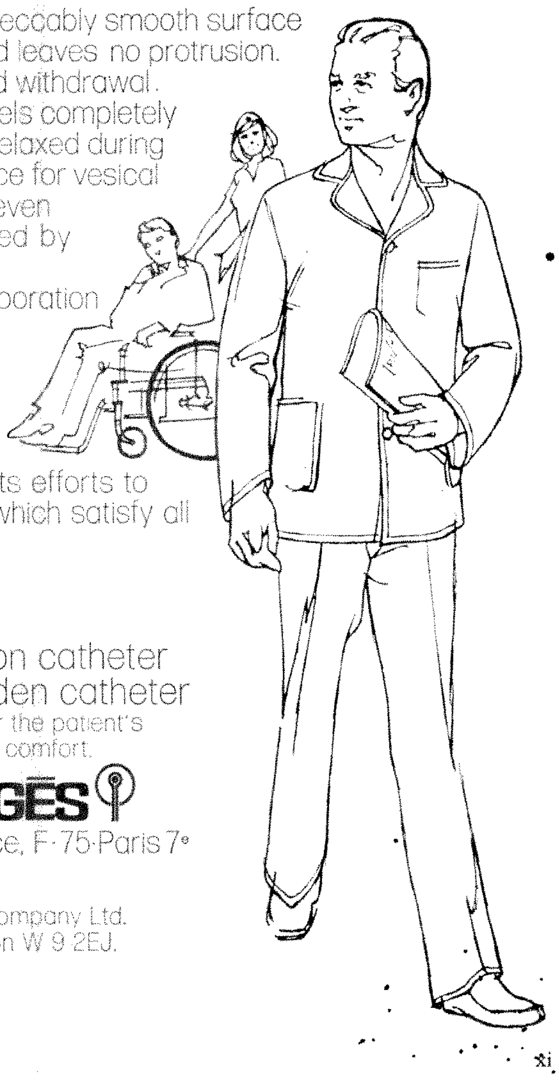
with a Porges golden balloon catheter

No pain : it has an impeccably smooth surface and the balloon when deflated leaves no protrusion. This allows easy insertion and withdrawal.

No fear : the patient feels completely reassured. He will be utterly relaxed during catheterization. A large surface for vesical support is obtained through even inflation of the balloon, ensured by reinforcing ribs.

No infection : the incorporation of active bacteriostatic compounds into the latex prevents any urinary tract infection.

Our research department has devoted all its efforts to the production of catheters which satisfy all clinical requirements :



The Porges balloon catheter
the golden catheter
created for the patient's
safety and comfort.

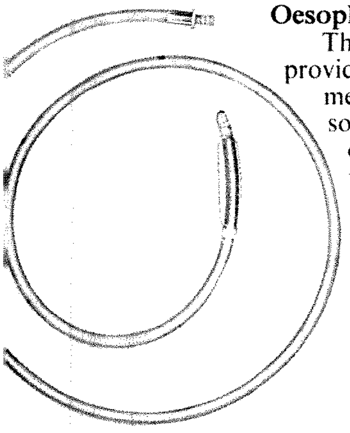
DUPUY COMPTON MEDICAL POR 011

Add your experience to
ours and you have the
beginning of a successf
operation.

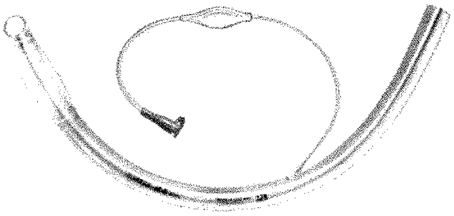
Our 30 years experience have been dicated to the advancement of surgical d medical practice throughout the rld. And although our contribution y be small, we take great pains to ke it important.

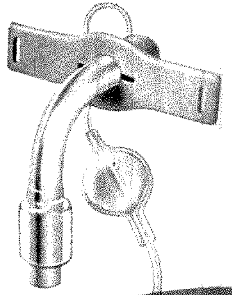
We maintain the highest ndards of quality. Which is why our products need no modification to meet the regulations of the most demanding public health bodies.

But we are never satisfied with past and present achievements. Our continuing programme of research seeks to develop new products. The products you'll want tomorrow.



Oesophageal Stethoscope
This is a new product which provides a simple, yet highly efficient method of monitoring heart sounds. It is particularly useful during paediatric and neurosurgical procedures. Available in three sizes, all double wrapped and sterile.





Cuffed Blue Line Endotracheal Tube Designed with a new thin wall to give up to ½ mm larger lumen than before and with even better slip properties. The cuff is inflated symmetrically via the airline which is incorporated into the wall without reduction of lumen.

e Line Tracheostomy Tube
The new Portex tracheostomy tube an extra smooth non-irritant finish. igned to allow easier suction heterisation. The strong inert floppy f allows lower inflation pressures. h tube is supplied with a one way ve and its own spool of neck tapes.

Why Dexon*?

Why not?

1. Easy to handle – similar to silk or linen thread
2. Packed dry – convenient to use
3. High tensile strength – excellent wound support
4. Smaller gauges needed for comparable strength compared with gut
5. Braided construction – secure knots – more security
6. Predictable absorption even in contaminated areas
7. Minimal tissue reaction and inflammatory response
8. Improved patient comfort
9. Permits undisturbed wound healing
10. Less painful wounds
11. Shorter hospitalization
12. Improved cosmetic results especially with subcuticular stitches
13. Is there when it is needed, but has gone when it is not
14. Multi-uses means greater economy
15. May be removed as usual when used for skin sutures but may be left to absorb if preferred – e.g. paediatric surgery, under orthopaedic plaster casts, episiotomy repairs, circumcisions, etc.
16. Simplified stock holding, laying up for operations, nurse training
17. It is supplied on the best suture needles made

1. The braided construction may mean an initial difficulty in tying knots
2. A slight increase in tissue-drag may be experienced. Can be improved by wetting
3. Absorption of blood and other body fluids may make Dexon more difficult to see
4. Suture for suture it appears to be more expensive than other materials – cost in use is probably less
5. It is different and you may need to especially ask for it

Vol. 59 OCTOBER, 1972 No. 10

ASSOCIATION OF SURGEONS OF GREAT BRITAIN AND IRELAND

The Annual Meeting of the Association took place in Harrogate and Leeds on 6, 7, and 8 April, 1972, with the President, Professor J. C. Goligher, in the Chair.

After the Business Meeting there was a Symposium on Crohn's disease at which the President acted as Chairman. On the following day there were several sessions of Short Papers, some of which were entered for the Moynihan Prize. The second Symposium, at which Professor G. W. Taylor was the Chairman, was entitled 'Thrombo-embolism—Current Management'.

SHORT PAPERS FOR THE MOYNIHAN PRIZE

[The prize was won by Messrs. C. S. Humphrey and A. R. Wilkinson (Leeds)]

THE NATURAL HISTORY OF VENOUS THROMBO-EMBOLISM*

By M. G. WALKER
ABERDEEN ROYAL INFIRMARY

INFORMATION not hitherto available can be obtained in relation to the site and extent of thrombus formation in early cases of venous thrombo-embolism using three diagnostic tools:—

1. Lung scanning with ^{131}I macro-aggregated human albumin.
2. Bilateral percutaneous femoral phlebography to visualize the iliofemoral segments.
3. Peripheral leg scanning using ^{125}I-tagged fibrinogen.

Two groups of patients were investigated. Group I consisted of a series of 84 patients with iliofemoral venous thrombosis, both non-occlusive and occlusive, confirmed by iliofemoral phlebography in which peripheral scanning was carried out. In 34 cases (40 per cent) non-occlusive thrombus was demonstrated in the iliofemoral segment and in only 3 cases was the peripheral leg scan positive. In 50 cases the iliofemoral segment was totally occluded and in only 16 cases (32 per cent) was the peripheral leg scan positive.

Group II consisted of a series of 86 cases presenting with pulmonary embolism as the initial sign of venous thrombo-embolism; all the patients were without signs or symptoms referable to the legs. Thirty-one patients showed non-occlusive thrombus in the iliofemoral segment and the peripheral scan was negative. In only 3 cases where the iliofemoral phlebogram was positive for non-occlusive thrombus was the peripheral scan positive. Eight cases had a positive peripheral scan and a negative phlebogram, the source of embolus possibly being in the peripheral segment. In 46 cases both the iliofemoral phlebogram and peripheral leg scan were negative, no source of thrombus being demonstrated by these techniques. Follow-up phlebography and peripheral scanning studies were undertaken in these 46 cases where no source of thrombus could be demonstrated. Subsequently in 8 cases non-occlusive thrombus was demonstrated in the iliofemoral segment, the peripheral leg scan again being negative. In each of these cases a further pulmonary embolism had occurred. Corrected figures for iliofemoral involvement are therefore $34+8=42$ (49 per cent).

---

* This article is a summary of the paper which was presented at the meeting of the Association of Surgeons.

CONCLUSIONS

1. In 49 per cent of the cases presenting with pulmonary embolism where the legs were clinically silent the source of emboli was in the iliofemoral segment, the right side being involved more frequently than the left in the ratio of 2 : 1.

2. Peripheral leg scanning gave a positive result in 27 (19 per cent) cases.

3. Cases in which thrombus formed in the peripheral venous segment seldom presented with pulmonary embolism.

4. Thrombus developing in the iliofemoral segment became occlusive without, in the majority of instances, thrombus forming in the peripheral venous segment.

As regards the investigation and treatment of deep-vein thrombosis, therefore, considerable emphasis should be placed on the iliofemoral segment, and visualization of these segments by phlebography is always an essential aspect of management. Peripheral scanning is of value in screening the peripheral venous segment, and is useful, as shown here, in helping to elucidate features of the natural history of venous thrombo-embolism. It is not, however, superior to ascending phlebography which gives a clearer picture of events, nor does it represent an 'early-warning system' for significant clinical venous thrombo-embolism. If diagnostic efforts are to be concentrated on the peripheral segment the more important, more insidious, and much more dangerous involvement of the iliofemoral segment is likely to be overlooked.

Acknowledgement.—I am deeply indebted to Mr G. E. Mavor for his advice, help, and encouragement in the preparation of this paper.

ALTERATION IN FIBRINOLYSIS ASSOCIATED WITH SURGERY AND VENOUS THROMBOSIS

By AVERIL O. MANSFIELD*
DEPARTMENT OF SURGERY, UNIVERSITY OF LIVERPOOL

SUMMARY

1. A marked increase in fibrinolytic activity occurs during surgical operations, especially major surgery.

2. This increase sometimes begins prior to the induction of anaesthesia.

3. There is reduced fibrinolytic activity during the postoperative period and this occurs earlier and to a greater degree in those patients who develop a venous thrombosis as shown by the ^{125}I-fibrinogen test.

THE term 'fibrinolysis' means the enzymatic liquefaction of blood or fibrin clot and it can be regarded as the physiological antithesis of coagulation. It is known that increased coagulability of the blood is a feature of surgical operations. It is also known that an alteration in fibrinolysis occurs during an operation. A haemostatic balance has been postulated between clotting and fibrinolysis. Although this is an oversimplified concept it is not unreasonable to suppose that some relationship probably exists between these two factors. Consequently an investigation has been undertaken to determine, in detail, the changes occuring in fibrinolysis in the peripheral blood during and after surgical operations. In addition, a further investigation has been undertaken to assess whether these differences are in any way related to the onset of venous thrombosis.

REVIEW OF THE LITERATURE

In 1937 MacFarlane made a chance observation that blood removed from a patient immediately following cholecystectomy clotted normally but was 'quite fluid' when inspected the following day. This was probably the earliest observation of fibrinolysis in relation to surgery.

In a later series of 34 patients MacFarlane and Biggs (1948) employed dilution of blood to demonstrate fibrinolysis, and in 50 per cent of cases after operation a positive result was obtained, even in some cases where only a minor procedure had been undertaken. The methods which they used failed to demonstrate fibrinolysis in the normal patient and so there was no way of obtaining a quantitative estimate of the change.

These findings were confirmed by Truelove (1952, 1953). Further investigation by Andersson, Nilsson, and Olow (1962) showed increased fibrinolytic activity during operation.

Several investigations were undertaken by Innes and Sevitt (1964) in patients who had recently been injured. One of these studies included the measurement of the fibrinolytic activity, which was found to be increased soon after injury, but because of the nature of the investigation base-line measurements were, of course, impossible.

Chakrabarti, Hocking, and Fearnley (1969) showed that there was prolongation of lysis time following surgical operations and that this prolongation was maximal on the fifth postoperative day. The authors referred to this period of reduced fibrinolytic activity as the 'fibrinolytic shut-down'. In the same investigation they showed a temporary increase in fibrinolysis shortly after electroconvulsive therapy. A previous investigation by the present author (Mansfield, 1970) demonstrated that the period of fibrinolytic shut-down was in fact preceded by a marked increase in fibrinolytic activity during and shortly after the operation. In summary, lysis time was shortened during the surgical operation and remained so in the immediate postoperative period.

---

* Present address: Consultant Surgeon, United Liverpool Hospital.

METHODS

1. **The Dilute Blood-clot Lysis Time.**—The method described by Fearnley (1964) depends on the differential reduction of inhibition as compared with fibrinolytic activity when blood is diluted. A photographically determined end-point has been employed in the present study.

2. **Euglobulin Lysis Time.**—The euglobulin fraction is obtained by dilution and acidification of plasma and the inhibitors are largely removed (von Kaulla, 1963). It is generally regarded as a measure of activator activity.

3. **Detection of Venous Thrombosis.**—^{125}I-fibrinogen was administered intravenously in a dose of 100 µc. at the termination of the operation. Employing a portable scintillation counter, counts were made at 8-cm. intervals from the groin to the ankle. The method employed has been fully described by Flanc, Kakkar, and Clarke (1968), Negus, Pinto, Le Quesne, Brown, and Chapman (1968), and Kakkar, Nicolaides, Renney, Friend, and Clarke (1970). Using this method, venous thrombosis can be accurately determined from the ankle to the groin but not in the pelvic vessels. *Fig.* 1 demonstrates thrombus formation in the calf.

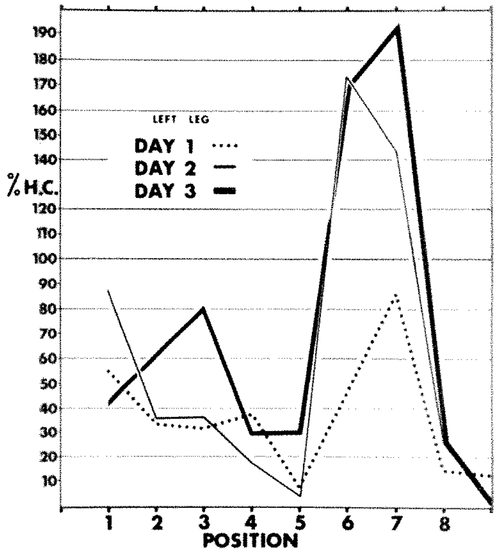

FIG. 1.—^{125}I-fibrinogen test demonstrating thrombus in the calf.

PATIENTS INVESTIGATED

A group of unselected patients undergoing routine general surgery was investigated. All the blood-samples were obtained with the patients fasting and resting in bed. A tourniquet was not applied because this increases fibrinolytic activity. The samples were placed directly in ice after their removal.

Timing of Blood-samples.—Two preoperative blood-samples were obtained on consecutive days. On the day of the operation blood was obtained in the anaesthetic room before the induction of anaesthesia and at half-hourly intervals during the operation. A further sample was obtained at the termination of the operation before the administration of the radioactive fibrinogen.

The investigations were continued daily after the operation for a period of 1 week. Five patients had to be excluded from the investigation because it proved impossible to obtain repeated blood-samples without the use of a tourniquet.

Eighty-nine patients have been investigated in the manner described.

Investigation of Venous Thrombosis.—Fifty-five patients undergoing major surgery were investigated using radioactive fibrinogen. All the patients were undergoing operations of a similar or greater magnitude to cholecystectomy, and all were over 40 years of age. A consecutive series of patients who fulfilled these two criteria was investigated.

Investigation of the Diurnal Variation.—There is known to be a normal diurnal variation in fibrinolysis (Buckell and Elliott, 1959). During the morning hours there is an increase in fibrinolytic activity. Ten normal volunteers and 12 preoperative patients were confined to bed and kept in the fasting state. The normal diurnal variation was suppressed in all those who were investigated, i.e., the normal shortening of blood-clot lysis time between 8.00 a.m. and 12.00 midday did not occur.

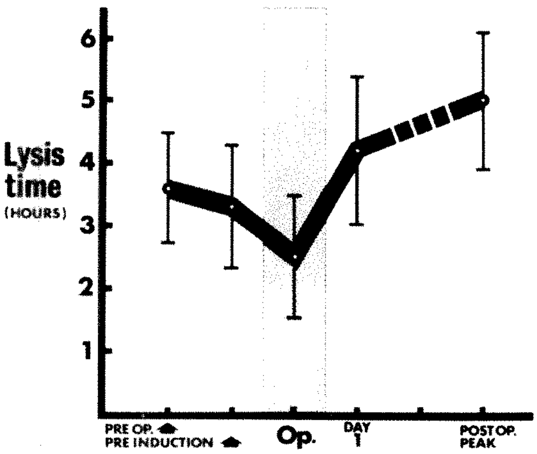

FIG. 2.—Changes in the euglobulin lysis time during and following operation.

RESULTS

Fig. 2 shows the mean values of the euglobulin lysis time in the 89 patients who were investigated during the operation period. Similar results were obtained for the dilute blood-clot lysis time. In the majority of patients there was a small increase in fibrinolysis before the induction of anaesthesia. There was a significant difference ($P < 0{\cdot}001$) between the preoperative values and the lowest value obtained during operation. It was concluded therefore that fibrinolytic activity is increased during surgery. On the first postoperative day this increase in activity was reversed and the patients either returned to their normal preoperative level of activity or had a lower level of activity on the first postoperative day. Although the graph of the results demonstrates an increase in fibrinolysis during operation, 20 per cent of the patients investigated failed to show this increase in activity. With 1 exception, however, the patients who remained normal during the operation were undergoing only minor surgery.

The pre-induction value appears to be affected by premedication. Thus, 13 out of 14 patients who received diazepam (Valium) as the premedication did not show any increase in fibrinolytic activity. The significance of suppressing fibrinolysis at this time is not known.

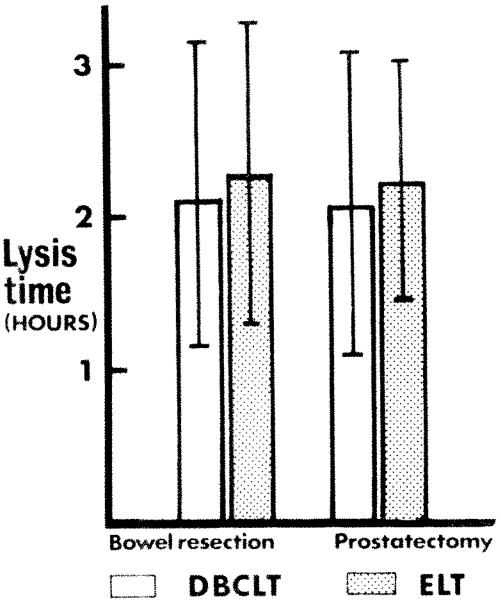

FIG. 3.—Lysis times during prostatectomy and bowel resection. DBCLT, Dilute blood-clot lysis time. ELT, Euglobulin lysis time.

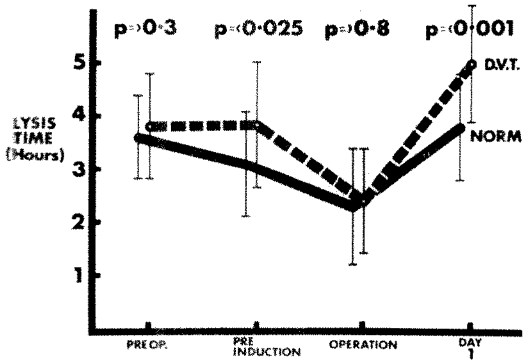

FIG. 5.—Euglobulin lysis time in normal patients and in patients who developed deep-vein thrombosis.

Two groups of patients were compared to see if there was any increase in fibrinolysis resulting from prostatectomy, which has often been stated to be associated with a high level of fibrinolysis. Nine patients undergoing prostatectomy were compared with 10 patients undergoing large-bowel resection. Both the dilute blood-clot lysis time and the euglobulin lysis time were shortened by these operations, but there was no significant difference between the operations (*Fig.* 3). These techniques simply measure fibrinolysis in the peripheral blood and local fibrinolytic activity is not taken into account by these methods.

Postoperative Lysis Time.—Prolongation of lysis time occurred in the postoperative period. All the patients showed a reduction in fibrinolysis time at some stage during the postoperative period as compared with their preoperative fibrinolytic activity. In the majority of patients the decrease occurred on the fifth or sixth postoperative day, but it was observed that in some patients it occurred on the first postoperative day.

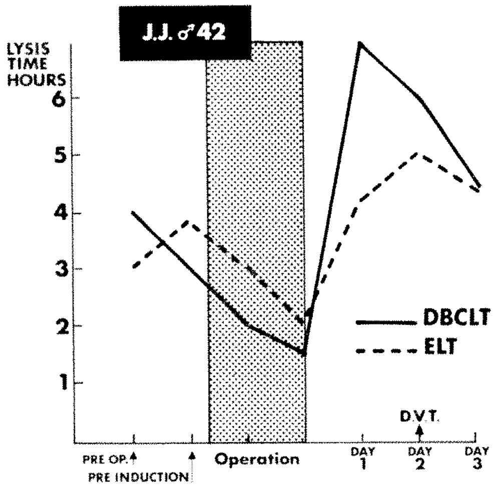

FIG. 4.—Lysis times in a patient who developed a deep-vein thrombosis. DBCLT, Dilute blood-clot lysis time. ELT, Euglobulin lysis time.

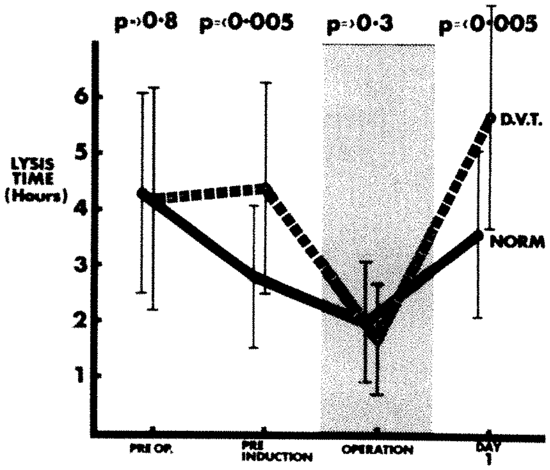

FIG. 6.—Dilute blood-clot lysis time in normal patients and in patients who developed deep-vein thrombosis.

Results of Investigations with ^{125}I-fibrinogen.—The alterations in fibrinolytic activity occurring in a patient who developed deep-vein thrombosis (as shown by radioactive fibrinogen studies) are shown in *Fig.* 4. It can be seen that there is an increase in fibrinolysis during the operation which is similar to that obtained in the larger group of patients. On the first postoperative day, however, there is a marked diminution in fibrinolytic activity which in this patient was particularly noticeable in the dilute blood-clot lysis time.

Two groups of patients have therefore been compared: those who developed signs of deep-vein thrombosis, as shown by the ^{125}I-fibrinogen test, and those who remained normal in this respect throughout their postoperative recovery. The investigations were exactly the same as for the 89 patients undergoing routine surgery. *Fig.* 5 shows the changes in euglobulin lysis time, and *Fig.* 6 demonstrates the alteration in the dilute blood-clot lysis time for the same group of patients. In both of these investigations it can be seen that there is an increase in fibrinolysis during the operation. These results are the same as those found in the overall group of patients. There was no significant difference in the lysis time of the two groups during the operation nor was there any significant difference between the two groups on their preoperative investigation.

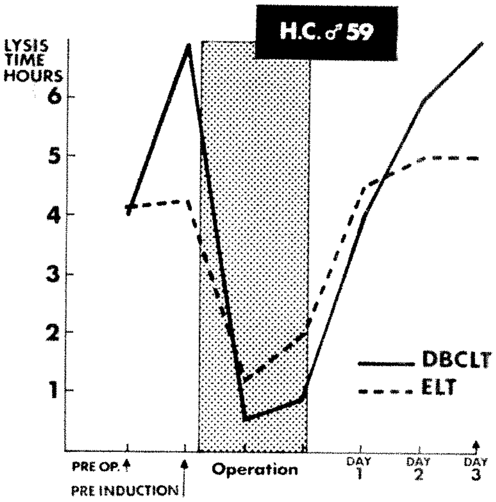

FIG. 7.—A further example of the changes in lysis time occurring in a patient who developed a venous thrombosis. DBCLT, Dilute blood-clot lysis time. ELT, Euglobulin lysis time.

Differences, however, emerge between the two groups in the pre-induction investigation, when those patients who later developed venous thrombosis failed to show the normal increased fibrinolytic activity prior to the induction of anaesthesia. The significance of this is not certain as there are so many factors which influence fibrinolytic activity at this time. Both groups of patients, however, were treated identically.

In the postoperative period the normal patients returned to a level of fibrinolytic activity which was similar to their preoperative level, but the patients developing a deep-vein thrombosis showed a marked and early prolongation of their lysis time, that is, diminished fibrinolytic activity on the first postoperative day. When the results on the first postoperative day were compared for the two groups employing Student's t-test, they gave $P < 0{\cdot}005$ for the dilute blood-clot lysis time and $P < 0{\cdot}001$ for the euglobulin lysis time. There is, therefore, a significant difference between the two groups at this time.

A further example of the alterations occurring in an individual patient is shown in *Fig.* 7. This patient went on to develop a venous thrombosis on the third postoperative day. There was a marked prolongation in the clot lysis time in the early postoperative period.

DISCUSSION

Previous investigations have shown that the majority of patients who develop venous thrombosis do so either during or shortly after their operation. It is known that there is an increased coagulability of the blood at that time and it is not unexpected to find that there is an increase in fibrinolysis during the period of the operation.

Chakrabarti and others (1969) were the first to point out that a reduction in fibrinolysis occurs in the postoperative period. Morrell and Dunnill (1968), in post-mortem studies, showed that in recurrent pulmonary embolism the thrombus in the pulmonary vessels failed to lyse in the normal manner. They postulated that the emboli may have occurred in a period of reduced fibrinolytic activity in the blood.

The present investigation has confirmed that there is a period of reduced fibrinolytic activity in the postoperative period. In patients who develop venous thrombosis there is a significant reduction in fibrinolysis on the first postoperative day at a time when the risk of thrombus formation is high.

EXPERIMENTAL ORGAN PRESERVATION

By K. C. CALMAN and P. R. F. BELL
DEPARTMENT OF SURGERY, WESTERN INFIRMARY, GLASGOW

SUMMARY

An experimental model for the study of organ preservation based on the isolated, biologically perfused rat heart is described. Using this model a standard storage solution has been evolved for use with initial perfusion and hypothermic storage. This solution contains Dextran 40 and insulin. Various perfusion characteristics including *p*H and infusion volume have also been studied. This solution has been modified and compared with two currently available storage solutions—Collins's C4 solution and the Gelin technique—and found to be superior to both. The technique consists of two parts; first, the organ is flushed with 0·5 per cent lignocaine in a buffered solution and is then perfused with the Dextran-40-based solution containing insulin and lignocaine. Further modification of the solution to contain a high magnesium concentration has resulted in a further improvement in survival after storage. These results are now being confirmed in the dog kidney.

The gradual acceptance of prospective tissue typing in organ transplantation has meant that more organs are now being transported to centres where recipients with the best tissue match are available (Batchelor and Joysey, 1969; Van Rood, 1969). With this development the need for simple and efficient methods of preservation during transportation has become more necessary. Many perfusates in conjunction with hypothermia have been recommended for short-term organ preservation, but the important constituents of each and their optimal concentrations have not been clearly defined. Two solutions in particular have been widely used for organ preservation. Collins, Bravo-Shugarman, and Terasaki (1969a, b) recommended a solution with an intracellular electrolyte composition which also contained phenoxybenzamine. This solution allowed efficient storage for periods of up to 36 hours. Although this perfusate may be very useful clinically, the importance of each individual constituent is still not definitely known. Similarly organ preservation using the Gelin technique (Brunius, Bergentz, Ekman, Gelin, and Westberg, 1968; Sells and Pena, 1970) involves a three-stage perfusion before storage: first, the organ is flushed with lignocaine (0·5 per cent w./v.) and heparin; secondly, the organ is perfused with a Dextran-40-based solution; and, finally, a fructose-bicarbonate solution is infused into the organ. It is not clear yet whether each step is of importance, or whether one particular aspect is the crucial one in preservation of the organ. For these reasons we have developed the technipue reported here based on a small animal model, which has allowed us to investigate single factors and analyse the results statistically. In this way it is hoped that the important constituents can eventually be aggregated into an ideal method for short-term clinical organ preservation, the small animal model being used as a screening technique prior to assessment with the dog kidney.

Our aim has been to investigate initial perfusion with hypothermic storage as technically the simplest method available. This paper reports on several aspects of organ preservation. First, the development of a simple, reliable, and reproducible method for assessing organ storage, a preliminary report of which has already been published (Calman, Macpherson, Wood, and Bell, 1970; Calman and Bell, 1971). Secondly, basic perfusion characteristics such as *p*H of the infusion, organ weight, infusion volume, and colloid content of the infusion medium have been studied. Thirdly, substances thought to enhance organ preservation, such as insulin, chlorpromazine, phenoxybenzamine, and lignocaine, have been assessed both individually and in combination in an attempt to analyse in detail the perfusion solutions widely used at present. Finally, the solution so evolved has been compared with the Collins solution and the Gelin technique.

MATERIALS AND METHODS

Experimental Model.—The isolated, biologically perfused rat heart was chosen as the experimental model for a variety of reasons. First, the method is cheap and allows large numbers of animals to be used for subsequent statistical analysis; secondly, viability of the organ is easy to assess within a short period of time; and, thirdly, the donor heart can be rapidly removed, cannulated, and stored in a variety of ways.

After precise time intervals the heart can be revascularized by attaching it in the manner to be described to a second rat referred to as the recipient (*Fig.* 1). Outbred Wistar rats weighing 200–400 g. were used throughout the experiments and anaesthetized with intraperitoneal pentobarbitone (6 mg. per 100 g.). Storage was timed from the start of the thoracotomy, prior to the removal of the heart, until revascularization was achieved.

Preparation of the Donor Heart.—The donor heart is exposed and the superior and inferior vena cava ligated. Forceps are then passed into the transverse sinus and the aorta and pulmonary artery are separated and cannulated using 18-gauge polythene cannulae. Finally, the pulmonary veins are ligated *en masse*. The heart is then removed by dividing the superior and inferior vena cava and pumonary veins (*Fig.* 2). This procedure takes, on average, 5 minutes to complete but there are several important points to note. First, during the mass ligature of the pulmonary veins care should be taken not to ligate the atria inadvertently. Secondly, the coronary artery must not be occluded by the cannula and, in practice, this means tying the cannulae in place as far from the heart as possible. Thirdly, the heart must not be unduly manipulated.

Preparation of the Recipient.—The abdomen of the anaesthetized recipient rat is opened and the aorta and inferior vena cava cannulated with 18-gauge polythene cannulae (*Fig.* 1). In order to maintain the recipient in the best possible condition several factors require attention:—

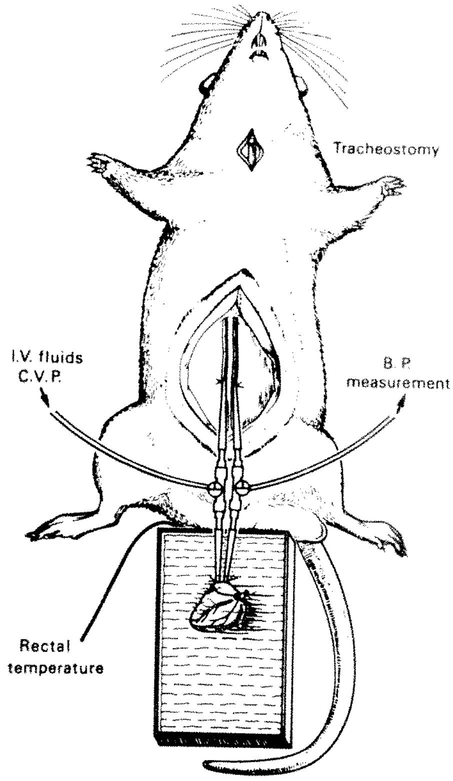

FIG. 1.—The preserved heart is revascularized by attaching it to cannulae previously inserted into the donor aorta and vena cava. The blood-pressure of the recipient is maintained by intravenous infusion of blood or saline.

a. Heparinization (500 U. per 100 g.) of the recipient is essential in order to prevent clotting in the cannulae.

b. Central venous pressure: The inferior vena caval catheter is connected to a T-piece, the long end of which is kept upright and open to the air. This serves as a central venous pressure monitor and allows transfusion of the recipient if this becomes necessary (*Fig.* 1).

c. Blood-pressure: Experience has shown that a systolic blood-pressure of at least 70 mm. Hg must be maintained in order to allow adequate perfusion of the donor heart. The blood-pressure is intermittently monitored via the aortic cannula using a three-way tap connected to a mercury manometer and is maintained as necessary by infusions of saline, dextran, or autologous rat blood.

d. Temperature: The recipient rat, lying exposed, very rapidly loses heat. Accordingly its temparature is maintained using a 100-W. light bulb. Rectal temperature is recorded during the procedure and kept at a constant level.

e. Respiratory function: The recipient, lying supine for periods of up to 4 hours, may retain secretions in the trachea. Tracheostomy is therefore performed so that secretions can be readily removed.

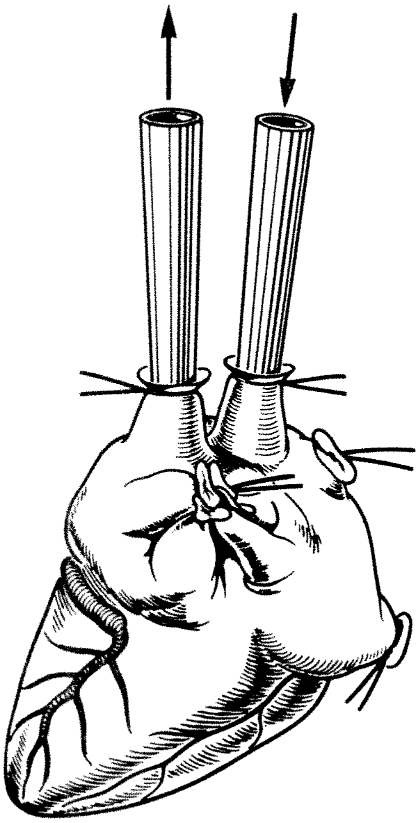

FIG. 2.—Cannulae are inserted into the aorta and pulmonary artery. When the heart is revascularized blood flows through the coronary system.

All of these factors are aimed at maintaining the circulation of the recipient rat so that error due to poor perfusion of the preserved heart can be eliminated.

Experimental Procedure.—Following removal, the donor heart is perfused and stored in the medium under investigation. It is then connected to the recipient in the manner shown in *Fig.* 1. Circulation of the donor heart is established for a period of 10 minutes, during which time the viability of the organ is assessed. It has been found over a series of 2000 rats that if the heart does not beat within 10 minutes it will not do so at all. On the other hand, if the heart beats within a few minutes of establishing the circulation and continues to do so for at least 10 minutes it will continue to beat for some hours afterwards. Using this technique, up to 20 donor hearts can be assessed using a single recipient, each heart being removed after a 10-minute observation period.

Criteria of Viability.—For a heart to be scored as viable all of the following criteria must be satisfied:—

1. There must be adequate perfusion of the donor heart. In practice this means that the blood-pressure of the recipient must be at least 70 mm. Hg.

2. The heart must beat and continue to beat for at least 10 minutes.
3. Venous return from the heart must be adequate.
4. Electrocardiographic evidence of electrical activity must be obtained.

RESULTS AND DISCUSSION

Establishment of the Experimental Model.—A previous report (Calman and Bell, 1971) has described the initial experimental work with this model and only the important features will be outlined here. The model was found to be reproducible and easy to use; large numbers of animals could be used in each experiment, making it possible for statistical analysis to be performed; the model was cheap to use and results could be rapidly obtained. One particularly useful feature was the sharp cut-off in viability (*Fig.* 3), making it possible to distinguish relatively small changes in the survival of groups of rat hearts treated in different ways. The model has, however, two main disadvantages. For clinical application of the results of this study in human kidney transplantation account has to be taken of the fact that the model utilizes the heart (a different organ) and the rat (a different species). It will be clear from the results presented, however, that though these differences must be recognized much useful information can still be obtained.

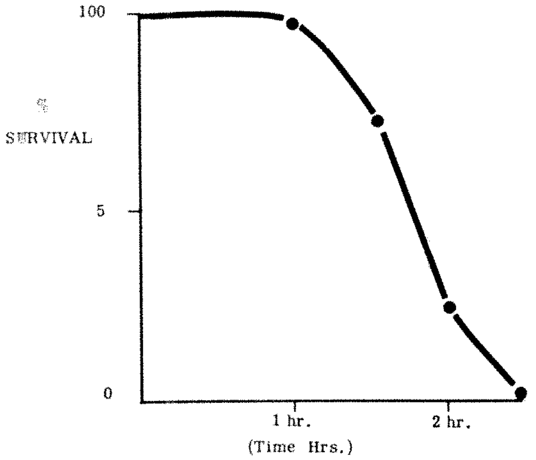

FIG. 3.—Illustrating the sharp cut-off in survival which occurs using the rat heart. The experiment shown was performed at 25° C. but similar results are obtained even if the storage time is prolonged by preservation at low temperatures.

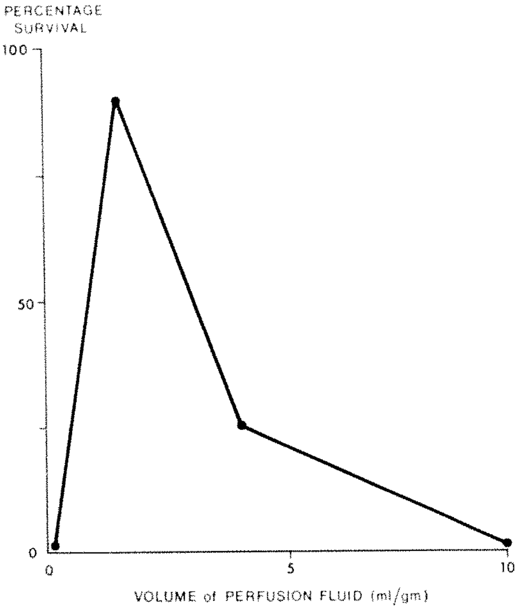

FIG. 4.—The viability of preserved hearts decreased with an increase in perfusion volume. Storage for 14 hours at 5° C.

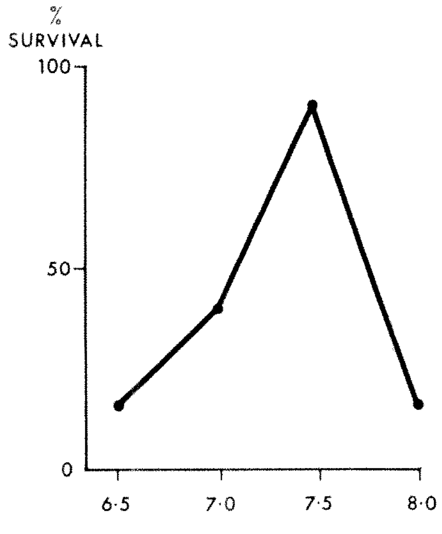

FIG. 5.—A *p*H of 7·5 at 5° C. was found to be optimal for organ storage, using a balanced salt solution with Rheomacrodex and a Tris buffer. Storage for 14 hours.

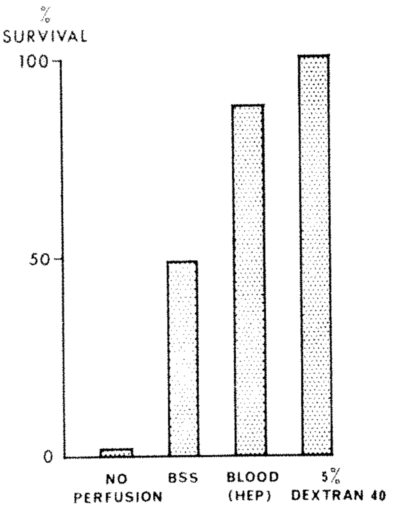

FIG. 6.—Dextran 40, 5 per cent, was found to be the best colloid for preservation of the rat heart. Storage for 10 hours at 5° C.

Throughout this paper results are expressed as the percentage survival of groups of rat hearts. In all cases these groups contained not less than 10 animals and usually 20. Thus each point or column in the results represents at least 10 animals.

Basic Perfusion Characteristics.—

1. *Rat Heart Weight.*—As an initial experiment the effect of rat heart weight was investigated. Two groups of animals, weighing 200 and 400 g. respectively, were studied using the same perfusate and perfusion was of the same volume per unit weight of the heart. The results showed that larger hearts of the heavier rats were easier to preserve ($P < 0{\cdot}02$). It may be that this is a phenomenon related only to the heart, since the myocardial cells enlarge with increase in organ size rather than increase in number. The experiment, however, is of importance in the design of experiments using the rat heart. In each series of experiments the rat weight was kept constant. This explains the differences recorded for the same solution between different experiments.

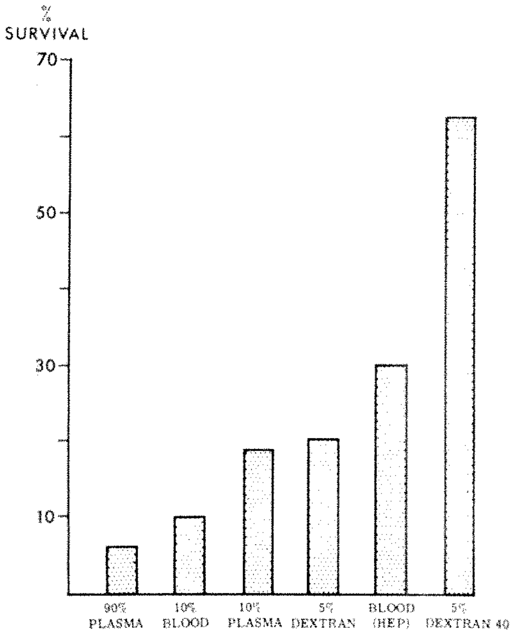

FIG. 7.—Extension of the storage time to 14 hours confirmed the superiority of 5 per cent Dextran 40 to preserve the rat heart.

2. *Effect of Infusion Volume.*—A series of rat hearts was perfused with different amounts of a standard solution. The results are shown in *Fig.* 4. Storage was at 5° C. for 14 hours. These results show that as the volume was increased over 2 ml. per g. the survival of the hearts decreased. These results have been confirmed using different storage times and solutions. It is likely that the damage is related to the washing out of essential substrates or ions (Keeler, Swinney, Taylor, and Uldall, 1966).

3. *The Effect of* pH.—Using a standard solution in which pH could be readily varied, the effect of pH on organ preservation was studied. The results are shown in *Fig.* 5. The optimum pH at 5° C. would appear to be 7·5. During this study the importance of temperature on the pH of the buffer was studied. It was found, for example, that if a Tris buffer (THAM) was used the pH varied by 0·5 unit over the temperature range 5–20° C. Thus the results could be significantly affected by the temperature at which the pH was standardized. A brief report on these results has been published (Calman, Quin, Macpherson, and Bell, 1971).

4. *The Effect of Colloid on Organ Preservation.*—The importance of different colloids on preservation of the rat heart was studied next. Groups of rat hearts were perfused with a variety of solutions each based on a balanced salt solution buffered with Tris-HCl (BSS). The results are shown in *Figs.* 6 and 7. These results show that the most suitable colloid is Dextran 40 and this is significantly better than other colloids ($P < 0{\cdot}05$). Dextran 40 has therefore been used as the colloid in all subsequent experiments.
